# Acknowledgments

---

There are so many people to thank for making this book possible. First and foremost, I thank my many gifted students who have worked in my laboratory over the last 35 years. They have taught me almost everything I know about organic electronics (and many other things as well). It is fair to say that everything that is right about this book I owe to them, and everything that is wrong is because of my own mistakes.

I have also had the pleasure of working with many collaborators who have also been my teachers. Professor Mark Thompson at the University of Southern California has collaborated with me on countless projects, and over the years we have become close friends. He is an amazingly creative chemist who has had the patience to teach me much about chemistry. In fact, I often joke that he has taught me just enough chemistry to make me dangerous.

Professor Vladimir Agranovich provided both the inspiration and motivation for me to take on this massive project. He has in so many ways been a role model and mentor to me, as well as being a giant of exciton physics. I would like to thank the people who have believed in me and supported my work that has led to such an exciting career in organic electronics. In particular I thank the management of Universal Display Corporation (Steve Abramson, Dr. Julie Brown, Sid Rosenblatt, and of course Sherwin Seligsohn) who have long supported my sometimes apparently aimless wanderings through the wilderness of organic electronics. Also, I thank Dr. Charles Lee at the U. S. Air Force Office of Scientific Research for his personal guidance and support over so many years, believing in my judgement and celebrating good results. I owe much of my success and happiness to these and many other supporters of my students and myself.

I owe a special thanks to my editor, Sonke Adlung, at Oxford University Press. Ever cheerful and

encouraging, he has patiently tolerated my delays for more years than either of us would like to be reminded of. I thank Joe Matthews, also at Oxford, for his assistance throughout the often complex production process of this volume.

I also owe a debt of gratitude to the Technion, The Israel Institute of Technology, for providing me with a Lady Davis Visiting Fellowship in 2014. It was there that I began the serious effort of writing this book. Without those months at the Technion (and the many weekend walks in the Galilee with my friends Profs. Moti Segev, Gadi Eisenstein, David Gershoni, and many others) it is unclear that this would have ever happened in the first place. I thank the University of Michigan, particularly the Departments of Electrical Engineering and Computer Science, and Physics, who gave me both the space and time to complete this monumental task. Special thanks go to my assistant of many years, Ms. Eva Ruff, who took care of my group when I was otherwise preoccupied by writing, and also for proofreading and doing so much more to help make this project a success. I thank Jonathon (Jack) Smith for helping with organizing the multitude of figures that comprise this text.

Finally, I want to thank my wonderful family, in particular, my mother and father, Esther and Jerry Forrest. They encouraged me to get the education that they never had, and particularly my mother who would never hesitate to let me know when I wasn't living up to expectations. And then, of course, there is Rosamund, my wife, best friend, and self-proclaimed "physics widow." What would I ever do without her love, persistence, support, and that inevitable question as I walked in the door each night, "How many pages did you write today?" Maybe we can all get back to what used to pass as normal, now that this project is finished.

---

# Preface

---

Organic electronics is the discipline at the core of the enormous, global organic light emitting device (OLED) display industry. Yet it is so much more. OLEDs also appear poised to be used as efficient lighting sources, organic photovoltaic solar cells may soon become a major source for converting solar into electrical energy, and electronic circuits based on organic thin film transistors may find their way into medical and a wide range of other sensing, memory and logic applications. What makes organic electronics such a compelling driver for these emerging applications is the unique features that they offer differ so remarkably from those of conventional semiconductors. Principally, organics serve as a platform for very low cost and high performance optoelectronic and electronic devices that can cover large areas (such as required for lighting, displays and solar cells), are lightweight when deposited on thin plastic substrates, and can be both flexible and conformable to fit onto irregularly shaped surfaces such as foldable smart phones. Due to the scale of the industries addressed by organic electronics, there are possibly 5000–10,000 scientists, engineers and technicians currently working to advance this field. Even so, very few texts are available that comprehensively cover the subject.

Organic electronics is an inherently interdisciplinary field, engaging experts in chemistry, in materials, in the physics of electronic and optical properties of disordered semiconductors, and in the engineering of practical, very high performance devices. To have a working comprehension of such a broad field, and ultimately to be an effective contributor to it, one must have knowledge of several disciplines that stretch well beyond the boundaries of traditional subjects taught in classrooms today. This book is structured to expose the student and the practitioner to the many aspects that define organic electronics, and provide an understanding that can allow the reader to be both knowledgeable and creative in extending our understanding of this exciting and explosively growing field.

This book is a product of both one and two semester courses that I have taught at both Princeton University and the University of Michigan over a period of more than two decades. During that period, the field has undergone dramatic changes, and my course material has changed accordingly. During this same period, many aspects of our fundamental knowledge of the field have also evolved to its current highly sophisticated, albeit still incomplete, level of development. Thus, while the field continues to move forward, it is essential that a text be available to capture the main ideas, and applications that define the subject today. It is these circumstances that have motivated me to write a book that presents the major elements of the field of organic electronics, and at the same time can serve as a resource for students, scientists and engineers alike. The target audience of the book, therefore, is students at all levels of graduate studies, highly motivated senior undergraduates, as well as practicing engineers and scientists.

The book is divided into two major sections. Part I, Foundations, lays down the fundamental principles of the field of organic electronics. It is divided into three principal subject areas: the basic properties and structures that define the broad class of organic semiconductors, followed by in-depth discussions of their optical and electronic properties. For Part I, it is assumed that the reader has an elementary knowledge of quantum mechanics, and electricity and magnetism. The reader is *not* expected to have a background knowledge of organic chemistry. The basic terminology of this field is provided in Chapter 1 to acquaint the reader with the vocabulary and a few important simple concepts that will be used throughout the book.

The foundations built in Part I are then extensively used in Part II, Applications, whose entire focus is on practical realizations of organic electronic devices. For this section, the reader is expected to have knowledge of the basic principles of semiconductor devices. Part II begins with a discussion of organic thin film deposition and patterning. I consider this to be the “how to”

section of the book, providing what I hope is valuable information about how devices and structures are made in modern laboratories and manufacturing facilities. This is followed by chapters on the three most important device classes addressed by organic electronics, that is, organic light emitters, detectors, and thin film transistors. These chapters are the longest and most comprehensive of the entire book. The last chapter (Chapter 9) describes several devices and phenomena that are not covered in the previous chapters, since they lie somewhat outside of the current mainstream of the field. Nevertheless, the topics of light emitting electrochemical cells, strongly coupled optical phenomena, thermoelectricity, memories and limited dimensional systems are all central to the field, and indeed may also eventually lead to substantial future applications unique to organic semiconductors.

Given the enormity of the field of organic electronics and its inherently interdisciplinary nature, this volume is correspondingly large. It is primarily organized as a teaching text meant for a two semester course. The first part of the book, Part I, is used in the first semester focused on teaching the fundamentals of organic semiconductors. The second semester is focused on applications (Part II). However, this entire subject matter can be covered at less depth in a single semester by condensing the most important aspects of foundations and applications into a 15 week course with approximately 45 hours of classroom lectures.

Topics are introduced in the beginning of each major section by laying the basic foundations to be discussed. Hence, a general introduction of a topic is followed by theoretical considerations. This lays the groundwork for discussing a few illustrative examples. This organization mimics the format of most easy-to-follow scholarly papers: introduction, theory, experimental results and discussion, and conclusions. The examples provided are never meant to be comprehensive—that type of treatment should be left to review articles. Rather, the descriptions of phenomenological observations or device demonstrations are chosen to illustrate or reinforce points made in the early sections of the topic or chapter.

It should be noted that in discussing a particular topic, I have intentionally avoided including “record results” to the extent possible. Rather, the foci of the chapters are on examples that are particularly innovative, or whose description can provide lessons about how things work. The intentional avoidance of record results is that in such a fast moving field, today’s record rapidly becomes “yesterday’s newspaper.” For this volume to remain relevant well past its

publication date, it must resist the temptation (no matter how large) to present only hero results or device demonstrations. Our aim is to provide a practical perspective by maintaining focus on concepts and results that have a realistic possibility for finding their way into future applications.

Each of the chapters contains numerous references to the literature, with the expectation that this book will serve both as a classroom text, and as a source book that directs the reader to important work beyond that treated within the volume. At the end of every chapter is a section called *Further reading*. As its title implies, these sections provide a short, curated list of books, review papers, and other references that the reader may wish to access to deepen his or her comprehension of a particular topic. Finally, every chapter also contains a section of approximately 10 problems. These problems are meant to challenge the readers’ understanding of selected topics contained within the chapter. Students in my graduate-level course are set a single problem every week to reinforce the material that they have learned during the previous lectures. Hence, many of the problems tend to be highly conceptual, somewhat lengthy, and challenging. In a few cases, the reader will need to refer to the literature to obtain a materials property or fill in a concept that is not completely provided in the problem or the book. Like any research problem, the solutions may not always be unique, or they may require the use of a computer. Once solved, they should provide a deeper understanding, and perhaps lead to new insights that are not fully addressed in the material presented within the chapters themselves.

### Using this book in class

I have taught both one and two semester courses using notes that are the basis for this book. Most recently I have taught these courses at the University of Michigan that has a 13 week semester, amounting to approximately 40 class hours. This is shorter than many schools whose semesters typically last from 15 to 17 weeks. Below is a table that provides example readings, topics and teaching cadences for a 15 week semester, assuming 3 class-hours/week. Sample curricula for both one and two semester courses are shown. There are three possibilities for 1 semester courses: the first column shows a comprehensive but necessarily brief coverage of the entire field. Covering such a breadth of material in one semester makes this more of a survey course that necessarily compresses or omits much important

material. Yet another format is to turn the two semester course into either a 1 semester course on fundamentals, or one that focusses only on devices (semesters 1 and 2 of the 2 semester course on the right hand column, respectively). The examples can be modified in many different ways to suit the interests of the class or the needs of the instructor. In all cases, the subject is laid out like the book: it starts by introducing the subject (Chapter 1), laying the foundational principles of organic semiconductors (Chapters 2–5), and then launching into discussions covering the important device operating principles, designs, and applications (Chapters 6–8). Note that for convenience in teaching a two semester course, Chapter 5 is moved into foundations. Several of the detailed sub-sections on materials, and mathematical

developments should be omitted. Yet the student can always use the text to dig deeper. The two semester course is much more comprehensive, although student schedules do not always permit such extended concentration on this subject. I encourage the instructor and the students to experiment with topics and formats. If you find a better alternative to this structure, drop me a line.

Companion lecture notes are available for downloading at [www.oup.co.uk/companion/organicelectronics2020](http://www.oup.co.uk/companion/organicelectronics2020) or <https://organic-electronics.engin.umich.edu>. These are once again meant to reinforce the material within the book and provide an aid to teaching by prospective instructors. Please feel free to download the notes, and use and distribute them as you wish. I only ask that you acknowledge their source.

Suggested study guide for one and two semester courses on Organic Electronics (15 week semester)

Week	Topic (1 semester)	Chapter/ Sections reading	Week (2 sem.)	Topic (2 semester)	Chapter/ Sections reading
1	Introduction to OE: Overview, history	1.1–1.3	1–1	Introduction to OE: Overview, history, language	1.1–1.3
2	Common language, crystal structure & binding	1.4, 2.1–2.4	1–2	Common language, crystal structure & binding	1.4, 2.1–2.4

## A few organizational notes

As mentioned above, the best use of this book will be made by those who have a suitable background in a few key subjects. Thus, a basic familiarity with quantum mechanics, electricity and magnetism, and semiconductor devices is highly recommended, although holes in your understanding of some topics will be filled by reading this book whose intent is to be instructional to a broadly interdisciplinary readership. Also, it is not important to have a background in organic chemistry, although that is helpful. This book is written by a physicist/electrical engineer who has worked for 35 years in the field without a formal background in that subject, although I have picked up a fair amount of it along the way. A few key chemistry definitions and concepts needed to proceed with this volume are provided in Chapter 1. Additional background is provided as it is encountered in the text to enable the understanding of a particular topic.

The chapters are replete with commonly used acronyms (e.g. VTE for vacuum thermal evaporation). Following conventions found in the scientific literature, these acronyms are generally defined by their first use in each chapter. However, a reader who is skipping ahead to research a specialized

point may find it challenging to locate the definition of a particular acronym. Hence, many common acronyms are collected for convenience in Appendix A. The chapters describe numerous example experiments, data and devices, each using a plethora of materials and layers. Identifying each compound by its chemical nomenclature based on the International Union of Pure and Applied Chemistry (IUPAC) standards is quite disruptive to the narrative flow. For this reason, in all but a few cases, the compounds are identified by their acronyms (e.g. PTCDA for 3,4,9,10-perylenetetracarboxylic dianhydride), with their IUPAC nomenclatures provided in Appendix B.

Each chapter begins and ends with a summary of the important points being addressed. Particularly useful equations are highlighted in boxes, and the first use of an important technical word or phrase (e.g. exciton) is identified by *italics*, along with a definition of that term.

We often use the very convenient Dirac bracket notation when discussing quantum mechanical wavefunctions and integrals. That is, wavefunctions are expressed using the ket-vector:

$$\psi_A = |A\rangle.$$

and its complex conjugate is given by the bra-vector:

$$\psi_A^* = \langle A|.$$

Similarly, integrals are replaced by the *bracket*:

$$\int \psi_A^* \Omega \psi_B d^3 r = \langle A|\Omega|B\rangle,$$

where  $\Omega$  is an operator. Finally, the expectation value of an operator is given by:

$$\langle \Omega \rangle = \frac{\int \psi^* \Omega \psi d^3 r}{\int \psi^* \psi d^3 r}.$$

# Introduction to organic electronics

---

*"There is no object so soft but it makes a hub for the wheeled universe."*  
**Walt Whitman, American Poet, *Song to Myself***

What makes organic semiconductors such a fascinating topic for study? Beyond the materials and physics vistas that open when we study such materials, we also should ask the question, are they useful? Since you are reading this book, you most likely already know that they are enormously useful. After all, their largest application is in organic light emitting diode (OLED) displays, today a multibillion dollar industry that exhibits massive growth each year. In this chapter, we briefly introduce the topic of organic semiconductors, and by extension their applications in organic electronics, by providing an overview of the scientific and technological scope of the field. We show that intensive study over the last 70 years has created extraordinary insights into the physics of disordered materials, while also launching global industries that employ thousands of scientists and engineers across multiple disciplines that stretch from physics and chemistry, to materials science, and electrical and mechanical engineering. Indeed, organic electronics is the quintessential interdisciplinary subject. To be conversant and innovative in this field, one must understand multiple technical languages and be able to collaborate effectively across the boundaries of traditionally "siloeed" fields of study.

This chapter (and book) is meant to motivate the reader to dig deeper into this literally limitless subject, and along the way perhaps explode a few myths that have swirled around the field almost from its beginnings. The chapter is meant to provide a common language that will help the reader bridge the gulf that separates the disciplines, and often creates a barrier to understanding and communication. Hence, at the outset, we define a few essential terms that will aid in understanding the context and terminology that is used throughout the book.

The materials have unique properties that are determined by their fundamental excited state, the exciton. The excitonic nature of organic semiconductors, that is distinct from the band-like character of inorganics, is a direct consequence of the weak intermolecular bonding forces that form the materials into their solid state. Given the frailty of those bonds, the materials tend to be disordered, leading to unusual properties beyond their tendency to form strongly bound excitons. We therefore devote a section to a comparison of the distinct properties of organic and inorganic semiconductors. Indeed, their differences lead to their satisfying very different applications when exploited in optoelectronic devices such as displays, transistors and solar cells.

Following this comparison, we provide a brief history of the field. It has been an interesting and colorful history indeed, extending from the discovery of organic semiconductors, to the awarding of a Nobel Prize, to the present day where organic electronics is the foundation of global industries. And to cap it off, organic electronics was launched into the twenty-first century by being the focal point of the largest fraud in the history of physics. Indeed, such a fraud could only have been perpetrated on an emerging field for materials

whose properties, even today, defy description by comprehensive theories that are nowhere near as complete and precise as that found for inorganic materials.

We next digress to briefly provide some useful terms that will help the reader navigate the more in-depth discussions found in subsequent chapters. There, we will provide important example molecular structures and common terminologies that can serve as a reference for the rest of the book. More specialized terminology will be provided within the context of the topic where it is first introduced. A section is included that confronts some pervasive myths that have been created about this field, for example, organics don't live long enough to be useful, or solution processing is less costly than vapor deposition, etc. These myths need to be confronted, however briefly, with more in-depth consideration of their origins, and what separates these impressions from the truth, found later in the book.

We finish our introduction by describing what makes organic electronics so appealing a topic for engineers and scientists worldwide. That is, we address the question, "What is organic electronics good for?" Is it a solution looking for a problem, or does it enable important optoelectronic device applications niches that are inaccessible to other, conventional semiconductors? We will lay out the rationale for organic electronic devices that have motivated the technical community, and large industries, to devote so much effort and resources over many years toward their development and application. We hope that by the end of this chapter, you too will be motivated to learn more about this exciting and promising field that is now making a difference to so many lives around the globe.

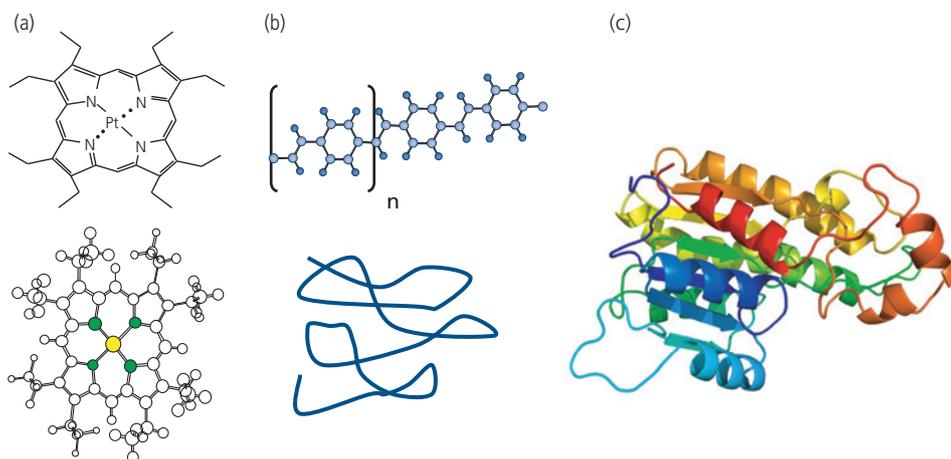

## 1.1 What is an organic semiconductor?

*Organic compounds* are formally defined as those that comprise at least one carbon-hydrogen bond. However, this term is often more loosely defined as simply referring to any carbon-rich compound. Thus, solely carbon-containing compounds such as the fullerenes (e.g. C<sub>60</sub>), or carbon nanotubes are sometimes incorrectly referred to as organic when used in devices. Nevertheless, these two types of materials find extensive use in photodetectors and solar cells. But strictly speaking, they are not organic compounds. Molecules without C–H bonds are known as *inorganic compounds*. In the solid state, organics are a member of a broad class of soft materials that are primarily bonded by weak van der Waals forces, although there may be small admixtures of other forces such as Coulomb attraction due to charge transfer between molecular units, hydrogen bonds, etc. A result of weak bonding forces in soft materials is a relatively high degree of disorder that is a combination of dynamic processes (i.e. thermal motion between neighboring molecules as well as intramolecular vibrations), as well as static disorder from crystalline defects. As we will find in Chapters 2–4, disorder is a significant factor that leads organic solids to have optical and electronic properties that are distinct from those of more strongly bonded solids, such as metals and semiconductors.

The preponderance of organic solids are electrical insulators, that is, they have a large energy gap that

substantially limits the number of thermally excited charges into the conduction level at room temperature, and hence their conductivity is very small. Also, the wide energy gap results in transparency in the visible. On the other end of the conductivity spectrum are metallic compounds that are based on charge transfer salts. The materials that have found the most use in organic electronics are those with intermediate energy gaps, ranging between 0.5 and 3 eV. Like all conventional semiconductors, their conductivity can be modified over many orders of magnitude by introducing either an electron-accepting or electron-donating compound to provide the host semiconductor with either p-type or n-type conductive character, respectively. Also, their intermediate energy gaps result in optical absorption or emission across the visible, and into the near infrared (NIR) regions of the spectrum. This feature makes organic semiconductors ideal candidates for optical emitters and detectors (including solar cells) that operate within these spectral zones.

The properties of organic compounds can be tuned over a nearly limitless range by modifying their composition; even the smallest modification, or chemical functionalization can lead to large changes in the optical or electronic properties of the molecule. And when that molecule is part of a solid, the bulk material itself can possess both physical and optoelectronic properties that are distinct and helpful for understanding their fundamental properties, or are useful in applications such as displays, lighting, or solar cells.

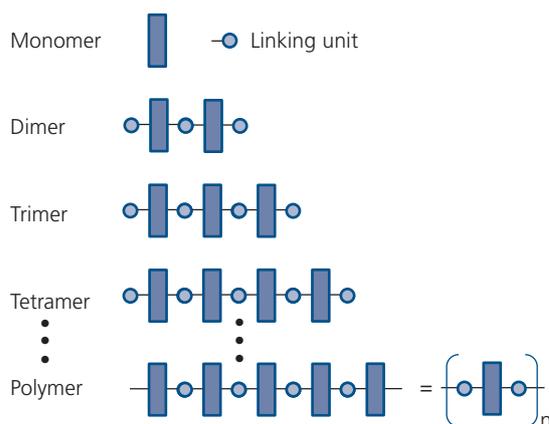

**Figure 1.1** Three types of organic molecules. (a) Molecular materials, represented by a monomer of platinum octaethylporphyrin. The upper diagram is the molecular structural formula, and the lower is a “ball and stick” representation of the same molecule. The metal (Pt) atom is shown in yellow, the small circles are H atoms, the larger open circles are C and N (the latter shown in green each bonded to the central Pt). (b) Polymeric materials consisting of an indefinite number ( $n$ ) of monomer units of *p*-phenylenevinylene. The lower diagram represents a long chain comprised of hundreds or thousands of these molecular links. (c) A protein molecule of biological origin (Wikipedia, 2019).

© Created by Boghog (user) and licensed by the Creative Commons Attribution-Share Alike 3.0 Unported (<https://creativecommons.org/licenses/by-sa/3.0/deed.en>)

Organic materials are broadly classified into three different types: small molecules, polymers and biological molecules, with examples provided in Fig. 1.1. *Small molecules* are organics with a well-defined molecular weight. The smallest molecular structure consists of a single unit, called a *monomer*. Here, *-mer* comes from the Greek, *meros*, or part. The example shown in Fig. 1.1a is platinum octaethylporphyrin ( $C_{36}H_{44}N_4Pt$ ), which is an intensely emissive red phosphorescent compound. The inclusion of a metal Pt atom in the molecule makes this a member of the class of metalorganic compounds. Its formal International Union of Pure and Applied Chemistry (IUPAC) nomenclature is platinum(II) 2,3,7,8,12, 13,17,18-octaethyl-21*H*,23*H*-porphyrin. Compounds are referred to in this volume by their common acronyms, in this case PtOEP. Their full IUPAC designations are found in Appendix B.

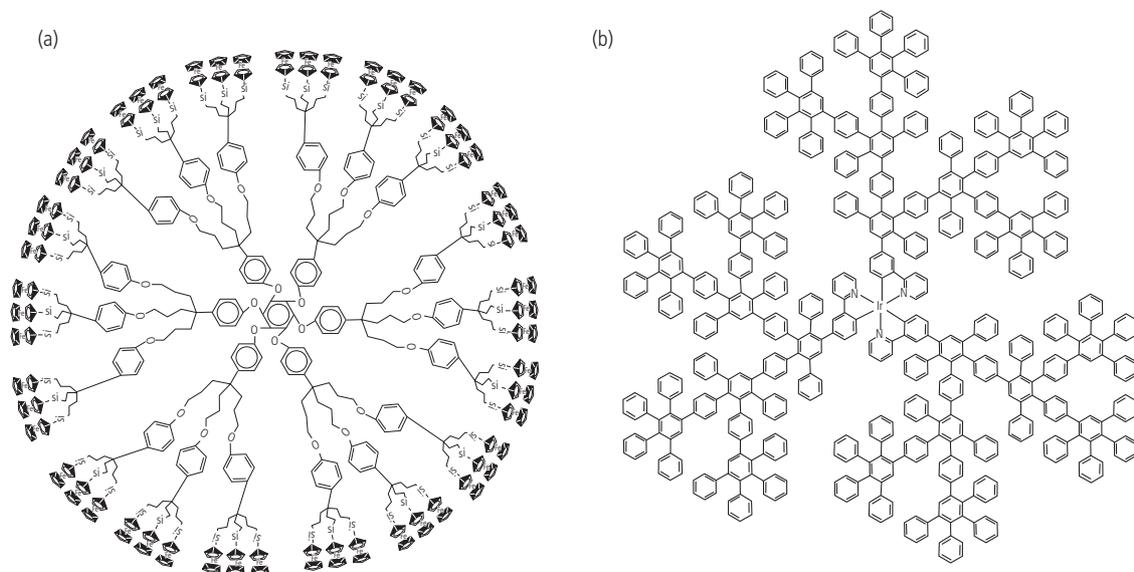

Two or more monomers can be connected into a molecule that consists of a well-defined number or repeat units called dimers (two units), trimers (three units), tetramers (four units), and so on. These are all members of the class of materials comprising a plurality of monomers, called *oligomers* (from Greek *oligoi* meaning “few”). Each monomer is linked by a connecting unit, which may be no more than a C–C bond shared between monomers, or it may consist of a moiety comprising multiple bonds and atoms. Like monomers, oligomers have well defined molecular weights, that is, an oligomer is composed of an exact number of atoms. A schematic representation of a series of oligomers is shown in Fig. 1.2.

**Figure 1.2** Hierarchical assembly of molecules from monomers to polymers. The linking unit may have a stable terminating group indicated by the circles. Also, the polymer can be represented by a single monomer unit repeated  $n$  times as shown in lower right.

A solid solution containing a population of oligomers may be *monodisperse*, where each member of the population is identical. For example, the solution comprises only trimers. However, solutions that contain populations of oligomers of different molecular weights are *polydisperse*.

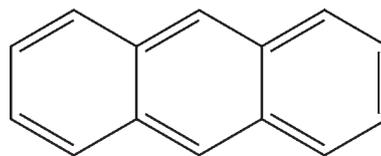

Another type of molecular material with monomers arranged in branches originating from a central core is a *dendrimer*. This species of molecule gets its name from its resemblance to dendrites, or branched projections from a single core such as found in hoar frost, ferns, neurons, and other “hub-and-spoke”

**Figure 1.3** Two example dendrimer molecules. (a) 54 ferrocene (so named due to the 54 ferrocene groups on its periphery), and (b) a fourth generation, luminescent metalorganic dendrimer with an Ir atom at its core.

structures. Two example dendrimers are shown in Fig. 1.3. The number of units along a single branch gives the “generation” of the dendrimer. That is, a molecule comprising only a core unit is a monomer. Formally, this is a first generation dendrimer. More interestingly, a second generation dendrimer comprises a core that is branched into a second rank of monomers, and if these are in turn branched yet again, it is a third generation dendrimer, and so on. Since a dendrimer has a well-defined molecular weight, it too is a member of the broad class of small molecular weight materials, although high generation dendrimers may have very large molecular weights, indeed. Dendrimers have found their primary applications in medicine, providing possible routes for directed delivery of drugs to specific sites (Tomalia et al., 2012). Unfortunately, these large, dandelion-shaped molecules do not form strong intermolecular couplings in the solid state. This inhibits both charge and energy transfer between molecules, thereby limiting their use as electronic materials, although they can be intensely luminescent.

Molecular compounds can be synthesized in the laboratory, or they can have natural biological origins. The first artificially synthesized molecule was urea. Credited to Friedrich Wöhler in 1828, this discovery ushered in the field of organic chemistry. A common example of a small molecule that can be synthesized or can be found in nature is anthracene, whose molecular structural formula is shown in Fig. 1.4. Anthracene, which is found in anthracite

**Figure 1.4** The molecular structural formula of anthracene ( $C_{14}H_{10}$ ). Each outer vertex is bonded to an H atom (not shown). Double and single C bonds are indicated.

(known as hard coal) and even in interstellar space (Iglesias-Groth et al., 2010), was discovered to have semiconducting properties over 60 years ago (Karl, 1989). Indeed, it was among the first organic materials to be developed for its optoelectronic properties, emitting dim blue light when electrically excited (Pope et al., 1963). Anthracene comprises three fused phenyl rings with alternating single and double carbon bonds. These single and double bonds are in resonance, that is, the bond arrangement can alternate between carbon atoms, finding equivalent positions shifted  $60^\circ$  from those shown in the figure without a gain or loss in energy. Thus, the electrons in the hybrid p-orbitals of the carbon atoms in the rings are delocalized, that is, they are shared by all the other carbons covalently bonded within the molecular plane. This electronic delocalization forms what is known as a *conjugated electron system*. A cyclic, planar, closed ring molecule with resonant bonds such as anthracene is an *aromatic compound*. Aromatic materials are of considerable interest in organic electronics due to their stability, their ease in forming films and

crystals by thermal evaporation in vacuum onto a substrate, and their very strong absorption bands from the visible and into the NIR. They are known as aromatics since many have strong odors. A prime example of this is the simplest, single carbon ring molecule, benzene ( $C_6H_6$ ), a principal ingredient of fossil fuels. Due to their intense absorption spectra, aromatics have long been used as dyes in textiles and paints, and as inks used in photography, printing, etc. Hence, many compounds are readily available in large quantities, and most importantly, they can be inexpensive, leading to their widespread application as dye stuffs.

In contrast to small molecules, a *polymer* is a chain of monomers or oligomers of indefinite length (see Figs. 1.1b and 1.2). Polymers are the basis for plastics, whose combination of light weight, stability, strength and flexibility has led to their ubiquitous adoption as materials used in construction, packaging, windows, etc. The first synthetic polymer was “Parkesine” based on cellulose introduced by Alexander Parkes in 1856, and the first fully synthetic polymer was Bakelite (Leo Baekland, in 1907) that found applications as an electronic insulator. The vast majority of polymers used today are insulators, and hence are optically transparent. Their stability has both benefits as well as significant deficiencies. Stable polymers resist degradation, which is beneficial in many applications where long-term durability is essential. On the other hand, their stability has generated an immense amount of refuse contributing to global pollution that humankind appears at a loss of how to manage.

The use of polymers as active electronic materials is a relatively new development, extending only over the last few decades. In 1963, Bolto and coworkers discovered conduction in the polymer, polypyrrolle (Bolto et al., 1963). This was followed in 1977 when the polymer, polyacetylene, was doped with an electron accepting molecule to vary its conductivity over several orders of magnitude (Shirakawa et al., 1977). This showed that the electronic properties of polymers can be varied by introducing extrinsic impurities, analogous to impurity doping that has made inorganic semiconductors useful as electronic materials. Today, polymer semiconductors are widely investigated for their potential applications in virtually all organic electronic devices.

In the solid state, both small molecules and polymers pack together to form amorphous, polycrystalline or single crystalline structures, depending on the physical and electronic properties of the molecules, and the processes used to

form the solid. The morphologies of small molecule and polymer solids can vary significantly due to their compact vs. extended and folded structures, respectively. Since the separate molecular units are not chemically bonded to each other, organic materials tend to be soft and fragile, although they can also be very flexible and even ductile.

Small molecules are deposited both from the vapor phase, or from solution when they are functionalized to have high solubility. In contrast, high molecular weight polymers are only deposited from solution since their mass prevents volatilization by heating below their decomposition temperatures. This results in significant differences in film stability and purity between these classes of compounds. Indeed, their different film-forming properties has led to the widespread adoption of small molecules rather than polymers in electronic devices. This topic will be considered further in Part II, on applications.

The last class of organic materials comprises highly complex molecules of biological origin (Fig. 1.1c). Exemplary molecules include deoxyribonucleic acid (DNA), proteins, and photosynthetic complexes. With only a few exceptions (e.g. DNA), this class of molecules has not been investigated for its electronic properties since the molecules are highly complex and cannot be synthesized in the laboratory, and they typically require an aqueous solution to maintain their function, shape or bulk morphology. Nevertheless, protein complexes can be solidified into well-defined crystal structures, such that detailed information on their molecular structures has been obtained. This understanding is central to our developing an understanding of the relationship between molecular structure and function in biological systems. And there are some examples where biological systems have provided important models for electronic systems as well, such as photosynthesis, neural networks, etc. A significant differentiating feature between biological and artificial electronic systems is that the former have the capacity for self-repair. Cellular damage that occurs during use, or exposure to environmental agents can sometimes be corrected by the biological machinery encoded in the genome. Artificially engineered organic or inorganic electronic devices have no such ability; when damage occurs it permanently impairs the operation of the device or system. Electronic systems manage this problem only poorly through the use of device redundancy in some applications where long-term operation is critical (e.g. in remote space-borne and undersea systems). Given their complexity, today we have only the most

primitive understanding of the chemical and electronic properties of biological molecules, and hence they have yet to play a significant role in the field of organic electronics.

## 1.2 The differences between organic and inorganic semiconductors

Before we can fully appreciate the rationale for using organic semiconductors in practical applications, we must first understand the key differences between these materials species and conventional, inorganic semiconductors. In this section, we address the question, "What are the characteristics of organic electronic materials that distinguish them from their inorganic analogs, and what is the impact of their inherent limitations and advantages on the performance of devices in which they are employed?"

A comparison of properties of organic and inorganic semiconductors is provided in Table 1.1. The single most distinguishing feature of organic semiconductors is their absence of intermolecular *chemical* bonds. Organic solids are primarily bonded by purely electrostatic *van der Waals bonds* due to induced dipole-induced dipole interactions discussed in the following chapter. These bonds can also have an admixture of Coulombic attraction due to charge transfer between neighboring molecules, or hydrogen bonds, but normally these contributions are small compared to those from van der Waals forces.

In any event, there are no chemical bonds between the molecules. This is in stark contrast to inorganic materials that consist of chemically bonded atomic species (Ashcroft and Mermin, 1976). Chemical bonds can be covalent due to sharing of electrons between atoms within the semiconductor (as in Si and Ge), or primarily ionic due to Coulombic attraction of anion/cation atomic pairs (CdTe, ZnSe, etc.). In some semiconductor alloys, bonding is via a mixture of both covalent and ionic bonds (e.g. InP, GaAs, GaN, TiP).

While *intramolecular* covalent forces are responsible for binding atoms within the compound, the lack of *intermolecular* chemical bonds results in starkly different electronic and mechanical properties in organic and inorganic materials, summarized in Table 1.1. This distinction is so profound that it governs all the physical, electronic and optical properties of these materials. The overriding importance of the bond type is emphasized by highlighting the entry in the table.

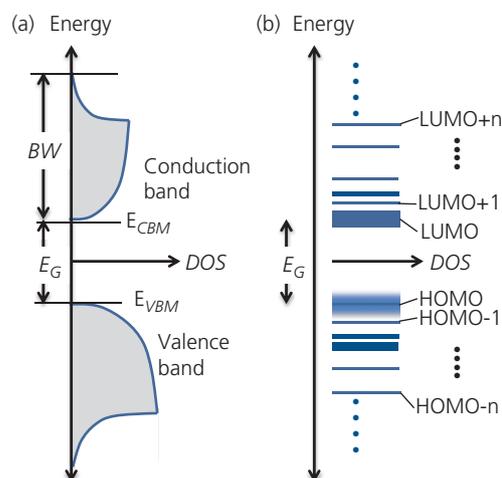

The strong chemical bonds in inorganic solids have a dissociation energy of  $\sim 1\text{--}5$  eV, which is at least an order of magnitude higher than for organics. Thus, organic materials are elastic and flexible, whereas inorganics are stiff and brittle. The low intermolecular binding energy of organics requires a comparatively low temperature to dissociate the molecules from the solid ( $\sim 100\text{--}500^\circ\text{C}$ ). However, most inorganic semiconductors thermally decompose at double to triple the highest temperatures tolerated by organic solids,

**Table 1.1** Comparison of typical properties of inorganic and organic semiconductors

Property	Organics	Inorganics
<b>Bond type</b>	<b>van der Waals</b>	<b>Covalent/ionic</b>
Intermolecular bond Energy	0.1 eV	1–5 eV
Energy band width	0.01–0.5 eV	1–4 eV
Charge transport	Polaron hopping	Band transport
Charge mobility	$\leq 1 \text{ cm}^2/\text{V s}$	$\sim 1000 \text{ cm}^2/\text{V s}$
Conduction levels	Frontier orbitals	Bands
Dielectric constant (Refractive index)	2–3 (1.5–2)	10–15 (3–5)
Peak absorption (Oscillator strength)	$10^5\text{--}10^6 \text{ cm}^{-1}$ (High)	$10^3\text{--}10^4 \text{ cm}^{-1}$ (Low)
Exciton species	Frenkel	Wannier–Mott
Exciton binding energy	$\sim 500\text{--}1000 \text{ meV}$	$\sim 5\text{--}10 \text{ meV}$
Exciton radius	$\sim 10 \text{ \AA}$	$\sim 100 \text{ \AA}$
Hardness	Soft	Hard
Flexibility	Flexible	Brittle

although there are compounds whose bond dissociation energies (BDE) are near the higher end of the range experienced by organics (e.g. HgTe). Not surprisingly, decomposition temperatures of organic compounds are often considerably higher than their evaporation temperatures, since the intramolecular chemical bond strengths are similar to those of inorganic materials. The low solid dissociation temperature of organics allows for film deposition at or near room temperature, leading to a low “investment” of energy required for device fabrication. On the other hand, low decomposition temperatures can be a source of thermal instability that shortens device lifetime, or may prohibit its use at even modestly elevated temperatures. At sufficiently high intermolecular bond energies, molecular decomposition occurs at lower temperatures than needed for evaporation. In this case, dissolving molecules in a solvent and then casting or spraying them onto a substrate is a more appropriate means of deposition. Solution processing is almost exclusively used for large molecular weight species such as polymers and dendrimers, as well as for many fragile small molecules (see Chapter 2).

Covalent bonds result in delocalization of electrons among all atoms arranged periodically in a crystal. Thus, charges move relatively unimpeded over large distances, and respond collectively to an applied electric field. This leads to a high charge mobility ( $100\text{--}10^4\text{ cm}^2/\text{V}\cdot\text{s}$  at room temperature in homogeneous and alloy semiconductors), and wide energy bands. Lattice periodicity results in the opening of a *band gap* of energy,  $E_G$ , between the conduction and valence energies. Charge delocalization creates a large *density of electronic states* (DOS) spread across a bandwidth ( $BW$ ) of several eV, as shown in Fig. 1.5. In contrast, organic semiconductors have an *energy gap* between narrow, frontier molecular electronic orbitals. The *highest occupied molecular orbital* (HOMO) is comprised of the most energetic electrons bound to the molecular  $\pi$ -system; they are the highest molecular valence states. Similarly, electrons in the *lowest unoccupied molecular orbital* (LUMO) comprise the least energetic conduction states. Rather than forming a continuous DOS, the deeper orbitals in organic crystals are relatively independent of each other due to weak electronic interactions between buried electronic states in neighboring molecules. The states deeper within the occupied and unoccupied orbitals are denoted HOMO- $i$  and LUMO+ $i$  states, where  $i$  is the index of an orbital relative to the frontier orbital (where  $i = 0$ ). Note too, that the DOS for inorganics begins at zero at a

**Figure 1.5** Characteristic energy level schemes of (a) an inorganic semiconductor with band gap energy,  $E_G$ , and (b) an organic semiconductor with an energy gap of approximately the same magnitude. Here, DOS is the density of electronic states, HOMO is the highest occupied molecular orbital, LUMO is the lowest unoccupied MO, and  $BW$  is the width of the corresponding band. The “fuzzy” depiction of the HOMO represents the case of a tightly packed organic crystal that has developed incipient, or narrow band-like character.  $E_{VBM}$  and  $E_{CBM}$  are the energies of the valence band maximum and conduction band minimum, respectively.

band edge, whereas for organics it is relatively constant and high within each narrow orbital. The density of states of each orbital is approximately equal to the molecular number density.

A situation analogous to organics obtains in engineered inorganic semiconductor structures such as quantum wells, wires and dots. In those cases, the bands disaggregate into a series of narrow energy levels characteristic of the size of the independent, nanometer-scale quantum confined regions. Indeed, quantum dots (QDs) play a role in inorganic semiconductors that is similar to the nearly independent molecules comprising a molecular crystal. This is particularly true of molecules that are doped at low concentration into a matrix comprising a different compound. For example, luminous dye molecules (called *lumophores*) within a wide energy gap matrix act independently of each other, exhibiting the same properties as the isolated molecule. Hence, the dopant can be thought of as a QD within a wider energy gap semiconductor, or insulator.

We note that the organic semiconductor energy  $BW$  is never 0 eV, as is characteristic of completely isolated atoms and molecules. If this were the case, there could be no carrier momentum within the level, and hence charge transport between molecules would be impossible. In fact, for the most tightly packed

organic crystals, relatively large energy band widths of  $\sim 500$  meV are observed. These levels are said to form *incipient bands* that give such organics many properties similar to those found in inorganic semiconductors. An excellent example of this class of molecules is PTCDA with a small intermolecular van der Waals spacing of only 3.21 Å. As a result of its band structure, PTCDA has been the subject of investigation for over 30 years, with properties that bridge the chasm between organic and inorganic materials (Forrest, 1997). This highlights a fascinating characteristic of organics: they have properties shared by both insulators and conventional semiconductors, and by the individual molecules and their bulk condensed state.

The distinction between band gap energy and energy gap is an important one that is often confused in referring to the energetic properties of organics. The existence of a band gap implies that there is an energy band with a continuum of electronic states that begins at the valence band maximum energy ( $E_{VBM}$ ) and extending to much lower energies, and from the conduction band minimum energy ( $E_{CBM}$ ), extending to much higher energies. The narrow bands characteristic of organics, therefore, make it more appropriate to simply refer to the energy separation of the HOMO and LUMO as the energy gap.

Band-like transport leads to a relatively high charge mobility. The bulk charge mobility of inorganic semiconductors is  $10^3$ – $10^6$  times higher than organic semiconductors, whose charge transport is due to incoherent *hopping* from one molecule to the next. Hopping refers to the process where momentum of a charge is randomized at each molecular site along its transport path. The transport, therefore, is incoherent: the history of where the charge has been has little or no influence on the next step that it takes as it drifts from molecule to molecule in an electric field. The hopping process can be activated either by temperature or an applied electric field. These are, respectively, known as thermally or tunneling-assisted hopping.

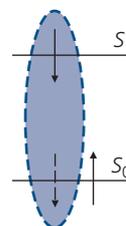

The optical characteristics of the solids, too, are dramatically modified by the nature of their cohesive forces. Chemical bonding leads to a high polarizability of a substance due to the collective response of a delocalized sea of electrons to an external electric field. This leads to relatively high dielectric constants and the corresponding refractive indexes compared to van der Waals bonded solids.

An incident photon can be absorbed by a single molecule in the solid. The excited state can subsequently transfer from a molecule to its neighbor,

thus resulting in the diffusive energy transport over substantial distances, sometimes as large as 50–100 nm. A mobile molecular excited state is known as an *exciton*. Since transitions from the ground to the excited state have a very high oscillator strength, the excitonic properties of organic materials dominates their optical response (Silinsh, 1980, Pope and Swenberg, 1982). For this reason, organic materials are often called *excitonic materials*, and the study of their optical properties is known as *excitonics*. In contrast, delocalized valence electrons and their distribution in energy over a broad DOS lead to a much lower oscillator strength in inorganic semiconductors. These transitions are thus between bands vs. discrete orbitals.

An archetype molecule can be represented by a two-level energetic system shown graphically in Fig. 1.6. The arrows represent electrons, one with spin up and the other with spin down in the ground state,  $S_0$ . The spin down electron is elevated in energy via photon absorption into the first excited state,  $S_1$ . As we show in Chapter 3,  $S_0$  and  $S_1$  connote quantum mechanical spin singlet states. The absent electron in  $S_0$  is a hole that is Coulombically bound to the unpaired, excited electron. The pair can hop from molecule to molecule, transporting energy contained in the excited state across the solid. The bound pair is the exciton, illustrated by the shaded oval in Fig. 1.6.

When the electron and hole are localized on a single molecule, the species is called a *Frenkel exciton*. Its radius is on the order of the dimensions of the molecule, as depicted in Fig. 1.7a. Due to the low dielectric constant of the material, its binding energy ranges from 0.5 to 1 eV, and hence it is stable at room temperature. This stability allows it to diffuse long distances before the excited electron relaxes back to the ground state, thus eliminating the exciton. The

**Figure 1.6** A molecular excited state. The arrows represent electrons with spins pointing up or down, the dashed arrow is the absence of an electron in the ground state, and the dashed oval is an exciton, or bound electron–hole pair. The singlet ground state is labeled  $S_0$ , and the excited state is  $S_1$ .

molecular relaxation can be either radiative or non-radiative via defect states within the material.

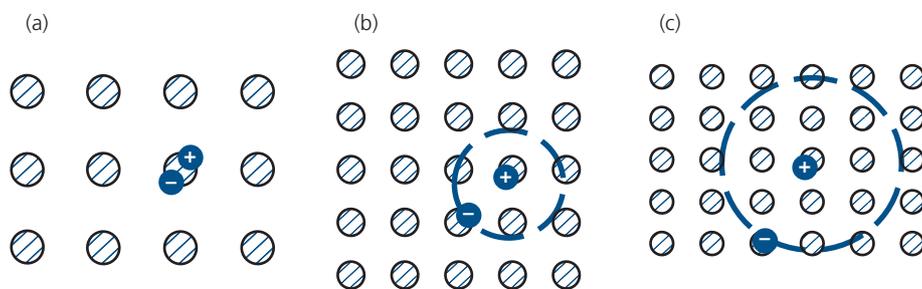

During transport, the excited electron can momentarily transfer to a neighboring molecule, creating an anion-cation pair of neighbors. The delocalization of the charge over a pair, or between only a few neighboring molecules is known as a *charge transfer (CT) exciton*, or charge transfer state, as shown in Fig. 1.7b. The binding energy of the CT state is substantially smaller ( $\sim 0.1\text{--}0.5\text{ eV}$ ) than that of a Frenkel exciton due to the reduced Coulomb attraction of the spatially separated charges. Finally, the high dielectric constant of inorganic semiconductors leads to effective field screening between the photogenerated electron-hole pair, resulting in a very loosely bound ( $5\text{--}10\text{ meV}$ ), and consequently a large *Wannier-Mott (W-M) exciton* that extends over many atomic sites (see Fig. 1.7c). This excitation is weakly absorbing, and is only stable at low temperatures. Structures such as quantum wells, wires or dots can be engineered to confine the electron and hole within a nanometer scale energetically bounded region, giving the W-M state more stable, Frenkel-like character. Hence, the optical properties of such artificial structures can also be dominated by excitons compared to the native, bulk semiconductor. In the absence of quantum confinement, the absorption of a photon in inorganic materials primarily results in the direct band-to-band generation of free charge, bypassing an exciton intermediate. These materials are, therefore, called “band-like,” with absorption features that are broad, extending from the band gap to much higher energies.

The very large oscillator strengths of primary transitions in organics make them highly absorptive over relatively narrow spectral bands (typically  $\sim 100\text{ nm}$  full width at half maximum), that are broadened by thermal motions (phonons) between atoms comprising the molecule. The absorption coefficients of organic semiconductors are  $\sim 10^5\text{--}10^6\text{ cm}^{-1}$ , which is on the

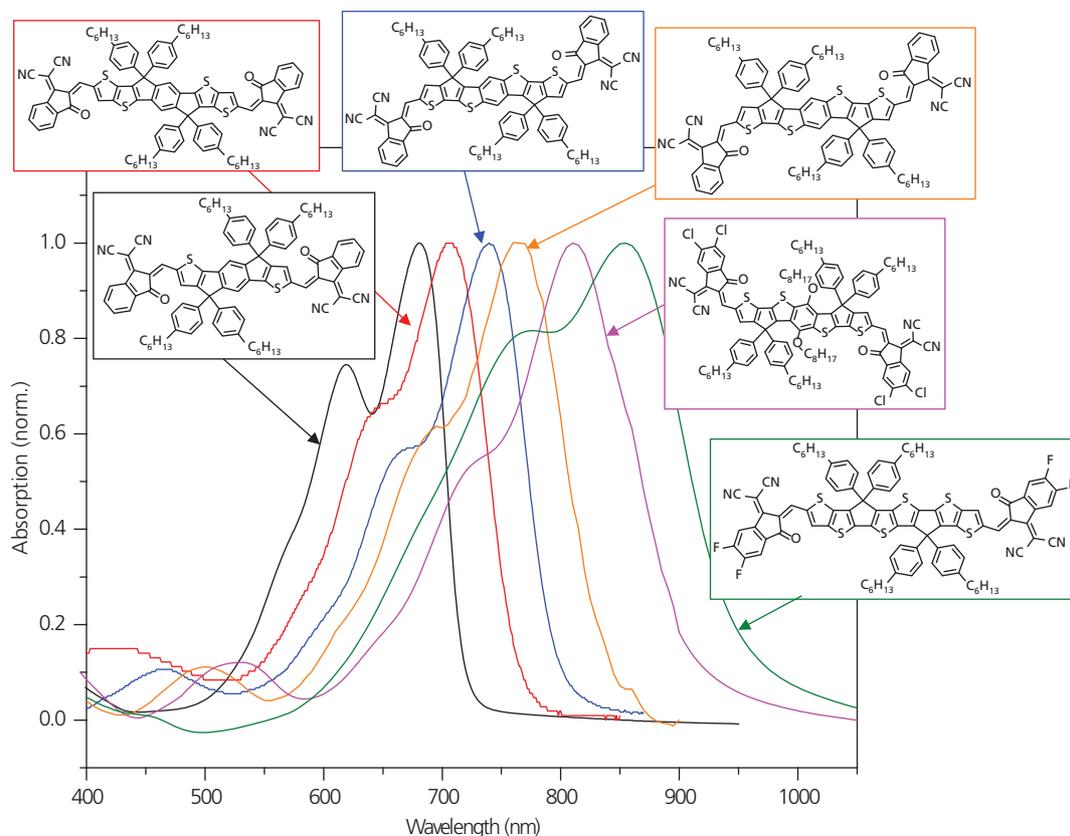

order of that of atomic systems. This is another outcome of the similarity between molecular and two-level atomic systems, whose densities of states are approximately equal to the number density of molecules in the solid.

The narrow and intense absorption spectra typical of molecular thin films are shown in Fig. 1.8 for several members of a class of non-fullerene acceptor molecules used in organic photovoltaic (OPV) cells. The excitonic absorption of each molecule is rigidochromically shifted from a peak wavelength of  $650\text{ nm}$  to  $850\text{ nm}$ , depending on the particular molecular structure. A *rigidochromic spectral shift* refers to the apparent translation of the spectra without significant line broadening or changes in shape from molecule to molecule. The double peaks of each exciton line are due to different intramolecular vibrational modes of the molecules; in this case they arise from the C-C bond stretch with energy of  $\sim 1500\text{ cm}^{-1}$  (Chapter 3). Several interesting properties of organics are readily apparent from these spectra. For example, the peak absorption wavelength blue shifts as the molecular backbone consisting of sulfur-containing (thiophene) rings is lengthened. Attaching Cl to the end-capping groups also increases the peak absorption wavelength. This series of molecules and spectra dramatically illustrates the versatility of function obtained by subtle modifications in the molecular design.

The large oscillator strengths of organics also lead to their highly efficient optical emission resulting from radiative recombination of excitons; the process opposite to exciton generation via absorption. In Fig. 1.9, we show several Ir-based organometallic compounds used in high efficiency, electrophosphorescent OLEDs, or PHOLEDs (Thompson et al., 2007). *Organometallic* refers to compounds that contain at least one bond between an organic *ligand*, or molecular grouping, that has coordinating bonds to a metal atom. The compounds in Fig. 1.9 are thus known as *coordination complexes*. The various compounds each

**Figure 1.7** (a) Frenkel, (b) charge transfer (CT), and (c) Wannier-Mott excitons. The molecules or atoms are the hatched circles on square lattice sites, and the electron and hole are denoted by “-” and “+,” respectively. The dashed circles are the approximate spatial limits of the corresponding excitons.

**Figure 1.8** Absorption spectra of thin films comprising the several molecules shown in the insets. These molecules are employed in efficient organic photovoltaics, and are members of a class of non-fullerene acceptors.

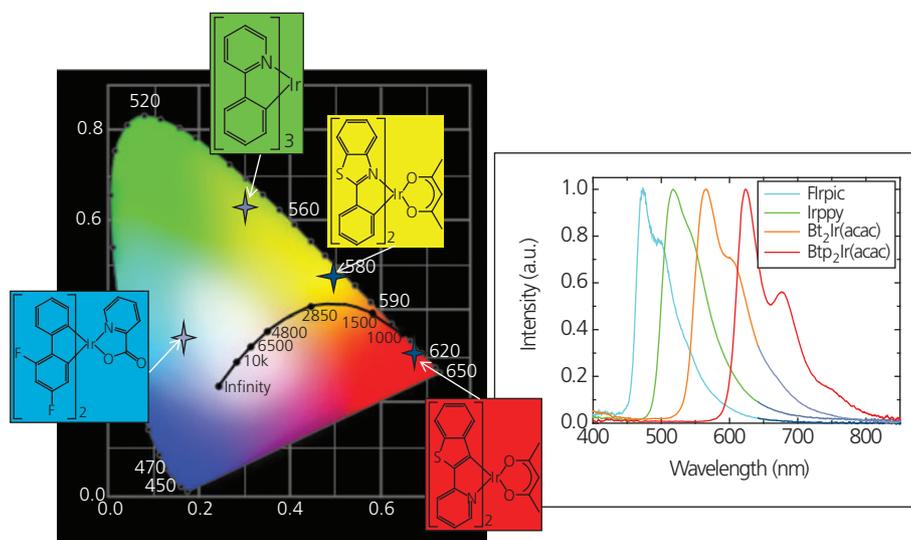

emit at a different wavelength, with their characteristic narrow emission spectra shown in the figure. As in the compounds in Fig. 1.8, the spectra are almost rigidochromically shifted from the blue to the NIR, depending on the exciton energy of the ligand. The color coordinates of the various PHOLEDs are located on the Commission Internationale d’Eclairage (CIE) chromaticity chart. This collection of molecules, whose emission ranges from cyan to deep red, is another example of the power of ligand functionalization—that is, by making subtle changes to their composition, the emission wavelengths of this set of molecules can span the visible spectrum.

In contrast to the spectra in Fig. 1.8, inorganic semiconductors tend to be broadly but weakly absorbing, with absorption coefficients one to two orders of magnitude smaller than organics. The oscillator strengths in inorganic materials are lower since the interaction with a photon is spread over a large number of delocalized electrons. Many common semiconductors such as Si, Ge, and GaAs have a black appearance due to their very broad bandwidths that stretch from

their band edge in the NIR and across the visible, although wider band gap semiconductors such as GaN are transparent since they only absorb from the blue into the ultraviolet (UV).

We noted above that the weak van der Waals bonds give molecular solids and polymers their soft mechanical character, opening up vast new opportunities for applications that are inaccessible to conventional, inorganic semiconductors. For example, organic solids can be flexible, whereas inorganic semiconductors are often very hard, brittle and subject to fracture. While organics are soft, and hence easily damaged by handling, they are also bendable, can conform to any number of oddly shaped surfaces, and can even be folded without cracking.

In this context, one of the drawbacks of weak intermolecular bonds is that the materials are prone to developing structural defects such as dislocations, and the incorporation of interstitial impurities during growth. Hence, it is challenging to grow large single crystals or thin films with low defect densities, as is commonly achieved in inorganic semiconductors. As

**Figure 1.9** Several Ir-based phosphorescent compounds used in OLED displays along with their color coordinates on the chromaticity chart (stars on graph at left), and the emission spectra of the molecules when used in phosphorescent OLEDs (PHOLEDs). Small changes in molecular structure result in large changes in emission properties. The subscripts for each compound indicate the number of identical ligands enclosed in the brackets that are coordinated with the central Ir atom. These ligands are distributed around the three-dimensional space surrounding the Ir atom. Courtesy, M. E. Thompson, 2019.

an example, 450 mm diameter single crystalline Si boules have been produced, whereas single crystals of organics are generally no larger than 10 mm on a side. The lack of chemical bonds also allows for ingress of foreign atoms and molecules, causing rapid oxidation, hydration or attack by solvents. Finally, the relatively weak intramolecular bonds can be easily dissociated by photophysical (e.g. exposure to high energy radiation such as UV light), chemical, photochemical (e.g. oxidation that is accelerated by simultaneous exposure to oxygen and light), or thermal means. For example, the C=C bond energy, one of the strongest in an organic molecule, is 602 kJ/mol, whereas for Si-Si it is 222 kJ/mol. However, in a Si crystal, each Si atom is bonded to four neighbors, resulting in a total bonding energy of nearly 900 kJ/mol. The relatively weak bonds in organic molecules are vulnerable to bond rupture and other routes to decomposition. The film crystalline morphology is similarly vulnerable to environmentally-induced changes. For this reason, organic electronic devices must be protected from exposure to atmosphere and high energy radiation if their long-term operational stability is to be assured.

An interesting feature of organics is the pronounced asymmetry of their properties along different crystalline directions. For example, intermolecular van der Waals bonds provide weak adhesion between polymer chains, although along the chains, strong chemical bonds give the material properties that are

more band-like. Similarly, small molecules are often asymmetric, with very different stacking habits parallel and perpendicular to a particular molecular axis. Hence, very large differences in refractive index, mobility, conductivity, and absorption (i.e. birefringence) are found along different crystalline directions. Even their stress tolerance has a well-defined directionality for ordered polymer or molecular solids (Forrest, 1997).

A qualitative summary of some of the attributes of organics compared to inorganic semiconductors is given in Table 1.2. This table provides a partial answer to the question, "What are organic semiconductors good for?" A positive attribute is noted by a "+," a very positive attribute by multiple "++," whereas negative and neutral attributes are noted by "-" and "0," respectively. Heading the list of differentially positive attributes for organics is their ability to be deposited on very large area substrates at low cost. Hence, organic semiconductors are ideally suited to fill the niche of "big devices" such as displays, lighting and solar cells whose performance and attractiveness scale with size. Inorganics fill the niche of the "very small." Their enablement of enormously complex circuits containing billions of transistors per square centimeter lies at the foundation of modern electronic technology. This is a domain that is completely unsuitable for organic electronic circuits whose smallest components (e.g. an OLED pixel in a high definition display) are at least three orders of

**Table 1.2** Qualitative comparison of attributes of organic and inorganic semiconductors when applied to electronic devices

Attribute	Inorganics <sup>a</sup>	Organics
Large area	---	+++
Cost	--	++
Complexity	++	0
Green processing	--	+
Easy to pattern	+	0
Tunable properties	0	++
Optical absorption	-/+	++

Conductivity	+	--
Device reliability	++	-

<sup>a</sup> “-” = negative, “+” = positive, and “0” = neutral attribute of a material. Repetition of a symbol indicates a higher emphasis on this attribute, either positive or negative.

magnitude larger than transistors in commercial circuits with dimensions of 5–10 nm. For this same reason, the “complexity” of organic electronic circuits is far lower than that of inorganics. In Chapter 8 we will see that organic transistor circuits comprising several thousand devices have been demonstrated, yet this pales by comparison to today’s computer central processing units (CPUs) with 5 billion transistors, or memories with 10–100 times that many devices. Of course, complexity is only a virtue in applications where it is needed. Hence, if we adhere to the principle that we only use technologies in applications that derive benefit from their use (i.e. we do not want to provide a solution in search of a problem), then large area devices such as displays and solar cells do not obviously improve simply by making more complex, and smaller pixels or device structures.

Large area devices are also ubiquitous devices. Solar cells, displays, lighting, and medical electronic devices (the latter provides a potential niche for organic transistor circuits), are found virtually in every corner of the globe, in almost every household and on every electronic appliance. In producing, using and ultimately disposing of these devices we must be concerned with their environmental impact. As noted above, the low bond energies of organics leads to low processing temperatures in their deposition and film formation processes. Hence, they can be produced at an energy expense far below that needed for strongly bonded inorganic substances such as Si or GaAs, the two most common inorganic electronic materials. Furthermore, the materials themselves are relatively non-toxic compared to, for example, perovskites and CdTe used in solar cells due to their heavy metal content, unstable bonds, etc. Hence, at

the end of their useful life, organic devices can be disposed of, and even recycled with a relatively small negative impact on the environment. Of course, plastics provide an enormous and growing environmental threat due to their lack of biodegradability. Generally, these types of plastics are not electronic materials. However, they are used as substrates for organic electronics, and in packaging of conventional electronic devices. This environmental threat requires immediate attention, and represents a challenge that extends far beyond the boundaries of electronic technology alone.

Circuit fabrication requires patterning that extends from the macro (i.e. >1 m<sup>2</sup> substrates) to the nanometer scales. As we will discuss in Chapter 5, device patterning is primarily based on photolithography. This requires the deposition of a thin, photosensitive polymer resist onto the circuit surface, followed by selective optical exposure and removal of the resist in areas where it is not needed. The resist itself is deposited, developed and stripped using a combination of solution and dry processing steps. A typical electronic circuit may require 50–100 applications, exposures and removals of resist during a fabrication sequence to create the numerous device layers and patterns required by the circuit. Unfortunately, organic materials can be damaged by solution-based photoresist processing. Also, there is often little “materials contrast” between an organic polymer resist and the organic active layer. This makes it difficult to selectively remove a resist from an underlying electronic layer based on chemical differences. For these reasons, patterning of organic devices creates challenges that are absent in conventional electronic device fabrication. Patterning techniques such as direct printing, stamp

transfer, laser patterning, etc. have been developed to accommodate the material vulnerabilities of organics. These techniques, however, are not nearly as well developed nor as versatile as is photolithography. This has proven to be an impediment to making organic circuits whose complexity is not anywhere near that of inorganic semiconductors. Of course, we have already noted that large area electronics generally do not need the same level of precision in features and complexities required for nanometer scale transistor circuits.

The entry in Table 1.2 entitled “tunable properties” refers to the facility with which a material or structural composition can be changed to meet a specific requirement of the target application. The vast flexibility in properties easily accessed through the synthesis of organic compounds precisely designed to meet an application need is a truly unique advantage of organic electronics; a field founded on the extraordinary versatility of organic chemistry. The solids themselves are soft, allowing for their layering into a variety of structures, albeit creating films that have a large degree of structural disorder. The situation is considerably different for inorganic semiconductors. Their stiff lattices require that a layer of the desired composition has a lattice structure that is matched in symmetry and size to that of the substrate on which it is grown. Hence, inorganic alloy semiconductors are constrained to lattice-matched, or to only minimally strained systems, such as GaAs/AlGaAs, GaN/InGaN, or InP/InGaAs(P). Engineered, quantum confined structures expand the range of properties and materials used, but ultimately these constraints are far more limiting than those hindering organic materials.

We have already mentioned that optical absorption and emission are exceptional strengths of organic materials due to their excitonic nature. But what about inorganics? The most pervasive of all semiconductor materials is, of course, Si. While this material is ideal for electronic applications, it is a poor optical material due to its indirect band gap. Direct absorption, particularly at energies near the energy gap of  $E_G = 1.1$  eV, is absent. Thus, optical detectors must have thick absorption regions to yield a high external quantum efficiency, that is, the ratio of photogenerated electron-hole pairs collected at the contacts to the number of photons incident on the photodiode. We will find in Chapter 7 that this forces a compromise between quantum efficiency and detector bandwidth that can be surpassed by organic materials. Nevertheless, if bandwidth is not an issue, the perfection achieved in Si purity and device performance can result in near unity quantum efficiency in solar cells

and detectors. The indirect band gap of Si prohibits its use as a light emitting diode or laser.

Direct band gap materials such as GaAs, GaN, and InP have excellent optical properties, although once again the range of wavelengths accessed with ease is not as great as for organics. Yet, fiber optic communication is based on extremely high efficiency light emission from InP-based lasers, and high bandwidth/high quantum efficiency detectors using this same materials system. Similarly, efficient and long-lived lighting based on InGaN technology is widespread. While inorganic semiconductors have inherent materials limitations that are absent in organics, time and again inorganics have been tailored to meet a diversity of optical device applications at the highest device performance.

Low charge mobility results from electronic states localized on individual molecules, with very limited overlap with adjacent molecules in the solid. As noted above, the conduction is via incoherent hopping from molecule to molecule. In a device, this property manifests itself as a very high resistivity. And high resistance, in turn, limits the current that can be transported in transistors, light emitters, and so on. Additional consequences of resistive materials are a low bandwidth response to optical or electrical signals, as well as Joule heating that can reduce the device lifetime or increase energy consumption. These deficiencies are not nearly as pronounced in inorganic devices due to their band transport nature, leading to charge mobilities orders of magnitude larger than for organics. Note, however, that the low bandwidth and current carrying capacity of organics can be partially mitigated by keeping molecular layers thin. The very high absorption coefficient of organics requires layers that are sometimes less than 10% of the thickness used in inorganic photodiodes with similarly high quantum efficiencies. Further, the emission efficiency in PHOLEDs routinely approaches 100% from layers that are <5 nm thick. Hence, while high resistance is undoubtedly a drawback, device and materials designs have been advanced that minimize the disadvantages that this property would otherwise engender.

The last entry in Table 1.2 brings up the topic of reliability. The weak chemical bonds in many compounds lead to their rapid decomposition under heat, atmosphere and/or light. Hence, organic materials have the reputation of being unstable. It is logical to expect that the devices employing such compounds will have an unacceptably short operational lifetime. While it is generally true that organic devices can be highly unstable and thus impractical for use, it is also

true that by using high purity, state-of-the-art materials in an appropriate package that prevents contamination from the environment, very long lifetimes can be achieved. In Chapter 6 we will show that OLEDs can have lifetimes extending to millions of hours, and OPV cells can possibly operate for tens to thousands of years. While reliability is an over-riding concern for all organic devices, there are many examples where this problem has been solved or reduced to provide electronic appliances that are as reliable as their inorganic semiconductor analogs. Ultimately, the standard for acceptable reliability is defined by the target application. A thermally unstable material cannot be employed in a device whose application demands use at elevated temperatures. Yet that same device may fill a niche where high temperatures are never experienced. In Part II, the issue of device reliability, and how to quantify it is addressed for OLEDs, OPVs and organic thin film transistors (OTFTs). We will find in each case that acceptable reliabilities have been achieved, although organic devices are rarely if ever as robust as those based on Si or alloy semiconductors employed in high bandwidth, high temperature applications.

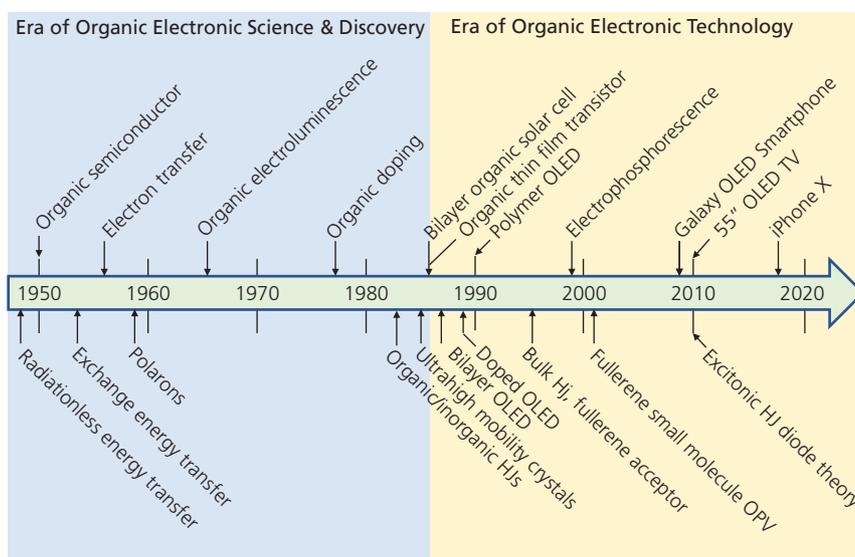

### 1.3 70 years of advances in organic electronics

One cannot understand where one stands today if one is unaware of the advances made in the past. To fully appreciate the subject of organic electronics it is, therefore, worthwhile to briefly review its history,

and some notable discoveries made along the way that led to its current state of advance. But the question is, where to start? Not with the synthesis of urea by Friedrich Wöhler in 1828. While that discovery arguably marked the foundation of the field of organic chemistry, a discipline that underpins every advance made in organic electronics, urea is not an electronic material, nor was it ever identified as such.

With this criterion in mind, I somewhat arbitrarily choose the foundation of the field of organic electronics by the discovery of semiconducting properties of violanthrone by Akamatu and Inokuchi (1950). Indeed, Hiroo Inokuchi is often regarded as the “father of organic electronics.” Akamatu and Inokuchi measured the resistivity of this molecular solid, which was found to decrease with increasing temperature. The thermal activation of the resistivity has a characteristic energy,  $\Delta\epsilon$ , that these investigators correctly identified as twice the energy gap of the material. This advance, more than any that had preceded it, clearly assigned semiconducting properties to an organic material, launching the field of organic electronics.

A timeline showing selected milestones in the subsequent development of the field is shown in Fig. 1.10. This timeline is admittedly brief, and only shows a few such milestones. I apologize in advance for all the important (even momentous) discoveries that have been omitted. Specific references made in the figure are provided in Table 1.3, listing seminal papers that have forever changed this exciting, and still evolving interdisciplinary field of science and technology. In the remainder of this section, we will briefly note the

**Figure 1.10** Historical timeline of organic electronics, highlighting a few significant milestones met along the way.

**Table 1.3** Several discoveries and innovations made during the 70 year history of organic electronics

Discovery/advance	Date	Type <sup>a</sup>	Reference
Radiationless energy transfer	1948	F	(Förster, 1948)

<sup>a</sup> Type refers to either fundamental (F) or technological (T).

specifics of these milestones, leaving more detailed descriptions for the reader to discover through the papers themselves, and in the remainder of this book where much of the important content of the papers can be found.

An interesting feature to note in Table 1.3, is that among the various discoveries and innovations, there is a dramatic shift between a focus on fundamental discoveries (denoted by “F” in the “Type” column) and those that are primarily technological (denoted by “T”). This change abruptly occurred with the demonstration of the first efficient, all-organic bilayer rectifying solar cell by C. W. Tang, at Kodak, in 1986 (Tang, 1986). This was soon followed by the announcement of a 1% quantum efficiency, low voltage (~10 V) bilayer organic light emitting device, later to be named an OLED (Tang and VanSlyke, 1987). In the midst of these announcements came that of the first organic polymer thin film transistor based on polythiophene (Tsumura et al., 1986). After these innovations, the organic electronics community turned much of its attention from past pursuits aimed at

understanding the fundamental properties of organics, toward developing these materials for use in what was apparently becoming a practical device technology. This is not to say that all important work was purely fundamental prior to these seminal discoveries, nor that afterwards only technological innovations were sought. Far from it. Indeed, such a broad categorization of any scientific or engineering work into fundamental or applied is admittedly arbitrary. Yet there is no denying that once an organic rectifier, a light emitter and a transistor were demonstrated to have potentially practical performance characteristics, that the attention of the scientific community swung hard toward the pursuit of even higher performance that would eventually fulfill the long-held hope that low cost and high performance devices based on soft, organic electronic materials would catalyze new global industries, realizing applications that were otherwise inaccessible to conventional semiconductors.

Given this unique turn of events, the historical timeline in Fig. 1.10 has been, again somewhat

arbitrarily, divided into two periods. The first is the “Era of Organic Electronic Science and Discovery,” and the second is the “Era of Organic Electronic Technology,” neatly divided in 1986 with the invention of the bilayer organic solar cell.

We begin our timeline two years before the landmark work of Akamatu and Inokuchi, with the theory of electrostatic energy transfer elucidated by Förster (1948, 1959). While the theory was derived with the purpose of describing energy transfer in photosynthetic complexes, it is now widely applied to describe energy transfer and exciton diffusion in organic electronic solids in general. The transfer process is known as *fluorescent resonant energy transfer*, or FRET (also known as *Förster resonant energy transfer*). While FRET occurs over distances of a few nanometers via dipole-dipole coupling between molecules, a tunneling-like transfer dominates at shorter distances. This is known as *exchange energy transfer*, or *Dexter energy transfer*, named after the person who first derived its properties in a landmark paper in 1953 (Dexter, 1953).

The process of charge transfer from molecule to molecule that underlies hopping conduction was developed by Rudolf Marcus, who won the Nobel Prize in Chemistry in 1992 for his seminal contributions. Known as *Marcus electron transfer*, it describes the general process of charge transfer in organic electronic materials, although it was first developed to understand charge transfer in chemical reactions (Marcus, 1956, 1957). This deceptively simple theory predicts unusual behaviors of electron transfer in molecular systems such as the so-called Marcus inverted region that governs charge transfer from the donor to acceptor molecules in organic solar cells. A natural extension of Marcus theory is the concept of the small *polaron* as the charge carrier in organic solids. An electron or hole within an organic significantly polarizes the surrounding medium, creating a shallow self-trapping site. Thus, the charge finds itself heavily “dressed” by the molecules in its immediate vicinity, taking on a large effective mass. This is a very different situation than exists in inorganic semiconductors, where a high density of surrounding, mobile charges screen the effects of a free charge, significantly limiting its polarization of the medium. The concept of the polaron, therefore, is central to our understanding of hopping transport that leads to low charge mobility in organic materials. This concept was quantitatively described by Holstein in a pair of papers in 1959 (Holstein, 1959a, 1959b).

Demonstrations of organic electroluminescence in anthracene (Pope et al., 1963, Helfrich and Schneider,

1965) introduced a new phenomenon to the organic electronics community. Injecting charge at high voltages (100 V to >1000 V) from aqueous electrodes into anthracene crystals produced faint blue emission. This was distinct, however, from work done 20 years later by Tang and co-workers, who employed very thin film bilayer devices that operated at very low voltages, and that emitted bright green light at much higher efficiencies.

Shirakawa, Heeger, and MacDiarmid were the first to electronically dope an organic polymer to vastly alter its conductive properties (Chiang et al., 1977, Shirakawa et al., 1977). This team doped the insulating polymer, *trans*-polyacetylene, with AsF<sub>5</sub> to increase its conductivity from 10<sup>-5</sup> S/cm to > 100 S/cm. Doping is essential in fabricating semiconductor junctions by converting intrinsic semiconductors to either a p- or n-type conductor. Likewise, the ability to dope an organic semiconductor opened the possibility that their conductive properties, too, would usher in new generations of organic electronic devices. This team was recognized for its contribution by receiving the Nobel Prize in Chemistry in 2000.

The rectifier is the most basic, active (i.e. non-linear) electronic component. Considerable research into the mid-1980s was therefore directed at demonstrating such a device using organics. Possibly the first such successful device was the demonstration of highly asymmetric current characteristics in the forward vs. reverse biased directions obtained by layering an organic semiconductor onto the surface of a Si wafer (Forrest et al., 1982). Today, organic-inorganic junctions are widely investigated for their use in QD solar cells, nonlinear optical devices, and as platforms for multiexciton generation in solar cells (Dexter, 1979). Interestingly, this organic-inorganic rectifier was the first device to employ the molecule, PTCDA, as an electronic material. As we will see in subsequent chapters, PTCDA is a remarkable material given its excellent film-forming capabilities, large and anisotropic charge mobility, and closely coupled electronic states from which an incipient band structure emerges. Indeed, it has become one of only a handful of model materials broadly studied to understand the properties of organic semiconductors.

It had long been thought that organic materials have very low charge mobilities. Thus, the work of Warta, Stehle, and Karl made a profound impact on our understanding of organics with their work on ultrapurified naphthalene and perylene (Warta et al., 1985). They found that by zone refining, mobilities of purified crystals of several hundred cm<sup>2</sup>/V s can be

obtained at low temperatures. Mobilities this high clearly suggest band transport, a property that was thought to be the sole domain of inorganic semiconductors. But that preconception changed due to these experiments. To this day, this work stands alone as having reported the highest mobilities for organic systems, largely due to the careful removal of impurities from the nearly perfect molecular crystals.

The work of Warta et al. marks the end of the Era of Organic Electronic Science and Discovery, since it was followed a year later by the landmark papers from Kodak on bilayer junction solar cells and OLEDs. One additional important, later contribution from the Kodak group was the demonstration of doping of the emission region of an OLED with a fluorescent lumophore (Tang et al., 1989). It was discovered that the efficiency (and ultimately the lifetime) of OLEDs can be increased by including only a few percent of the luminescent molecule within a conducting, wider energy gap matrix, whose combination forms the emission layer. In a doped device, excitons are formed on the matrix material by electrical injection, and are then transferred with near unity efficiency via FRET to the lumophore. The lumophore itself radiates with higher efficiency than if it were used as a neat layer in the OLED due to the elimination of *concentration quenching*: the process whereby an excited state on a molecule is non-radiatively quenched due to vibronic coupling to neighboring molecules. The excited state is readily quenched by contact between similar molecules that dissipates by coupling to inter- and intramolecular vibrational modes. Isolation of the individual fluorescent molecules traps the excited state on the luminescent species, reducing its ability to dissipate energy. Hence, the demonstration of doping was an important step toward realizing efficient OLEDs.

The work of Tang and VanSlyke focused on vacuum deposited small molecule devices. However, an unfulfilled promise of organic electronics was that solution deposition can significantly simplify the fabrication of device into a one-step, one beaker procedure. The demonstration of the first solution-processed polymer OLED was a step toward realizing this dream (Burroughes et al., 1990). The active material used in this single layer device was poly(phenylenevinylene) (PPV). Its yellow emission exhibited only 0.05% external quantum efficiency, although it operated at reasonably low voltage and demonstrated how a simple, solution-processed device might eventually become a practical light source.

Polymers were soon shown to have uses in solar energy harvesting with the invention of the bulk heterojunction (BHJ) solar cell. (Halls et al., 1995, Yu et al., 1995) The BHJ comprises a bicontinuous, or interpenetrating network of donor (D) and acceptor (A) materials that creates a large surface area for exciton dissociation at the D–A junction. By blending these materials excitons dissociate into free charges very near to their point of origin (i.e. the point of photon absorption), thereby decreasing losses from exciton diffusion that are experienced in bilayer junctions. The BHJ is now found in many high efficiency OPVs. An additional advance by Yu et al. was the introduction of a solution-processed fullerene acceptor, PC<sub>61</sub>BM, into the device active region (Yu et al., 1995). The rapid charge transfer from a donor to the fullerene with its high thin film electron mobility has since led to its widespread use in OPVs.

Fluorescent OLEDs are limited through spin statistics to only 25% internal quantum efficiency. The internal efficiency is the ratio of the number of photons emitted to the number of electron–hole pairs that undergo radiative recombination within the device. The injection of electrons produces a random population of spins, resulting in the formation of singlet and triplet excited states at a statistical ratio of 1:3 within the emission layer of the OLED. Unfortunately, only singlet states are quantum mechanically permitted to radiatively recombine on fluorescent molecules, thus wasting the energy used to generate the 75% triplet population (see Chapters 3 and 6). In 1998, a solution to this problem was offered. Employing metalorganic molecules comprising a heavy metal atom such as Pt or Ir couples the spin on the luminescent molecular ligand with the orbital angular momentum of the heavy metal atom. Using a heavy metal with a large electronic orbital momentum ensures strong mixing of the singlet and triplet states (Baldo et al., 1998, 1999). This so-called *spin–orbit coupling* allows the singlet state to rapidly cross to the triplet state manifold on the ligand, and for the triplet to become radiative. This enabled what is now known as *electrophosphorescence*. When heavy metal atoms are used in electrophosphorescent OLEDs, or PHOLEDs, the internal quantum efficiency increases to 100%. This innovation led to intense interest in PHOLEDs for use in high efficiency displays and lighting, giving birth to today's multibillion dollar OLED display industry.

A similar design used in PHOLEDs was then incorporated into a double heterojunction small molecule OPV, employing the first vacuum-deposited fullerene, C<sub>60</sub>, in an organic solar cell (Peumans and

Forrest, 2001). This work, combined with that of Yu on solution-processed polymer photodiodes, was followed by a series of innovations on fullerene acceptor-based solar cells that has led to consistent improvement in efficiency persisting for over two decades.

No history of organic electronics would be complete without mentioning the singular events surrounding the largest fraud in physics, perpetrated by J. H. Schoen at AT&T Bell Laboratories, that extended from 2000 to 2001. The understanding of the properties of disordered soft materials is sufficiently incomplete that it allowed for a breathtaking abuse of scientific norms that were reported in a series of astonishing papers that regularly appeared in *Science* and *Nature* magazines, and a few other scientific journals. These papers appeared to literally rewrite all of our understanding of condensed matter physics. Over a period of approximately 2 years, startling discoveries were reported, ranging from organic lasers to extremely high performance monolayer OTFTs employing ultrahigh mobility materials. Almost all major phenomena known to condensed matter physics including the quantum Hall effect, the formation of Wigner crystals, and superconductivity were reported to have been observed in organic semiconductor crystals in a series of publications until, inevitably, it was discovered to be a fraud. Numerous papers and books have been written about this period, and its causes (Beasley, 2002, Reich, 2009). Had it not been for the emerging industrial success of OLEDs, it is plausible that the entire field of organic electronics could have been set back, or even irreparably damaged by the scale of this abuse. Also, too many verifiable and exciting results were emerging from other labs, admittedly not nearly as apparently profound as those from Bell Labs, that helped to prevent the damage of scientific trust from having too great an impact. Yet as is typical of all aspects of organic electronics, there is much to be learned from this experience by the larger scientific community. It opened up questions about the responsibilities, both technical and ethical, of collaborators when one of their own is serially, and somewhat openly abusing scientific norms. What is the role of the scientific supervisor and of the larger scientific community for calling out, and halting this abuse? What is the role of the journals to ensure that standards of careful scientific review are followed? These will remain open, but nevertheless essential questions that the Schoen affair has placed uncomfortably before the scientific establishment. In spite of the unprecedented scale of the fakery, the field of organic electronics was not

mortally wounded, although many individual victims suffered from pursuing false leads and results created over the 2 years that Schoen was most active.

In spite of this setback, advances in organic electronic science and applications have been sustained to the present day. A pivotal event in its success was the launch in 2009 of the first major organic electronic product: Samsung's Galaxy smartphone series employing active matrix OLED (AMOLED) displays. Today, more than 2 billion such phones have been sold, along with OLED tablets, phablets, and so on, leading to a rapidly expanding US\$20 billion market. Next, LG Electronics introduced 55", 65", and 77" OLED TVs in 2012. Now these TVs are available in high definition versions, and work is progressing toward commercializing "roll-up" OLED TVs that can be stowed in a compact box. Most recently, Apple has entered the OLED display world by the introduction of the iPhoneX. Beyond OLEDs, major products are soon to emerge in lighting and organic solar cells. The future is certainly bright for organic electronics, following its long history of discovery and innovation.

One other fundamental advance worth noting that applies particularly to organic solar cells, was the derivation in 2010 of an ideal diode equation for excitonic heterojunctions. In 1949, William Shockley derived the first ideal diode equation for inorganic semiconductor p-n junctions (Shockley, 1949). As noted above, the rectifier is the most basic active element of an electronic circuit. The Shockley equation created the foundation on which semiconductor electronics has been built. However, we have seen that the fundamental physics of charge generation and transport is fundamentally different for excitonic semiconductors. Giebink and co-workers undertook the task of deriving a similar theory for organic junctions starting with the generation of an exciton in systems governed by the nearly isolated electronic orbitals of molecular systems (Giebink et al., 2010a, 2010b). This resulted in a theoretical framework similar to that of Shockley, but faithful to the underlying physics peculiar to molecular solids. This framework is helpful in understanding many important aspects of organic semiconductors, particularly in the context of photogeneration such as in predicting the thermodynamic limits to organic solar cell efficiency (Giebink et al., 2011). This work is an example of a fundamental discovery that has emerged well within the "Era of Organic Electronic Technology."

The foregoing provides but a few of the many examples of significant advances that have led to the current high state of sophistication in our understanding of the fundamental phenomena of soft organic

materials. And this understanding has led to their exploitation in devices that are now enjoying widespread commercial success. It bears repeating that this historical account omits many important discoveries and innovations, as it is only meant to give a thumbnail sketch of a rich and vibrant history of this fascinating subject. Likewise, separating the timeline into two “eras” is in itself wholly artificial, yet it helps to clarify the arc of progress within the field, and it highlights some of the most transformational events within that history. Ultimately, this “division” has also informed the structure of this volume, dividing it between Part I: Foundations, and Part II: Applications.

### 1.4 Aligning on language: a few useful definitions

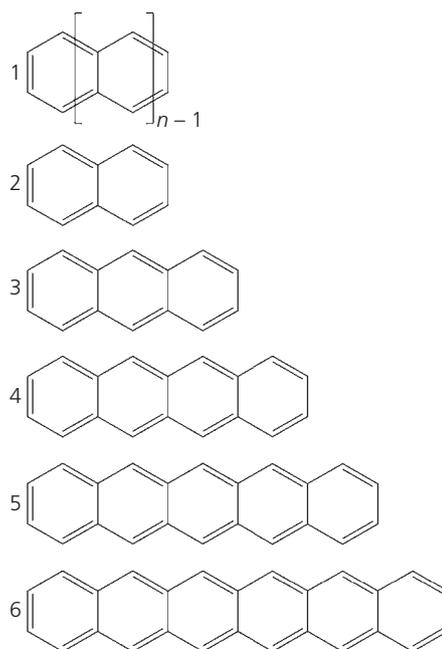

This is not a chemistry text. It is written almost entirely from a physics/engineering perspective that is reflective of the training of its author. But organic electronics is a deeply interdisciplinary subject, where chemists, physicists, engineers and materials scientists must all convene to effect the progress essential for new discoveries and innovations. It is nevertheless hoped that this text will be accessible to readers from all of these communities, independent of background in fields that lie beyond the scope of one’s personal training. For this objective to be met, we must establish a common language. The goal of this section is to provide a handful of chemical terms that can serve as a useful reference when they are encountered in later chapters. No effort is made to be comprehensive, as there are abundant resources one can draw upon to learn more about organic chemistry. Here, we provide an introduction, with more specialized terminology defined in the text where it first appears.

**Conjugation:** Organic electronic compounds comprise conjugated electron systems, that is, those systems that share p-orbitals between neighboring atoms that merge to form a delocalized orbital both below and above the molecular plane. The delocalized electronic systems are known as  $\pi$ -orbitals, or  $\pi$ -bonds. They increase molecular stability by ensuring structural planarity. Conjugation results from resonant, alternating single and double C–C bonds that delocalize electrons along the molecular backbone.

**Aromaticity:** Aromatic compounds form a class of conjugated molecules that are highly stable, have excellent film forming characteristics when deposited in vacuum, are generally insoluble, and are commonly found in organic electronic devices. An aromatic

compound is one that has an uninterrupted cloud of  $\pi$ -electrons that are located above and below a planar core. The  $\pi$ -orbital must contain an odd number of pairs of  $\pi$ -electrons. This is referred to as *Hückel’s rule*, where the  $\pi$  orbital of an aromatic must contain a total of  $4n+2$   $\pi$ -electrons, where  $n$  is an integer. A subclass of aromatics are the linear polyacenes of benzene (a single C ring with  $n = 1$ ), naphthalene ( $n = 2$ ), anthracene (3 fused rings) and so on, with examples shown in Fig. 1.11. These constitute a homologous series of fused ring, planar molecules containing only C and H atoms. For example, tetracene (compound 4) has nine pairs of  $\pi$  electrons (count the double bonds in the figure), or 18 such electrons, giving  $n = 4$ . This series of compounds is found throughout organic electronics, often used as archetypes to reveal physical or chemical attributes of a specific material of interest.

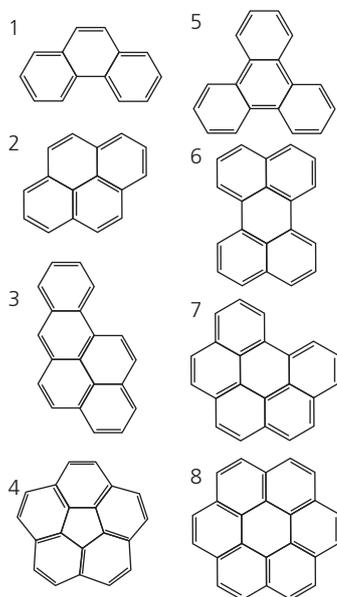

Linear polyacenes are members of a larger class of *polycyclic aromatic hydrocarbons* (PAHs). A few important examples of these planar, fused ring aromatics are shown in Fig. 1.12. PAHs can be found in nature, particularly in fossil fuel deposits. They are also products from burning organic matter, and are found in abundance in interstellar space, having been forged in the interiors of stars. Likewise, they are easily synthesized in the laboratory. Their stability and rich hues make them useful in clothing dyes, paints, and as ink

**Figure 1.11** The six lowest order linear polyacenes. **1** = general formula for the linear polyacenes.  $n = 1$  corresponds to benzene. **2** = naphthalene, **3** = anthracene, **4** = tetracene, **5** = pentacene, **6** = hexithene.

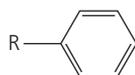

jet printing pigments. Like their linear analogs, PAHs are insoluble, but are sufficiently stable to be thermally evaporated (most PAHs sublime in vacuum on heating, although a few compounds first go through a liquid phase).

**Functionalization:** If the conjugated molecules and their analogs described above were the end of the story, the list of organic compounds used in organic electronics would indeed be short. However, the versatility of organics rests on their ability to be functionalized to gain attributes not present in the parent molecule. Functionalization is the substitution of a chemical group (a substituent) on a bond or bonds of a parent molecule to alter its characteristics. For example, the molecule benzene in Fig. 1.13 is functionalized by replacing one of its peripheral H atoms with an R-group. An R-functionalization implies the attachment of a non-aromatic, non-conjugated hydrocarbon. While it more loosely can include other atoms besides C and H, it formally applies to a series of C–H molecules known as *alkanes*, with the formula,  $R = C_nH_{2n+1}$ . A series of lowest order alkanes is shown in Fig. 1.14. The alkanes are also products of fossil fuels, and are

**Figure 1.12** A series of polycyclic aromatic hydrocarbons.

1 = phenanthrene, 2 = pyrene, 3 = benzopyrene, 4 = corannulene, 5 = triphenylene, 6 = perylene, 7 = benzoperylene, 8 = coronene.

**Figure 1.13** Benzene functionalized by substitution of an H atom with an R-group.

almost all found in the liquid or gas state at room temperature. Alkanes are most often attached to PAHs and other molecules to make them soluble in organic solvents.

Another functionalizing substituent is the *Ar-* or *aryl group*. This is a group derived from an aromatic ring. Most commonly, *Ar-* refers to a phenyl (i.e. benzo) group, but it can also refer to naphthyl derived from naphthalene, or xylene, pyrene, etc. Hence, an *Ar* group is one that derives from an aromatic hydrocarbon parent.

The last functionalizing group to be considered comprises heterocyclic substituent molecules. These are aromatic rings where one (monocycle) or more (polycycle) carbon atoms are replaced by other atomic species, such as O, S, N, etc. These heterocyclic additions can introduce substantial changes in molecular character, and hence are pervasively used to modify molecules employed in organic electronics. Figure 1.15 provides a reference of many common heterocyclic substituents found in organic semiconductors.

**Ligand:** In inorganic chemistry, a ligand is a functional group that is attached to a metal atom (e.g. Al, Cu, Ir, Pt, etc.) to form a *coordination complex*. Metalorganic compounds are ubiquitous in organic electronics. For example, PHOLEDs employ such compounds to induce spin-orbit coupling via metal-ligand charge transfer between a heavy metal atom and the light emitting ligand. Also, the metal complex,  $Alq_3$ , was used in the first bilayer OLED due to its intense green fluorescence when electrically excited. (Tang and VanSlyke, 1987) One or more ligands can coordinate with the metal atom, depending on the valences of the atom. The metal-ligand bond can range from the purely ionic to covalent. In Fig. 1.16 we show the molecular formula of  $Ir(ppy)_3$  comprising three identical ligands attached to an Ir core. This is known as a *tridentate* molecule (having 3 ligands, or “teeth”) that is *homoleptic* (all ligands are identical). In contrast,  $Ir(ppy)_2acac$  is a *bidentate, heteroleptic* molecule. Both are phosphors that emit in the green, although  $Ir(ppy)_2acac$  is by far the most efficient of the pair, having been used in PHOLEDs with 100% internal quantum efficiency (Adachi et al., 2001). The acetylacacetate (acac) ligand, is a non-emissive *ancillary ligand* that is attached to satisfy the bonds of the Ir atom. The general formulation of these molecules is  $IrL_3$  for the homoleptic compounds, and  $IrL_2X$ , for heteroleptic molecules with one ancillary (X) ligand.

**Porphyryns and phthalocyanines:** These two classes of compounds have optical and electronic properties

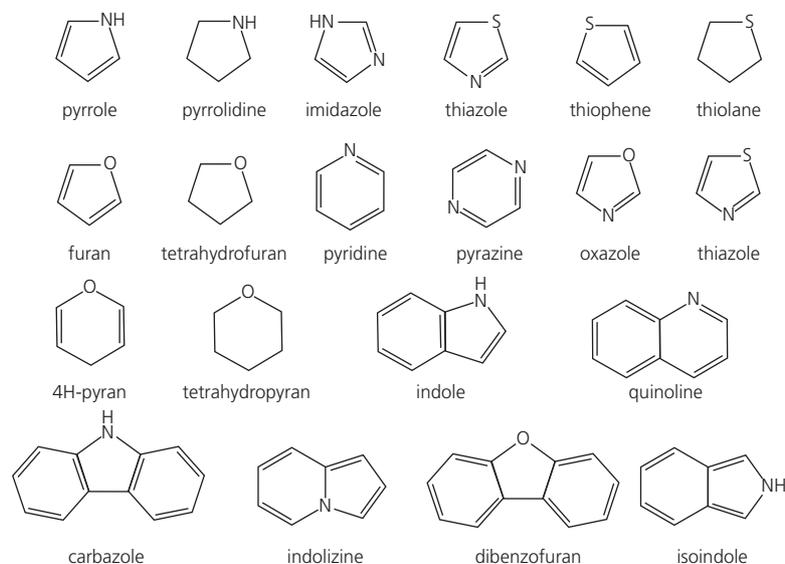

Name	Formula	Structure	State (at room temp.)
Methane	CH <sub>4</sub>	<pre>       H             H-C-H               H           </pre>	Gas
Ethane	C <sub>2</sub> H <sub>6</sub>	<pre>       H H               H-C-C-H                 H H           </pre>	Gas
Propane	C <sub>3</sub> H <sub>8</sub>	<pre>       H H H                 H-C-C-C-H                   H H H           </pre>	Gas
Butane	C <sub>4</sub> H <sub>10</sub>	<pre>       H H H H                   H-C-C-C-C-H                     H H H H           </pre>	Gas
Pentane	C <sub>5</sub> H <sub>12</sub>	<pre>       H H H H H                     H-C-C-C-C-C-H                       H H H H H           </pre>	Liquid
Hexane	C <sub>6</sub> H <sub>14</sub>	<pre>       H H H H H H                       H-C-C-C-C-C-C-H                         H H H H H H           </pre>	Liquid

that are commonly found in devices ranging from light emitters, to optical detectors, and transistors. A porphyrin is a heterocyclic compound comprising four pyrrole subgroups. The heterocycle consists of 26  $\pi$ -electrons, but only 18 of those electrons form a continuous, conjugated path around the periphery of the molecule, as shown for PtOEP in Fig. 1.17. The parent porphyrin, comprising two H atoms coordinated with the pyrrole groups is known as porphine. When the H atoms are replaced by a metal coordinated to the pyrroles, the molecule is known as a porphyrin. These molecules are characterized by rich colors and crystal packing arrangements that can lead to high charge mobilities along the resulting discotic stacks. *Discotic* refers to the planar, disc-like molecules that can stack like poker chips to form continuous conducting pathways due to overlapping  $\pi$ -electron systems on adjacent molecules. Porphyrins are found in biological systems. Examples are Mg porphyrin which is a light absorbing molecule in photosynthetic complexes, and Fe porphyrin (so-called heme) found in red blood cells as a part of the

hemoglobin protein. In organic electronics, heavy metal porphyrin complexes, particularly those containing Pt, are used as highly efficient phosphor dopants in organic electronics. Indeed, PtOEP was used in the first PHOLED, efficiently emitting in the deep red (Baldo et al., 1998). Similarly, tetraphenyl porphyrin (TPP), which lacks a heavy metal atom, is an efficient fluorescent molecule also emitting in the deep red (Shen et al., 1997). An attractive feature of both the porphyrins and phthalocyanines is that their optical properties are strongly affected by the choice of coordinating metal. Hence, minor chemical adjustments can be made to result in metal porphyrin phosphors that narrowly emit from the NIR into the blue spectral regions.

The phthalocyanines (Pcs) are similar to porphyrins in that they form a class of highly stable, easily deposited compounds that are deeply absorbing across the visible, depending on the transition metal used to coordinate between the four, peripheral isoindole groups. Like the porphyrins, 18  $\pi$ -electrons make up an extensive, conjugated macrocycle. The parent, or

**Figure 1.15** Common heterocycles found in organic electronic molecules.

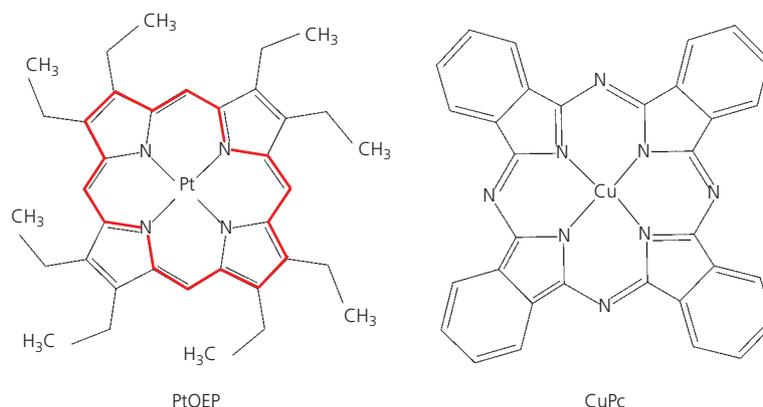

**Figure 1.16** Two green emissive phosphors: Ir(ppy)<sub>3</sub> and Ir(ppy)<sub>2</sub>acac.

free-base Pc, H<sub>2</sub>Pc, replaces the metal atom with two H atoms. By virtue of both their stability and deep coloration easily modified by changing the metal atom (Cu, Zn, Pb, VO are just a few of the metals and compounds used as the coordination center), the phthalocyanines are used in dyes and even in hydrodynamic therapy. CuPc shown in Fig. 1.17 absorbs in the red, and hence appears to be blue-green to the eye. Indeed, CuPc was used as a donor molecule in the first bilayer OPV, exhibiting a power conversion efficiency of approximately 1% under simulated solar illumination (Tang, 1986). Their excellent film-forming characteristics have also led to uses in transistors. Much less frequently, metal Pc (MPc) molecules have been incorporated into OLEDs as contact layers, although this application has been

limited by their strong absorption of the emitted radiation.

## 1.5 The myths of organic electronics

Since the earliest years of its development, myths have swirled around unfounded suppositions about the physical properties, and capabilities of organic electronics. After all, organics could not possibly be useful in practical electronic devices since they are inherently unstable, right? We know that living organisms that are comprised of organic molecules eventually die, they ordinarily cannot be subjected to high temperatures, and they cannot be exposed to bright sunlight for any length of time without degrading. All of these preconceptions,

**Figure 1.17** Molecular structural formulae of the porphyrin, PtOEP, and the phthalocyanine, CuPc. The red line in the PtOEP molecule traces the 18  $\pi$ -electron cycle.

and many more have slowed the investment in, and ultimately the progress of organic electronics science and technology.

But long experience has told us that many of these prejudices are not founded in fact. After all, some OLEDs have demonstrated lifetimes of  $>10^6$  h, and OPVs have been shown to slowly degrade over periods as long as decades. These findings have led to the development of global industries. Indeed, many organic electronic devices are fit for countless unexpected, but wholly practical applications, many of which that are yet to be developed. My opinion, with caveats, is that organics can “do anything” that ordinary semiconductors can do, within the appropriate application space.

Within this context, it is helpful to enumerate some pervasive myths, and to explain the current state of our understanding that contradicts common preconceptions. A partial list is provided in Table 1.4, along with a brief explanation. The chapters in which these myths are more fully addressed are found in the last column on the right.

Many myths involve supposed costs of organic electronic devices and processes. While these are difficult to estimate without data supplied by manufacturers, the costs of semiconductors are rarely dominated by the cost of equipment used in their production. For example, a semiconductor production facility (a “fab”) typically costs over US\$5 billion to build and fully equip, yet the cost of semiconductor chips represents only a minimal fraction of the application in which they are employed (e.g. in a laptop computer). The costs of high precision equipment, and an expensive fabrication facility that maintains extreme levels of purity in a dust-free environment are amortized over the volume of chips produced.

That is, the most important determinant in cost is not the capital expense, but rather by the throughput and yield of the end product.

There are many other myths (and facts) than those listed in the table. It is an interesting challenge to think about our notions of the strengths and weaknesses of organic materials and devices. This listing should get one started down the path of separating fact from fiction that will increase our appreciation of the advantages and weaknesses that characterize this rich and useful field of study, and its applications. And with this knowledge, we are prepared to meet the challenge of exploding yet another myth.

## 1.6 Summing up

In this chapter, we have provided the definition of an organic semiconductor, and how its properties differ in fundamental ways from those of conventional, inorganic semiconductors. We have given a thumbnail sketch of the 70 year history of this most exciting scientific field, and through that discussion have seen why it motivates so many scientists to uncover the mysteries of disordered, soft materials. The ability to modify materials characteristics offered via organic chemical synthesis promises unprecedented opportunities for scientists and technologists to engineer properties “on demand” that satisfy the needs of a particular application unserved by other electronic technologies. Indeed, organic electronics is unique in its versatility and ability to change the way we interact with, and sense the world around us.

Yet, we have not directly answered the question that we posed at the beginning of this chapter: “What is organic electronics good for?” In fact, we have already answered this question to some extent. After all,

**Table 1.4** Facts and myths in organic electronics

Myth	Fact	Chapters
Surface morphology can be used to reveal the crystallinity of an organic thin film	While rough surfaces may indicate a bulk crystalline structure, or a smooth surface an amorphous one, often the opposite is the case. X-ray and other structural probes are the only way to tell the true film morphology.	2, 5
Charge mobilities in organics can approach those of crystalline inorganics	Hopping dominates in organics, and without exception at room temperature, dynamic disorder limits bulk mobilities to $< 5 \text{ cm}^2/\text{V s}$ .	4
Organic thin film transistors (OTFTs) can lead to reliable mobility measurements.	Yes and no, it depends on what you mean by mobility. OTFTs can give a value for the mobility at the dielectric interface, but not the bulk. The most reliable mobilities are obtained from OTFT frequency response.	4, 8
Organic devices will always be unreliable	Red PHOLEDs have lifetimes in excess of $10^6$ h. Longer lifetimes are possible, depending on the device. OPVs, too are showing lifetimes well in excess of 25 years.	6–8
Organic devices are inexpensive since the fabrication processes and materials do not need the high purity of inorganics	There is no example of a practical devices, either organic or inorganic, whose performance is not improved by using the purest materials and most controlled processes possible.	5–8
Ir and Pt complexes used in PHOLEDs need to be replaced by materials containing atoms less expensive than Ir or Pt.	The cost of materials rarely determines the cost of electronic devices. However, the cost of synthesizing materials and fabricating devices do impact device cost. Also, the amounts of these precious metals used in PHOLEDs are negligible.	6
Solution processing is less costly than deposition in vacuum, hence making solution processes preferable.	In any manufacturing environment, product throughput is the most important factor determining cost, not the expense of the machines employed. Further, whether solution or vapor phase processing is used, it must be done in an ultraclean environment with highly controllable and therefore expensive equipment, and there is always likely to be at least one vacuum deposited layer (e.g. metal contacts) on a completed device.	5
Single layer polymer devices should be less expensive than multilayer, complicated structures used for small molecule devices.	All photonic devices, and most electronic devices require multiple layers to achieve high performance and long lifetime.	6, 7
The performance and cost of organic transistors is insufficient to make them competitive with emerging metal-oxide transistors that can also be solution processed.	For many applications, this is undoubtedly true. However, organic transistors with their form factors, design flexibility, etc. have opportunities in large area, conformable electronics, medical devices, stretchable electronics, etc. that are difficult or impossible to address with other materials systems.	8
LED lighting is so efficient and low cost that OLEDs will not compete.	The conformability, transparency, fixture design capabilities, attractiveness, and high efficiency make OLEDs extremely well suited to many spatial lighting applications.	6
QD LCDs have a color gamut as large as OLEDs. They will eventually dominate the TV and monitor industries.	QD LCDs are quite attractive, but they still suffer from almost all other disadvantages of LCDs that are not drawbacks of OLEDs: slow response, viewing angle and temperature dependence, etc.	6
OPV efficiencies will always be too low to become important for solar generation	OPV efficiency has gone through numerous “steps” over the years. Today at $>15\%$ , it is poised to make another step toward the predicted single cell thermodynamic limit of 20–25%. This, combined with lightweight, semitransparency, etc. make it promising for many unique solar energy harvesting applications.	7
An electrically pumped organic laser will be achieved by finding materials with sufficient conductivity and robustness to create population inversion.	At high currents, the losses of triplets confined to the lasing medium overwhelm the gain from electrical pumping. Hence, achieving <i>direct</i> electrical pumping of the gain medium is unlikely.	6
Plastic substrates are inexpensive.	The multilayer organic/inorganic stacks needed to provide a barrier to moisture and oxygen penetration through plastic substrates for long device lifetime are costly to manufacture. Glass, and especially metal foils are much less expensive. The latter is the least costly if lack of transparency is acceptable.	5-8

OLEDs have generated a massive mobile and TV display industry that is poised to unseat the long time, but in many ways inferior incumbent liquid crystal display technology. And given their very high efficiency and superb color rendition, OLED lighting is emerging as a new application opportunity for organics. OPVs, too, appear to be heading toward commercialization, and perhaps later, a new medical sensing technology based on flexible OTFTs will develop. We do not know for sure what the future holds, but we do know that the enormous strides made in understanding organic semiconductors, driven in large part by the intense interest in creating and exploiting the new market opportunities they have created, is opening vistas in physics, chemistry and materials science that daily increase our understanding of the nature of disordered materials.

In this context, we now define those applications where the distinct characteristics of organic electronics provide a clear advantage over other electronic technologies.

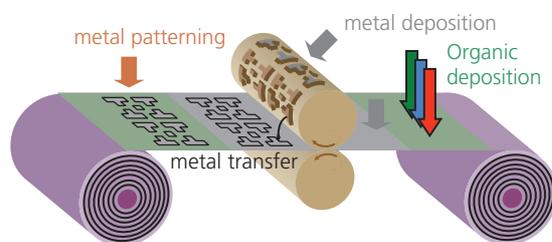

*Large area:* With their ability to be deposited over very large (square meter and larger), reasonably smooth substrates without regard to the constraints of matching its lattice to that of the substrate, makes organics ideally suited for applications requiring large devices. These include displays, lighting and solar cells where large scale (sometimes the larger the better) is a virtue.

*Flexibility, conformability, foldability:* Organic semiconductors are soft materials, suggesting that they can be twisted, stretched and folded without creating large stress within the thin films comprising the devices. Combined with their ability to be deposited on almost any smooth surface allows, them to serve applications where flexibility (e.g. in a roll-up OPV), conformability (e.g. on a display used on a curved instrument panel or a shaped lighting fixture), or even where the device must have a crease, such as in a fold-up smart phone, are necessary. There are many challenges to be met to achieve this vision, since the substrate and the contacts must also allow for the necessary distortions during use without breakage or degradation.

*Environmental compatibility:* The use of generally non-toxic materials within the application and in its manufacture is important when we consider the life-cycle of a product, from chemical synthesis, to fabrication, to its use, and finally to disposal when it is no longer needed. Since organics are destined for use as large area, ubiquitous consumer products, attention to environmental impact becomes especially important. The low energy investment

required for their near-room-temperature fabrication is also an advantage compared to conventional semiconductors such as Si whose process temperatures are  $\sim 1500^{\circ}\text{C}$ .

*Low cost:* Here it can be argued that organics have a significant advantage over other semiconductor technologies. The materials are often dye compounds that can be manufactured in bulk. We will see in subsequent chapters that thin film deposition on flexible substrates opens the door to roll-to-roll (R2R) manufacture of organic devices as conceptualized in Fig. 1.18. This requires a significant paradigm shift away from producing electronics by the batch as we do today, to generating product by the kilometer tomorrow! High throughput, R2R manufacturing however, must be accompanied by high manufacturing yield. This is a significant challenge for displays that require micrometer-scale pixel patterning. However, significant strides have been made in both demonstrating R2R manufacturing, as well as nanoimprint patterning that are well suited to continuous web production. The combination of these manufacturing functions is also illustrated in Fig. 1.18. As suggested in Section 1.4, the R2R environment must be contaminant-free, that is, organics are as susceptible to degradation due to impurities, dust, and other extrinsic agents as is every other electronics technology. Indeed, there are few, if any examples of an electronic device technology in widespread use that has not gone to great lengths to use the highest purity materials and manufacturing processes. The experience of the OLED industry in constantly improving device and materials purity to improve performance is a prime example of the importance of maintaining the highest standards from materials purification, all the way through to device fabrication and packaging. As noted previously, however, the cost of maintaining materials purity and processing integrity is more than offset by increased throughput offered via high speed, continuous R2R production.

**Figure 1.18** Roll-to-roll concept for the deposition and patterning of organic devices consisting of organic thin films and printed metal contacts (Forrest, 2004).

First published in Forrest, S. R. 2004. Nature (London), 428, 911.

In aggregate, organic materials can lead to dramatic transformations in how we manufacture, and use semiconductor devices—allowing for low temperature solution or vapor-phase-compatible R2R, processing and deposition on flexible substrates comprised of plastic, ultrathin glass, or metal foils. One vision of the future enabled by this unique combination of properties is that custom circuits, prepared to meet the needs of specialized applications, can be produced “on demand” on the desktop using an organic electronic printer connected to a laptop computer. This concept might be particularly attractive to a physician who needs to create a custom monitoring device for personalized medical applications. Indeed, this customization paradigm is already making inroads in the manufacture of mechanical structures using 3D printers. Surely, printing of organic optoelectronic circuits cannot be far behind!

### Problems

1. Table 1.4 provides a list of “myths” that have pervaded the field of organic electronics over many years.
  - a. Select a myth, and briefly describe why, or why not it is a myth. You should find a paper or papers to back up your arguments: do not just state opinion but provide support backed up by evidence that your conclusion is correct. Fully reference your sources (authors, date, title, volume, page numbers).
  - b. Find an important and pervasive myth that is not on the list. The same standards of proof apply as in part (a).
2. An organic semiconductor has a dielectric constant of 2.5, and an inorganic has a dielectric constant of 12. Assuming for the organic that the electron effective mass is  $m_e^* = 1m_0$  and the hole effective mass is  $m_h^* = 0.5m_0$ , where  $m_0$  is the electron mass:
  - a. Calculate the exciton radius,  $a_0$ , and binding energy,  $E_B$ , assuming the Bohr model of the atom is an appropriate model for an exciton.
  - b. Redo part (a) for an inorganic semiconductor with  $m_e^* = 0.1m_0$ .
3. A CT exciton in the organic material is found to have  $E_B = 0.4$  eV. Calculate its radius. Assuming a molecular dimension of 0.5 nm separated by 0.35 nm, what is the maximum number of molecules over which this CT state can spread?
3. This problem requires that you find some information about materials from the literature. For the materials Si, TiO<sub>2</sub>, CdSe, anthracene, and assuming the Bohr model of an atom, (put your answers to this question in tabular or graphical form):
  - a. Calculate their exciton binding energies and exciton radii.
  - b. Which would you consider to be Wannier–Mott and which would be Frenkel excitons?
  - c. What is a typical intermolecular bond energy in each case?
4. Akamatu and Inokuchi were the first to observe semiconductor-like behavior in an organic by measuring the dependence of conductivity on temperature.
  - a. Starting with the basic theory of Fermi statistics in semiconductors, derive expressions that describe the conductivity ( $\sigma$ ) as a function of temperature,  $T$ , from high temperature to near 0 K. Assume that the semiconductor is n-type with band gap  $E_G$ , effective densities of states  $N_C$ ,  $N_V$  for the conduction and valence band edges, respectively, and a donor concentration  $N_D \ll N_C$ ,  $N_V$  at energy  $E_D$  below the conduction band edge. To keep things simple, we assume that the  $T$ -independent mobility of electrons  $\mu_e \gg \mu_h$  (the mobility of holes), and that the effective masses are  $m_e$ ,  $m_h$ , respectively.
  - b. Plot the results in (a) for Si and Ge with  $N_D = 10^{15}$  cm<sup>-3</sup> and  $E_D = 20$  meV. The plot should be of the form,  $\log(\sigma)$  vs.  $1000/T$ .
  - c. From Akamatu and Inokuchi’s resistivity data (in units of  $\Omega$  cm) in Fig. P1.4, determine the energy gap of

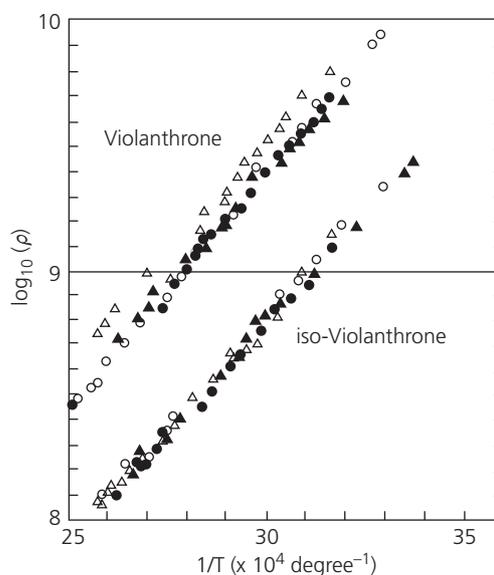

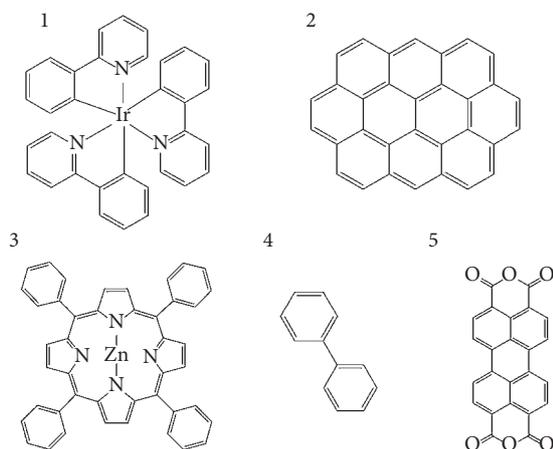

Figure P1.4 Resistivity data from Akamatu and Inokuchi (1950).

violanthrone, as well as the lower limit to the donor energy,  $E_D$ . Assume  $m_e^* = m_0$ , the rest mass of the electron,  $\mu_e = 0.001 \text{ cm}^2/\text{V s}$ , and that there is one electronic state per molecule. The value of  $E_D$  is rather insensitive to these choices, so you can make intelligent estimates.

5. Several molecules used in organic electronics are shown in the accompanying Fig. P1.5.
  - a. Which of the compounds are aromatics? How many paired electrons exist in the  $\pi$ -orbitals?
  - b. Which of the molecules can potentially emit light efficiently?
  - c. Can you identify a homoleptic compound? A heteroleptic compound?
  - d. Write the chemical formulae for each of the compounds in the figure.

**Figure P1.5** Molecules used in organic electronics.

# Bulk and thin film organic crystal structures

---

*“Beware of over-confidence; especially in matters of structure.”*

**Cass Gilbert, American Architect**

Crystal structure ultimately determines the properties of a solid. Its binding forces, symmetry, and electrical and optical properties all arise from the structure of the material. In this chapter we begin our discussion of the basic concepts of crystalline structures by defining the various types and symmetries that a crystal lattice might take. Various definitions and conventions used to describe crystal structure, including the concept of the unit cell, symmetry space groups, identifying and indexing crystal planes, and lattice types, will be discussed with particular focus on those features most pertinent to organic materials. Next we consider the fundamental forces that bind materials into solids. These cohesive forces include *ionic*, *covalent*, *metallic*, and most importantly for organic materials, *van der Waals* and *hydrogen bonds*. Our treatment of these bonding forces is based on seeking the minimum total energy of the crystal—an approach that is conceptually straightforward but in practice is very difficult to implement on a macroscopic scale.

Almost all optoelectronic devices are comprised of thin films rather than bulk crystalline materials. This is particularly true for organic semiconductors. The films are typically grown on a supporting substrate that may consist of a structure very similar to the layers themselves, or they may have a completely different structure, ranging from amorphous, to nanocrystalline, to single crystalline morphologies. In every case, the growth mode and resulting film morphology is determined by both the energy between film and substrate, and the thermodynamic conditions employed during layer growth. We will discuss factors relating to the lattice potential energy that result in a particular film structure or morphology. We find that the modes of growth are determined by the thin film structure and its relationship to the substrate that results from the particular binding forces at play. Here, we distinguish between the principal forms of layer templating with the substrate, which include *epitaxy*, *van der Waals epitaxy*, and *quasiepitaxy*. Indeed, since molecular materials are primarily bonded via flexible (i.e. soft) van der Waals forces, the resulting structures are a result of the many degrees of freedom that soft bonding allows. Moving beyond simple layered structures, self-assembly provides a driving force for many organic and indeed inorganic structures that are of both scientific and practical interest. Indeed, self-assembly is an example of a multi-scale process whereby individual units at one length scale (e.g. atoms or molecules) are functionalized to assemble into organized units of a much larger scale (from nanometers in the case of thin films, to microns in biological systems, to even the centimeter scales and beyond). Both molecular and polymeric organic material structures are strongly influenced by forces that lead to larger assemblies that produce a broad and rich range of structures.

While this chapter considers the fundamental properties of molecules and assemblies that lead to micro- or mesoscopic order, it does not provide guidance on how to achieve a desired structure. Further discussions on growth kinetics leading to target morphologies can be found in Chapter 5, and the following chapters in Part II when it relates to the performance of a particular device.

## 2.1 Molecular materials: definitions

As discussed in Chapter 1, organic materials are broadly categorized into the large class of “soft materials.” That is, the materials have a low bulk modulus (i.e. they are compressible and elastic) compared to covalently or ionically bonded materials. It is the lack of chemical bonds between the individual cohesive units (e.g. the molecules comprising the solids) that lends them their numerous physical, optical and electronic properties. Generally, the term molecular material refers to that class of materials whereby the individual cohesive units are not chemically bonded, but rather cohere due to the presence of purely electrostatic van der Waals and/or hydrogen bonds. An alternative definition of a molecular material coined by Kitaigorodsky (Robertson, 1958, Kitaigorodsky, 1973) is a material where the atoms within a molecular unit in the crystal are more closely spaced than the atoms residing on neighboring molecules. For example, the nearest point of contact between molecules in a solid ranges from 3.1 Å to 4.5 Å. However, the C–C bond distance ranges between 1.2 Å and 1.5 Å, whereas a H–C or H–N bond length is ~1 Å. Hence by this metric, in the solid state, small molecules and polymers fall within the general class of molecular materials.

Almost all molecular materials are organic. There are notable exceptions, however. These include non-carbon containing molecules such as O<sub>2</sub>, N<sub>2</sub>, and solid phases of the noble gases such as Ar, Ne, Xe, etc. In addition, the fullerenes (e.g. C<sub>60</sub>, C<sub>70</sub>, C<sub>84</sub>, and so on) and collections of carbon nanotubes are inorganic materials that also fall within the class of molecular materials.

In this chapter, we are primarily concerned with organic small molecule materials and the forces that lead to their peculiar physical properties. We begin by discussing the crystal lattice structure, crystal symmetry and the packing of molecules in the solid state. This provides a framework for understanding the specific properties of organic solids. We note that this discussion covers all classes of structure, but concentrates primarily on those found in molecular materials. Since equilibrium structures are those found at the lowest lattice free energy, we need to consider crystalline cohesion; examining the major bonding forces including ionic, covalent, metallic, van der Waals and hydrogen bonds.

## 2.2 Lattices and crystal structure

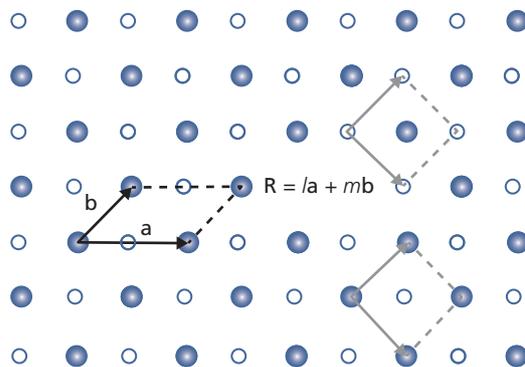

A *Bravais lattice* is an infinite array of points that define the symmetry of the crystal. A three-dimensional (3D)

vector that translates one point to another, identical point in space, defines the lattice itself. That is, we introduce the *lattice translation vector* as

$$\mathbf{R} = l\mathbf{a} + m\mathbf{b} + n\mathbf{c}, \quad (2.1)$$

where  $l$ ,  $m$ , and  $n$  are integers corresponding to the number of lattice translations, and  $\mathbf{a}$ ,  $\mathbf{b}$ , and  $\mathbf{c}$  are *primitive* translation vectors that, taken together, define the smallest *unit cell* within the lattice that can be translated to any other identical position via  $\mathbf{R}$ . That is, we consider an arbitrary vector,  $\mathbf{r}$ , and then any translation to a point  $\mathbf{r} + \mathbf{R}$  will be at a position equivalent to  $\mathbf{r}$  within the lattice. The magnitudes of the translation vectors,  $\mathbf{a}$ ,  $\mathbf{b}$ , and  $\mathbf{c}$  are called *lattice constants* or *lattice parameters*. Figure 2.1 gives examples of  $\mathbf{R}$  and the primitive translation vectors of a two-dimensional (2D) square lattice comprising two atoms (symbolized by open and closed circles). We see that the choice of primitive vectors is not unique. Indeed, the only requirement is that their choice is established by Eq. 2.1, in that every point in the lattice can be accessed by integer multiples of the displacement vectors,  $\mathbf{a}$  and  $\mathbf{b}$ .

In an actual material, the atoms or molecules lie within the unit cell, defined by the primitive translation vectors. To be a Bravais lattice, the unit cell must be space-filling; that is, when replicated and translated by vector  $\mathbf{R}$ , it must completely fill the crystal volume with no gaps or spaces between adjacent cells. A notable exception to this rule is the quasicrystal with fivefold symmetry. Such a structure is not

**Figure 2.1** An example two-dimensional square lattice with a basis of two atoms (one solid, the other hollow). The primitive displacement vectors are  $\mathbf{a}$ ,  $\mathbf{b}$ , and the translation vector  $\mathbf{R}$  takes each lattice point into another equivalent point for all integers,  $l$ ,  $m$ . The unit cell is the area bounded by the parallelogram, and is space filling. Other possible unit cells are shown in gray.

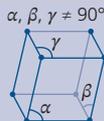

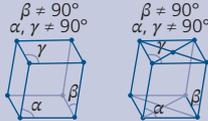

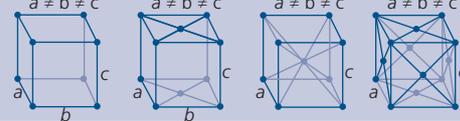

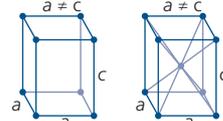

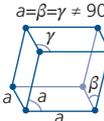

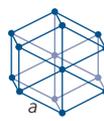

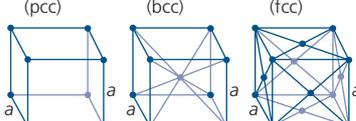

space filling, yet is found in some insulators (Shechtman et al., 1984). When one or more atoms or molecules are located within each unit cell, the Bravais lattice then defines the crystal structure. The number of atoms or molecules comprising the cell is known as the *basis*. For example, NaCl has a basis of 2, consisting of 1  $\text{Na}^+$  and 1  $\text{Cl}^-$  ion within each primitive unit cell. Figure 2.1 is an example of a square lattice with a basis of two.

In three dimensions, there are 14 possible Bravais lattices in seven lattice systems shown in Table 2.1. Molecular crystals form close packed arrangements that almost always are in the cubic (face and body centered), orthorhombic, monoclinic, or triclinic unit lattice systems, with a basis of one, two or four molecules. The most common lattices found in organic materials are highlighted by the shaded box in the table. As we will find in Section 2.4, close packing

arrangements result in the lowest energy, equilibrium molecular lattice.

The number of neighboring units (i.e. atoms or molecules) in a lattice contacting a molecule is known as the *coordination number*. For a simple cubic lattice the coordination number is 6, increasing to 8 for body centered cubic (bcc), and 12 for face centered cubic (fcc). Interestingly, the diamond structure of Si and Ge is also cubic consisting of two interpenetrating fcc lattices, with one atom at the vertex of one fcc lattice positioned at the origin,  $(0,0,0)$ , and its nearest neighbor anchoring the second fcc lattice at  $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})\mathbf{a}$ , where  $a = |\mathbf{a}|$  is the lattice constant. The coordination number of the diamond structure is 4 and the basis is 2. Note that the zincblende structure characteristic of many alloy semiconductors such as GaAs and InP is also a diamond structure, but where the nearest neighbor atoms are different (e.g. Ga and As). The volume of the unit cell is

**Table 2.1** Classification of Bravais lattices

Lattice system	Bravais lattice

Cubic	

$$V_{\text{cell}} = \mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}). \quad (2.2)$$

It is clear that a cubic structure, where all sides are mutually orthogonal, has  $a = b = c$  and  $V_{\text{cell}} = a^3$ .

To minimize lattice energy, van der Waals solids almost always form either monoclinic or triclinic structures. Indeed, the total free energy that must be minimized in an equilibrium structure where the closest packing is achieved is  $E_{\text{tot}} = E_{\text{lat}} + E_{\text{vib}}$ . Here,  $E_{\text{lat}}$  and  $E_{\text{vib}}$  are the lattice and vibrational energies, respectively. The vibrational energy comes from internal degrees of freedom both within and between the molecules or atoms. There are no known exceptions where the equilibrium structure is not close-packed, whereby each molecule is separated by the van der Waals radii (i.e. the distance at which the repulsive nuclear core potential energy equals that of the attractive binding energy, see Section 2.4) of the nearest atoms from adjacent molecules. We define the *packing coefficient* or *packing fraction* of a lattice as the fraction of space that is filled (normalized to a unit volume), taking into consideration the minimum intermolecular contact distances (i.e. the van der Waals radii), the bond lengths between atoms comprising the molecules, and the valence angles. Then, the lowest packing fraction of a molecular crystal in its lowest energy phase is 0.65–0.77 (Kitaigorodsky, 1973). The packing fractions of several different common lattice structures are provided in Table 2.2 if the molecules are approximated by spheres. We see that molecular materials fall within the ranges predicted for the packing of spheres, even though the shapes of and symmetries molecules can differ significantly from this simple approximation.

The symmetry of a crystal structure is defined by its *space group*, which gives the number and type of translational, rotational or mirror operations that a lattice can undergo that will bring it back onto itself; that is, for the lattice to find an orientation equivalent to its original. One space group is the *point group* where the symmetry operation is around a fixed point that once more leaves the lattice invariant.

**Table 2.2** Packing fractions for several cubic lattices

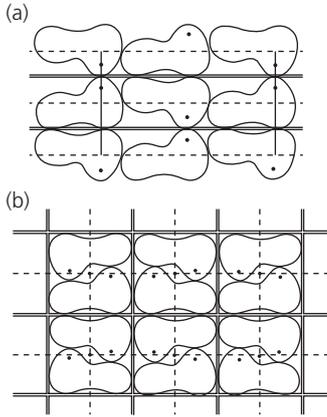

Lattice structure	Packing fraction
Simple (point centered) cubic (pcc)	$\pi/6 = 0.52$
Body centered cubic (bcc)	$\pi\sqrt{3}/8 = 0.68$
Face centered cubic (fcc)	$\pi\sqrt{2}/6 = 0.74$
Hexagonal close packed (hcp)	$\pi/3\sqrt{2} = 0.74$
Diamond	$\sqrt{3}\pi/16 = 0.34$

There are 230 symmetry or space groups for a lattice with a basis, but only a small subset of these groups are found in molecular crystals due to the limited number of crystal habits that such close-packed, asymmetric materials can assume. In addition, there are 32 point groups. It is beyond the scope of this discussion to enumerate all of the various space and point groups, so we will confine ourselves to considering the basic symmetry operations, and then listing those groups in which molecular crystals are found.

Table 2.3 lists the symmetry operations and their notations, from which the nomenclature for all groups can be decoded. In identifying a space group for a given lattice, it is essential to find the highest possible symmetry. The space groups for molecular crystals are the primitive groups for close packing of molecules without symmetry: P1, P2<sub>1</sub>, P2<sub>1</sub>/c, Pca, Pna, P2<sub>1</sub>2<sub>1</sub>2<sub>1</sub>; and with a center of symmetry, the space groups are P $\bar{1}$ , P2<sub>1</sub>/c, C2/c, Pbca. These notations are defined as follows: P = Primitive, C = centered on the **a** or **b** face of the lattice. Then, for example, P2<sub>1</sub>/c is a primitive lattice, with twofold screw axis along **b** for a monoclinic cell, followed by a glide along the **c** axis (here, the subscript following the 2 indicates the number of *half* translations along an axis). A glide plane is a reflection about a plane followed by a translation along the same plane. An n-glide is along half a diagonal of the face of the plane, and a glide is along a body diagonal. Similarly, Pca is a primitive lattice with glide planes along **c** and **a**. Examples of 2D molecular plane groups and their symmetry operations are shown in Fig. 2.2. The coordination

number of the structure in Fig. 2.2a is 4, and the space group is *cm*, that is, there is one mirror symmetry operation possible about the horizontal planes that take the molecular lattice sites back onto themselves when folded about the planes. In Fig. 2.2b, the coordination number is also 4, with two mirror symmetry operations about the perpendicular and horizontal planes denoted *cmm*.

### 2.3 The reciprocal lattice, Miller indexes, and the Brillouin zone

Crystals are periodic structures. As with all periodic systems, it is convenient to analyze not the periodic data set describing the system, but rather its Fourier transform where its periodicity can be more easily managed analytically. In the case of crystals, the Fourier transform is useful for analyzing X-ray diffraction data that reveal the structure, the electron density surrounding the atomic or molecular sites on equally spaced locations within the lattice, and so on. To simplify the analysis of the physical properties of periodic (lattice) structures, we construct the *reciprocal lattice*, which is the Fourier space equivalent of the real space lattice. Thus, the reciprocal lattice vector,  $\mathbf{G}$ , defines a plane wave at position,  $\mathbf{r}$ , given by  $e^{i\mathbf{G}\cdot\mathbf{r}}$ , which is equivalent under any lattice translation,  $\mathbf{R}$ , in Eq. 2.1 such that

$$e^{i\mathbf{G}\cdot\mathbf{r}} = e^{i\mathbf{G}\cdot(\mathbf{R}+\mathbf{r})}. \quad (2.3)$$

In this case, we have the condition for  $\mathbf{G}$  where

$$\mathbf{G}\cdot\mathbf{R} = 2\pi \quad (2.4)$$

such that  $e^{i\mathbf{G}\cdot(\mathbf{R}+\mathbf{r})} = e^{i2\pi}e^{i\mathbf{G}\cdot\mathbf{r}} = e^{i\mathbf{G}\cdot\mathbf{r}}$ , thus satisfying condition in Eq. 2.3. Note that the reciprocal lattice,

as defined by  $\mathbf{G}$ , has an identical symmetry to the physical lattice defined by  $\mathbf{R}$ .

It is then straightforward to show that the primitive reciprocal lattice vectors are defined in terms of the real space lattice constants via

$$\bar{\mathbf{a}} = 2\pi \frac{\mathbf{b} \times \mathbf{c}}{V_{Cell}}, \quad (2.5)$$

$$\bar{\mathbf{b}} = 2\pi \frac{\mathbf{c} \times \mathbf{a}}{V_{Cell}}, \quad (2.6)$$

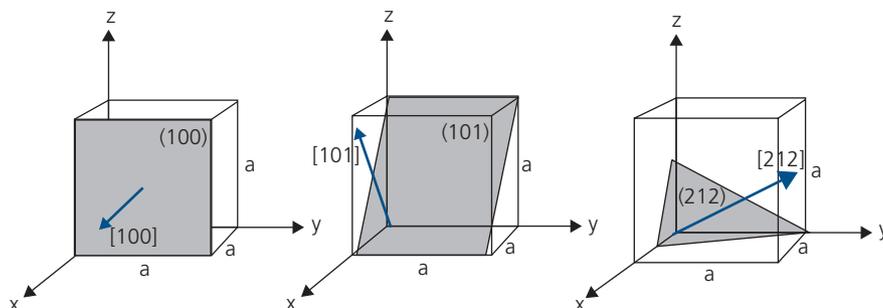

$$\bar{\mathbf{c}} = 2\pi \frac{\mathbf{a} \times \mathbf{b}}{V_{Cell}}. \quad (2.7)$$

Now, the unit cell volume in reciprocal space is:  $\bar{V}_{Cell} = \bar{\mathbf{a}} \cdot \bar{\mathbf{b}} \times \bar{\mathbf{c}} = (2\pi)^3 / V_{Cell}$ .

The primitive unit cell in the reciprocal lattice that is centered on a lattice point, and that is constructed by bisecting all distances between the lattice point and its nearest neighbors, forms a *Wigner–Seitz primitive cell* (Ashcroft and Mermin, 1976). This cell encloses the volume of the first *Brillouin zone* in reciprocal space, which is to say the primitive volume in momentum- or *k*-space. For example, for a cubic lattice with lattice constant  $a$ , the first Brillouin zone has sides of length  $k_x = k_y = k_z = 2\pi/a$ . Throughout the rest of this text, we will use the brief discussion in this and previous sections, including the construct of the reciprocal lattice, to describe and understand the physical properties of crystals that are comprised of periodic arrays of molecules.

Miller indexes are used to identify crystal planes and directions within the solid. This plane identification is a critical component to identifying crystal structure based on X-ray diffraction data. The axes in a crystal are defined by its symmetry. Hence, for a cubic lattice, the  $\mathbf{a}$ ,  $\mathbf{b}$ , and  $\mathbf{c}$  axes are orthogonal forming a Cartesian system. However, in a monoclinic lattice, the angles between  $\mathbf{a}$  and  $\mathbf{c}$ , and  $\mathbf{b}$  and  $\mathbf{c}$  are  $\alpha = \beta = 90^\circ$ , whereas the angle between  $\mathbf{a}$  and  $\mathbf{b}$  is  $\gamma \neq 90^\circ$ , thus defining a non-Cartesian, skewed coordinate system.

The following discussion focuses on the simple case of the cubic lattice with lattice constant,  $a$ , shown in Fig. 2.3, although the indexing system is easily adapted to any Bravais lattice type. A vector normal to its surface defines the plane that intersects one or more axes. Accordingly, the reciprocal lattice vectors  $\bar{\mathbf{a}}$ ,  $\bar{\mathbf{b}}$ ,  $\bar{\mathbf{c}}$  in Eqs. 2.5 to 2.7, are normal to the real lattice vectors,  $\mathbf{a}$ ,  $\mathbf{b}$ ,  $\mathbf{c}$ . Hence, the vectors in reciprocal space define the planes in the real lattice. For example, in Fig. 2.3 (left to right) we show three planes whose normal vectors are defined by the coordinates  $(a,0,0)$ ,  $(a,0,a)$ ,

**Figure 2.3** Miller indexes of three planes (in parentheses) and their normal direction vectors (in square brackets) in a cubic lattice.

and  $(\frac{1}{2}a, a, \frac{1}{2}a)$ . To identify the plane, we use the convention of Miller indices,  $h, k, l$ , whereby its normal vector given by  $\mathbf{G} = h\mathbf{\bar{a}} + k\mathbf{\bar{b}} + l\mathbf{\bar{c}}$  defines the plane. Here,  $h, k, l$  are the lowest integers that are the inverse of the intercepts between the plane and the axes. Thus, the planes in Fig. 2.2 are defined by the indices (100), (101) and (212). By convention, the commas are omitted. To avoid confusion with negative intercepts, the minus sign is written above the index; for example,  $(\bar{1}11)$  is written as  $(\bar{1}11)$ . Similarly, the coordinates of a vector direction are written between square brackets; thus [111] is the real space vector given by  $\mathbf{R} = a(\hat{x} + \hat{y} + \hat{z})$ . The vector index values are referenced to the origin.

Oftentimes, planes are equivalent due to symmetry of the specific Bravais lattice. For example, in a cubic lattice, the planes of (110), (101), (011),  $(\bar{1}10)$ ,  $(0\bar{1}1)$ , etc. are all equivalent. In this case, the set of equivalent planes is denoted  $\{110\}$ . Similarly, equivalent vector directions are enclosed in angled brackets as  $\langle 110 \rangle$ .

X-ray diffraction data are used to determine the separation of crystal planes. If we define the normal to the plane identified by the coordinates  $h, k, l$ , then the spacing between planes with these Miller indices is called the *d-spacing*, denoted by  $d_{hkl}$ . Once again for the example of the cubic lattice, we have  $d_{100} = a$ ,  $d_{101} = \sqrt{2}a$ , and so on.

## 2.4 Crystal energy and cohesion

Crystals are held together by cohesive forces between their constituent atoms and/or molecules. The *lattice potential*, or *lattice energy*, is the total ground state energy contained in the bonds that comprise the crystal structure. That is, when energy comparable to the lattice energy is supplied to the crystal, it will fragment into its smallest constituent parts. The lattice energy, therefore, provides a measure of the thermal energy (applied, for example, during evaporation or

sublimation) needed for the material to undergo a phase change from the solid state.

The lattice energy arises from the competition between the short-range repulsion between atomic or molecular cores that keeps the solid from collapsing, and the longer-range attraction of the electronic systems of the atoms or molecules. In addition, the *zero-point energy* at  $T = 0\text{K}$  is a quantum mechanical phenomenon whose origins are in the uncertainty principle with no classical analog. The uncertainty in the atomic (or molecular) momentum in the lattice,  $\Delta p$ , is related to its positional uncertainty,  $\Delta x$ , via:  $\Delta p \Delta x > \hbar$ , where  $\hbar$  is Planck's constant divided by  $2\pi$ . For a molecule of mass  $M$ , the zero point energy is

$$E_{00} \simeq \frac{\hbar^2}{M\Delta x^2}. \quad (2.8)$$

This energy, which is due to the zero point molecular vibrational motion, increases for molecules with smaller masses. We can estimate the magnitude of  $E_{00}$  for a "typical" organic molecule used in organic electronics. In this case, a molecule consisting of approximately 20 carbon atoms and with a length of  $\Delta x \sim 1\text{ nm}$  will have  $E_{00} \sim 10^{-5}\text{ kcal/mol}$ . As this is several orders of magnitude lower than even the weakest cohesive forces binding most crystals stable at room temperature, it can be neglected.

As temperature is increased, the nuclear cores gain thermal motion, and the lattice potential must be amended to include entropic contributions via a calculation of the Helmholtz free energy. This becomes important when considering the kinetics of crystal growth where the structure is a sensitive function of the thermodynamic conditions used in the formation of the solid itself. However, these considerations are beyond the scope of this discussion, and the interested reader is encouraged to consult the literature for detailed treatments (see *Further reading*).

In Chapter 1 we saw that many if not all of the unique properties of organic semiconductors come

from the fact that there are no chemical bonds between adjacent molecules, although such bonds exist between atoms within a given molecule. This is the case for both molecular as well as polymeric materials. By chemical bond, we imply that the electrons within the valence shells of atoms forming the crystal are shared, that is, they are *delocalized* between neighboring ionic cores. The cohesive forces that bind molecular materials are purely electrostatic without the sharing of electron systems, which are therefore highly localized to the molecules themselves. These bonds are typically via van der Waals forces in combination with hydrogen bonds. Chemical bonds include ionic, covalent, and metallic. In this section, we will discuss all bond types, as they play a central role in determining the properties of the materials. Conveniently, van der Waals bonds lend themselves to simple analytical expressions that allow for calculating many of the most important properties of molecular crystals, although longer-range ionic forces can also be calculated with reasonable accuracy in some simple cases. We begin our discussion with ionic bonds, then consider metallic and covalent bonds. Following that, we will discuss the physical origins of the van der Waals force, and apply it to the calculation of several molecular solids to determine its accuracy in predicting crystal structure. The discussion will conclude with a consideration of hydrogen bonds that are also important in the cohesion of organic solids.

Ignoring the zero point energy and entropic contributions, the energy between two atoms or molecules separated by distance  $|\mathbf{r}_i - \mathbf{r}_j|$  within a crystal is given by

$$U_{tot}(|\mathbf{r}_i - \mathbf{r}_j|) = U_{repulse}(|\mathbf{r}_i - \mathbf{r}_j|) - U_{attract}(|\mathbf{r}_i - \mathbf{r}_j|). \quad (2.9)$$

In equilibrium  $U_{tot}$  is negative, that is,  $U_{attract} > U_{repulse}$ . Now the total crystal potential is obtained by summing Eq. 2.9 over all  $N$  atoms in the solid, while ensuring that each bond is counted only once (thus the factor of  $N/2$ ), to give

$$U_{crystal} = \frac{1}{2} \sum_{i \neq j}^N U_{tot}(|\mathbf{r}_i - \mathbf{r}_j|). \quad (2.10)$$

The equilibrium (i.e. lowest energy) configuration of the crystal is determined by setting the first spatial derivative of  $U_{crystal}$  to zero. There are too many degrees of freedom to use this energy minimization approach to calculate actual crystal structures of any meaningful scale (i.e. with  $N$  larger than only a few

tens of lattice sites). Indeed, determining whether or not the energy minimum found by a given calculation method is a global minimum (corresponding to the true equilibrium crystal structure) or is only a local minimum (corresponding to a metastable structure) is also difficult to determine. In the remainder of this chapter, we will present the basic physical concepts by which the lattice potential can be determined, and in some cases provide examples whereby small molecular crystal structures are predicted with reasonable accuracy.

### 2.4.1 Ionic bonds

Ionic bonds exist in substances comprised of an assembly of an equal number of negatively and positively charged ions that are held together by long-range Coulomb forces that decrease as  $1/r^2$ , where  $r$  is the distance between ions. Clearly, because the solid consists of ions of both charges, the force is both attractive (between opposite charges) and repulsive (between like charges). However, for the solid as a whole, the net force must be attractive. The energy between two singly charged ions in vacuum, one at  $\mathbf{r}_i$  and the other at  $\mathbf{r}_j$  is simply

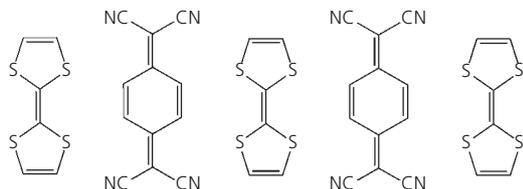

$$U_{ij} = \pm \frac{q^2}{4\pi\epsilon_0|\mathbf{r}_i - \mathbf{r}_j|}, \quad (2.11)$$

where  $q$  is the electronic charge and  $\epsilon_0$  is the permittivity of free space. Here, the “+” is for like charges, and the “-” for opposite charges. For a solid, these pairwise ionic interactions must be summed over all  $N$  ions, which leads to a net attractive energy of

$$U_{attract} = \frac{q^2}{4\pi\epsilon_0} \sum_{i,j}^N \left( \frac{1}{\mathbf{R}_{ij}} - \frac{1}{|\mathbf{R}_{ij} - \mathbf{a}|} \right), \quad (2.12)$$

where similarly charged ions are on lattice sites  $\mathbf{R}_{ij} = \mathbf{R}_i - \mathbf{R}_j$ , and oppositely charged ions are displaced by  $\mathbf{a}$  from the lattice site. That is, while the sum is over both positively and negatively charged ions, the largest contribution to the energy is from nearest neighbors of the opposite sign.

Ionic bonds are found in both inorganic and organic materials whenever there is significant charge delocalization over a particular ion pair. The most well-known example of such a material is the insulator, NaCl, or table salt. Inorganic semiconductors consisting of alloys of elements found in columns III and V of the periodic chart (e.g. GaAs and InP) are bound by covalent forces with a slight ionic content, with even greater ionic content found in compounds

**Figure 2.4** Chemical structural formulae of molecules of the charge transfer complex, TTF-TCNQ. From the left, the sulfur-containing TTF serves as the electron rich anion which extracts its electron density from the neighboring TCNQ cation.

more widely separated in the periodic chart (e.g. the II–VI compounds such as CdTe and CdS, and the I–VII compounds such as LiF with even larger ionic content). Organic salts are also partially bound by ionic forces via electron transfer from the cation to the anion. Examples of charge transfer salts include DAST or TTF-TCNQ. This latter molecular pair is shown in Fig. 2.4. Such organic salts are also known as *charge transfer complexes*.

The series in Eq. 2.12 can be difficult to evaluate in practice, since it is slowly convergent, conditionally convergent (i.e. convergence is only achieved dependent on the order in which the sum is taken), or even non-converging. However, for cubic lattices with a nearest neighbor distance,  $r$ , we can replace the series by its summation,  $a$ , such that

$$U_{\text{attract}}(r) = -\frac{aq^2}{4\pi\epsilon_0} \frac{1}{r}. \quad (2.13)$$

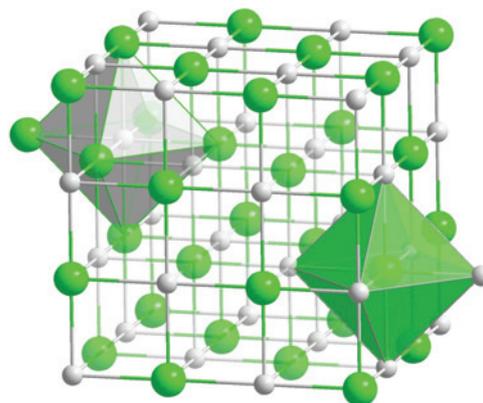

Here,  $a$  is a sum over all lattice sites, known as the *Madelung constant*, that depends on the crystal structure. Note that the dielectric constant of the material is not included in Eq. 2.13, since the expression is for the energy required to assemble the crystal from atoms in vacuum.

Consider the NaCl structure in Fig. 2.5 which forms an fcc lattice, coordination number 6, basis  $Z = 2$ , and with nearest neighbors of  $\text{Na}^+$  and  $\text{Cl}^-$  spaced at a distance of  $r = a/2$ . In this case, there are 6 nearest neighbors, 12 second nearest neighbors at  $r = a\sqrt{2}$ , 8 neighbors at  $r = a\sqrt{3}$ , and so on, such that

$$a_{\text{fcc}} = \left( 6 - \frac{12}{\sqrt{2}} + \frac{8}{\sqrt{3}} - \frac{6}{2} + \dots \right) = 1.7476. \quad (2.14)$$

In Table 2.4 we show Madelung constants calculated for several cubic lattice examples.

Extending these calculations to lattices beyond the cubic examples above is complex. Much work has been done to simplify the calculation of the

**Figure 2.5** NaCl fcc crystal structure. Here,  $\text{Na}^+$  is represented by small gray spheres, and  $\text{Cl}^-$  by the larger green spheres. The shaded regions enclose the volume containing nearest neighbors to the central ion. (chemistry.stackexchange.com)

**Table 2.4** Madelung constants for three cubic lattices

Lattice	Example	Coord. no.	Basis ( $Z$ )	$a$
fcc	NaCl	6	2	1.7476
pcc	CsCl	8	2	1.7627
Zincblende (fcc)	CdS	4	2	1.6381

Madelung constant for a range of geometries, with one convenient approach given by Nijboer and deWette (1957).

The attractive potential in Eq. 2.13 becomes infinite as the atomic cores approach each other (i.e. in the limit of  $r_{12} \rightarrow 0$ ). Thus, the equilibrium condition of  $U_{\text{crystal}}(r) < 0$  includes the core repulsion potential that prevents the crystal from collapse. The physical origin of the core repulsion is due to the combination of the nuclear repulsion and the Pauli exclusion principle, which asserts that a quantum state can be occupied by only a single particle. The repulsion can be thought of as a “hard core” whose potential becomes abruptly positive at the equilibrium separation,  $r_0$ . More realistically, it can be modeled as a high, positive power in  $r$ , that is,  $U_{\text{repulse}}(r) \sim 1/r^l$ , where  $l$  is typically (and somewhat arbitrarily chosen) between 8 and 12. Thus,  $U_{\text{repulse}}(r)$  is a very short range but strongly positive function of distance. In our discussion of van der Waals bonding, we will show that  $l = 12$  is chosen as a convenient repulsive core potential power law, although the crystal energy is relatively insensitive to this choice. Often, an exponential form of the repulsive interaction, known as the Born–Mayer potential, is used

to more accurately approximate its spatial dependence (Abrahamson, 1969). In this case,

$$U_{\text{repulse}}(r) = \beta \exp[-\gamma r], \quad (2.15)$$

where  $\beta$  and  $\gamma$  are empirical constants. Hence, the energy per ion is

$$U_{\text{tot}}(r) = \beta \exp[-\gamma r] - \frac{aq^2}{4\pi\epsilon_0} \frac{1}{r}. \quad (2.16)$$

Alternatively, assuming a power law repulsive potential:

$$U_{\text{tot}}(r) = \frac{\sigma}{r^l} - \frac{aq^2}{4\pi\epsilon_0} \frac{1}{r}, \quad (2.17)$$

where  $\sigma$  is also an empirical constant. While Eq. 2.16 may more accurately predict the equilibrium spacing of ions, Eq. 2.17 tends to be more mathematically manageable. For example, the equilibrium interionic separation is found by setting

$$\left. \frac{\partial U_{\text{tot}}}{\partial r} \right|_{r=r_0} = 0, \quad (2.18)$$

whence

$$r = \left[ \frac{l\sigma}{aq^2} 4\pi\epsilon_0 \right]^{1/(l-1)} \approx \left[ \frac{l\sigma}{aq^2} 4\pi\epsilon_0 \right]^{1/l}, \quad (2.19)$$

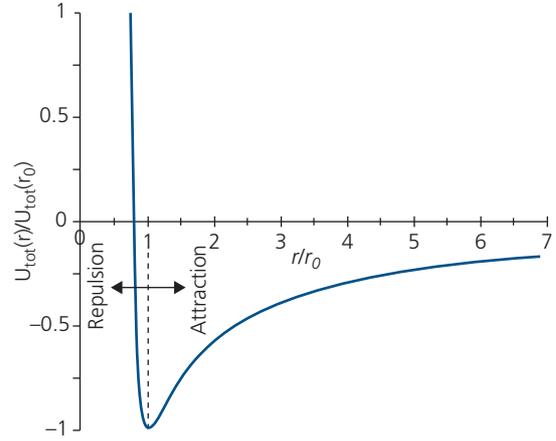

corresponding to a minimum energy of

$$U_{\text{tot}}(r_0) = \left( \frac{aq^2}{4\pi\epsilon_0 l} \right) \frac{1}{r_0} (1-l). \quad (2.20)$$

For large  $l$ , the total energy is negative and is simply equal to the value of the Coulomb attraction in Eq. 2.13 at  $r = r_0$ , which corresponds to the equilibrium atomic separation. From Eq. 2.10, the total crystal energy is then obtained by summing the contributions in Eq. 2.20 from all ions over the  $N$  lattice sites. Their pairwise interactions are accounted for by the Madelung constant,  $a$ .

Equation 2.17 is plotted in Fig. 2.6. The hard-core repulsion is a very rapidly increasing function for  $r < r_0$ , whereas the  $1/r$  dependence of attraction leads to a very slow asymptotic approach to  $U_{\text{tot}} = 0$  at large  $r$ . This slow decay makes the calculation of crystal structure problematic due to the long range of Coulombic interactions.

The *elastic constant*,  $k$ , or restoring force for molecules displaced from their equilibrium separation provides a quantitative measure of the elasticity of the crystal. Now  $\mathcal{F} = -k\Delta r$  is the restoring force on a simple harmonic oscillator in a parabolic potential displaced from  $r_0$  by a distance,  $\Delta r$ . Then the

**Figure 2.6** Calculation of energy vs. distance from an ionic core assuming Coulomb interactions between neighboring ions.

displacement energy is simply given by  $\Delta U = -\frac{1}{2}k\Delta r^2$ . The parabolic potential is a reasonable approximation for the shape of the Coulomb potential near  $r_0$ . For uniaxial strain exerted on a cubic lattice,  $k$  is obtained from the second derivative of  $U(r)$  with respect to  $r$  at equilibrium:

$$k = \left. \frac{\partial^2 U(r)}{\partial r^2} \right|_{r=r_0} = \left( \frac{aq^2}{4\pi\epsilon_0} \right) \frac{1}{r_0^3} (l-1). \quad (2.21)$$

*Uniaxial pressure*, or pressure exerted along a single crystal axis, will compress the lattice constant along that axis. However, minimum energy is generally maintained by conserving the unit cell volume. As a result, the lattice expands along the remaining crystal directions. In a cubic lattice, pressure along the (100) direction will tend to increase the lattice constants along (010) and (001). This is known as *tetragonal distortion*. The distortion is quantified using *Poisson's ratio*, defined as the fraction of linear expansion along one direction by the fraction of compression along a different direction. We express this ratio for small strains as

$$\nu = -\frac{d\epsilon_t}{d\epsilon_a}, \quad (2.22)$$

where  $\epsilon_t$  is the strain transverse to the (axial) strain,  $\epsilon_a$ . Here,  $\epsilon_t < 0$  and  $\epsilon_a > 0$  for axial tension, with the signs reversed when the solid is compressed. Note that in some structures, compression (or tension) along one axis can induce compression (or expansion) along one or more of the other axes. In this case, the signs of the inequalities are the same, such that  $\nu < 0$ . Such structures are said to have a negative Poisson's ratio.

Similar to the elastic constant, the *bulk modulus* quantifies the compressibility or stiffness of a solid, and hence its measurement can provide information about both cohesive forces and symmetry of a crystal. The bulk modulus,  $B$ , is defined as the change in volume,  $V$ , due to a change pressure,  $P$ , at a constant temperature,  $T$ . That is,

$$B = -V \left( \frac{\partial P}{\partial V} \right)_T = V \frac{\partial^2 U_{\text{tot}0}}{\partial V^2}, \quad (2.23)$$

where the last term is obtained at  $T = 0$  at pressure  $P = -\partial U_{\text{tot}0}/\partial V$ . Then, solving for  $B$  at  $r = r_0$ , and assuming uniaxial compression, we get

$$B = \left( \frac{\alpha q^2}{4\pi \epsilon_0} \right) \frac{1}{r_0^3} (l - 1). \quad (2.24)$$

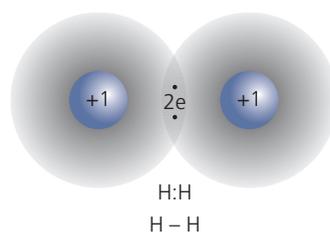

Hence, measuring the bulk modulus and the density for a given crystal structure, we obtain a value for the core potential exponent,  $l$ , which as noted above, typically ranges from 8 to 12.

### 2.4.2 Covalent and metallic bonds

The structure of individual molecules is determined by the sharing of valence charges of separate atoms that are covalently bonded. This situation is visualized for the  $\text{H}_2$  molecule in Fig. 2.7. The two, shared 1s orbital electrons of each H atom have their maximum density in the region of nearest atomic contact. Inorganic covalent materials are exemplified by Si and Ge, each with four valence electrons that are shared with their nearest neighbors in a diamond structure. As noted in Section 2.4.1, Group III-V compound semiconductors such as InP and GaAs are also primarily bonded by covalent forces, with a small ionic bonding content arising from charge exchange between nearest atomic neighbors.

Similarly, the ionic cores in metals are bonded by the valence electron “gas” that is delocalized throughout the solid. Metallic bonds are similar to covalent bonds although there is an even greater degree of electron delocalization in the former. The shared electron distribution leads to solids that are highly stable at room temperature, requiring very high energies ( $>100$  kcal/mol) to decompose. In addition, the delocalized electron systems result in material hardness and in some metals, ductility and high conductivity.

Calculating covalent bond energies and the resulting equilibrium crystal structure cannot be accomplished by determining individual atom–atom (or molecule–molecule) bond energies since the valence electrons are delocalized; a situation unlike that for

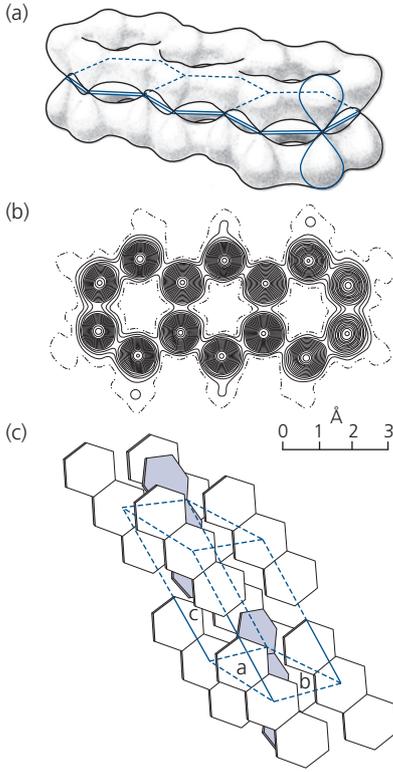

**Figure 2.7** Illustration of covalent bonding of the  $\text{H}_2$  molecule. Here the two valence electrons denoted by  $\bullet$  are shared by the two cationic (proton) cores, with the maximum electron density located in the region between the ions. The localized electrons form the molecular bond denoted by  $-$ .

ionic, and van der Waals bonds considered below. Hence a full quantum mechanical treatment is required to determine the electron distribution, and ultimately the bond energy of the solid. One such treatment is called *density functional theory* (DFT), which is useful for calculating electron distributions in relatively small molecular ensembles, and will be considered in Section 3.3 (Giustino, 2014).

An example calculation of the electronic bond configurations in the anthracene molecule ( $\text{C}_{14}\text{H}_{10}$ ) is shown in Fig. 2.8a and b. Anthracene consists of three fused benzene rings where the covalent carbon bonds forming the structure distribute the highest energy bound electrons in a cloud both above and below the molecular plane. In this case, the electrons are in the atomic p-orbitals of the molecule, and hence have their greatest density approximately  $1 \text{ \AA}$  from the plane of the atomic nuclei. The collection of p-orbitals forms the  $\pi$ -electron system that ultimately binds the molecules into a crystal by intermolecular van der Waals attraction, as discussed in Section 2.3.3.

Before describing the full DFT analysis use in calculating electron distributions in complex molecules which is the topic of Sections 3.3 and 3.4, it is instructive to start here by considering the simplest case of the hydrogen molecular ion,  $\text{H}_2^+$  as a means for understanding the basic nature of covalent bonds. The  $\text{H}_2^+$  molecules comprise two protons sharing a single electron. Given that this is a three-particle system, approximations must be made to allow for an analytical solution. Recognizing that the electron distribution can adjust to perturbations on a time scale much faster than that of the far more massive nuclei, we assume that the nuclei are stationary immediately following such a perturbation. This central assumption for calculating molecular ground states is known as the *Born–Oppenheimer approximation* (cf. Section 3.2).

**Figure 2.8** (a) An anthracene molecule viewed from the edge of the molecular plane. The electronic p-orbitals extend both above and below the molecular plane to form a conjugated  $\pi$ -electron system (Pope, 1966). (b) Calculated electronic density of states in anthracene. The positions of the 14 C atomic cores are clearly apparent. The denser contour line packing corresponds to a higher electron density (Robertson, 1958). (c) The equilibrium packing of anthracene molecules in a monoclinic lattice showing the lattice translation vectors **a**, **b**, and **c**, along with the unit cell (frame). Adapted from Pope (1966).

While this approximation is reasonable for ground states, it can lead to significant inaccuracies when calculating molecular excited state energies.

To calculate the ground state energy of the  $H_2^+$  ion, we start by writing the Hamiltonian for both the electronic and nuclear energies for a multinuclear molecule:

$$H = -\frac{\hbar^2}{2m} \nabla_{\mathbf{r}}^2 - \sum_i \frac{\hbar^2}{2M_i} \nabla_{\mathbf{R}_i}^2 + V(\mathbf{r}, \mathbf{R}_i), \quad (2.25)$$

where  $\hbar$  is Planck's constant divided by  $2\pi$ ,  $m$  is the electron mass,  $M_i$  is the mass of the  $i$ th nucleus, and  $V(\mathbf{r}, \mathbf{R}_i)$  is the potential for an electron at  $\mathbf{r}$  and the nuclei at  $\mathbf{R}_i$ . The square of the gradients,  $\nabla_{\mathbf{r}}^2$  and  $\nabla_{\mathbf{R}}^2$  are relative to the electronic and nuclear coordinates, respectively. The total energy is given by a solution to Schrödinger's equation:

$$H\Psi(\mathbf{r}, \mathbf{R}) = E\Psi(\mathbf{r}, \mathbf{R}), \quad (2.26)$$

where  $\Psi(\mathbf{r}, \mathbf{R})$  is the total molecular wavefunction that depends on the positions of both the electron and protons. For the case of  $H_2^+$ ,  $i = 1, 2$  and Eq. 2.26 reduces to

$$\begin{aligned} H\Psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) &= E\Psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \\ &= E\psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2)\Phi(\mathbf{R}_1, \mathbf{R}_2), \end{aligned} \quad (2.27)$$

where the second term on the right assumes that the wavefunction (and hence the solution) can be separated into an electronic part,  $\psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2)$ , that depends on both the electron and nuclear positions, and a purely nuclear component,  $\Phi(\mathbf{R}_1, \mathbf{R}_2)$ . Finally, the potential energy of the system is

$$V(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) = -\frac{q^2}{4\pi\epsilon_0} \left( \frac{1}{|\mathbf{r} - \mathbf{R}_1|} + \frac{1}{|\mathbf{r} - \mathbf{R}_2|} - \frac{1}{|\mathbf{R}_1 - \mathbf{R}_2|} \right), \quad (2.28)$$

where the first two terms are the attractive potentials of the electron to the two nuclei, and the third term is the repulsive interaction of the protons.

Now, inserting Eq. 2.25 into Eq. 2.27 gives

$$\begin{aligned} H\psi(\mathbf{r})\Phi(\mathbf{R}_1, \mathbf{R}_2) &= -\frac{\hbar^2}{2m} \Phi(\mathbf{R}_1, \mathbf{R}_2) \nabla_{\mathbf{r}}^2 \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \\ &\quad - \sum_i \frac{\hbar^2}{2M_i} \left[ \left( 2\nabla_{\mathbf{R}_i} \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \nabla_{\mathbf{R}_i} \Phi(\mathbf{R}_1, \mathbf{R}_2) \right. \right. \\ &\quad \left. \left. + \Phi(\mathbf{R}_1, \mathbf{R}_2) \nabla_{\mathbf{R}_i}^2 \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \right) \right. \\ &\quad \left. + \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \nabla_{\mathbf{R}_i}^2 \Phi(\mathbf{R}_1, \mathbf{R}_2) \right] \\ &\quad + V(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \Phi(\mathbf{R}_1, \mathbf{R}_2) \end{aligned} \quad (2.29)$$

Now, the Born–Oppenheimer approximation implies that the first two terms in the square brackets are insignificant compared to the other terms due to the large nuclear mass,  $M$ . Then our problem is simplified to the following two eigenvalue equations, one for the nuclear and the other for the electronic wavefunctions:

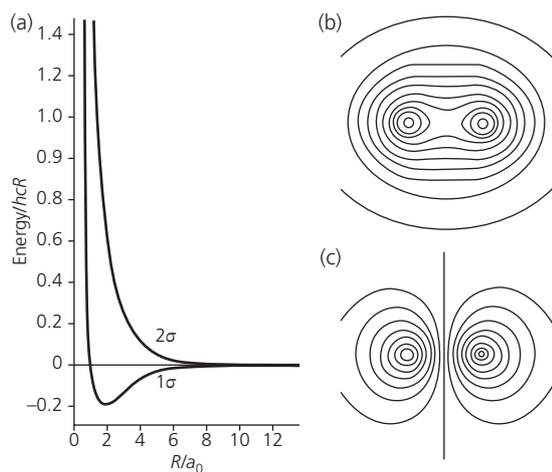

$$\begin{aligned} E\Phi(\mathbf{R}_1, \mathbf{R}_2) &= -\sum_i \frac{\hbar^2}{2M_i} \nabla_{\mathbf{R}_i}^2 \Phi(\mathbf{R}_1, \mathbf{R}_2) \\ &\quad + E^*(\mathbf{R}_1, \mathbf{R}_2) \Phi(\mathbf{R}_1, \mathbf{R}_2) \end{aligned} \quad (2.30)$$

and

$$\begin{aligned} E^*(\mathbf{R}_1, \mathbf{R}_2) \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) &= -\frac{\hbar^2}{2m} \nabla_{\mathbf{r}}^2 \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \\ &\quad + V(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2) \psi(\mathbf{r}, \mathbf{R}_1, \mathbf{R}_2). \end{aligned} \quad (2.31)$$

The solution to Eq. 2.31 using the potential in Eq. 2.28 provides the locus of electron energies corresponding to different nuclear separations  $|\mathbf{R}_1 - \mathbf{R}_2|$  in the  $\text{H}_2^+$  molecule, and whose minimum provides the equilibrium molecular radius.

Even for the three-body problem considered, however, the solution is complex. Nevertheless, analytical solutions can be found using elliptical coordinates (Atkins and Friedman, 1997). The solutions show that the relative internuclear distance results in a positive, repulsive term as the nuclear separation  $|\mathbf{R}_1 - \mathbf{R}_2| \rightarrow 0$ , and a negative, or attractive interaction that vanishes at large nuclear separations, as illustrated in Fig. 2.9a. Only the potential energies of the two lowest energies, labeled  $1\sigma$  and  $2\sigma$ , are shown. The  $1\sigma$  bonding state has a potential minimum at an internuclear separation of  $R = |\mathbf{R}_1 - \mathbf{R}_2| \approx 2a_0$ , where  $a_0$  is the Bohr radius of an H atom. Furthermore, as shown in Fig. 2.9b, the electron concentration is highest in the region between the atoms, forming a stable covalent bond between the nuclei. On the other hand, the electron density of the  $2\sigma$  antibonding state is considerably less in the internuclear region, being more highly localized at the nuclear cores themselves. The  $2\sigma$  state increases for all  $|\mathbf{R}_1 - \mathbf{R}_2|$ , and hence the ion is unconditionally unstable.

**Figure 2.9** (a) The two lowest potential energies of a  $\text{H}_2^+$  molecular ion corresponding to the bonding ( $1\sigma$ ) and antibonding ( $2\sigma$ ) states vs. the internuclear separation,  $R/a_0$ . The electron density contour plots for the states are shown in (b) and (c), respectively. The  $1\sigma$  state has a higher concentration of electron density between the nuclear cores than the  $2\sigma$  state shown by the connecting contours in the former in contrast to the localized contours in the latter. Here,  $a_0 = 0.5 \text{ \AA}$  is the Bohr radius. The energies are in units of  $hcR_\infty = 13.6\text{eV}$  (the Rydberg energy), which is the ionization energy of an H atom, with  $h = \text{Planck's constant}$  and  $c = \text{speed of light}$ . From Atkins and Friedman (1997).

Moving beyond the simplest case of a  $\text{H}_2^+$  molecular ion is extremely complex, and does not lead to exact, analytical solutions. Hence, several approaches have been developed to determine the lowest energy bond configurations, most notably the method of *linear combination of atomic orbitals* (LCAO). The molecular structures resulting from intramolecular covalent bonds are responsible for many of the morphological, electronic and optical properties of organic solids. The dependence of optical properties on the molecular configuration in the ground and excited states can be accurately predicted by LCAO and other methods, and is the subject of Chapter 3.

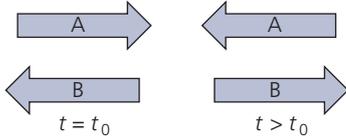

### 2.4.3 Dipolar interactions and van der Waals bonds

The most prevalent cohesive force binding molecular crystals and polymeric films is the van der Waals force. This attractive force is due to induced dipole-induced dipole interactions between non-polar molecules. However, in many cases the molecules themselves have a fixed dipole moment in the ground state, in which case the strength of the bond is determined by the magnitudes of the individual dipoles.

In induced dipole interactions, the valence electrons are spatially distributed over a large proportion of the molecular surface. The covalent carbon bonds within the molecule result in the distribution of the highest energy bound electrons both above and below the molecular plane. The electrons in anthracene, for example, occupy the  $\pi$ -orbital of the molecule, with the greatest density approximately  $1 \text{ \AA}$  above and below the atomic nuclear plane, as shown in Fig. 2.8a.

A dipole or higher order multipole is formed by an instantaneous fluctuation in the equilibrium electron distribution of neighboring molecules. Regions that experience this instantaneous increase in electron density are balanced by regions where the density is depleted, thereby forming an electrostatic dipole. This dipole then induces an oppositely directed instantaneous dipole in a neighboring molecule. According to the Born–Oppenheimer approximation, the electronic charge redistribution occurs on a time scale too short for the nuclei to respond, and hence we consider the molecular structure to be stationary.

The two oppositely directed dipoles Coulombically attract, thereby forming the van der Waals bond as illustrated Fig. 2.10. Since the dipoles are perturbations in the electronic distributions, they continue to fluctuate on a time scale on the order of the

**Figure 2.10** Illustration of the fluctuating induced dipole–induced dipole van der Waals attractive interaction. The arrow points in the direction of the dipole (from a negative to a positive charge at the arrow point). “A” and “B” refer to two adjacent molecules. The fluctuation is implied by the time ( $t$ ) dependence of the relative dipole orientations.

interatomic vibrational time (or phonon lifetime) of  $\tau_{ph} \sim 10^{-14}$  to  $10^{-12}$  s, continually inducing the opposite response in the neighboring molecule, thus forming a stable, electrostatic bond. Now the highest energy phonon in anthracene is due to the C-C stretch vibrational mode, with energy  $E_{ph} \sim 0.12$  eV, leading via the uncertainty principle to  $\tau_{ph} = \hbar/E_{ph} \sim 30$  fs. The quantum mechanical origin of the fluctuations suggest that they are present even at  $T = 0$  K as a result of the zero-point energy of the molecule.

A similar attraction can exist between two molecules with fixed dipole (or higher order multipole) moments, or a molecule with a fixed moment and one with an induced moment. In all cases, the force is attractive, with the molecular distance ultimately reaching its equilibrium value depending on the magnitude of the ground state dipole moments, the relative molecular orientations, and the repulsive force of the atomic cores.

To determine the molecular potential due to the van der Waals interaction, we first consider the electric field due to charge multipoles. Consider a molecule with a charge density  $\rho(\mathbf{r})$  determined from the covalent bonds between atoms comprising the compound, such as that in Fig. 2.8a and b, where  $\mathbf{r}$  is the distance to an arbitrary origin. Then, the total (monopole) charge, is given by

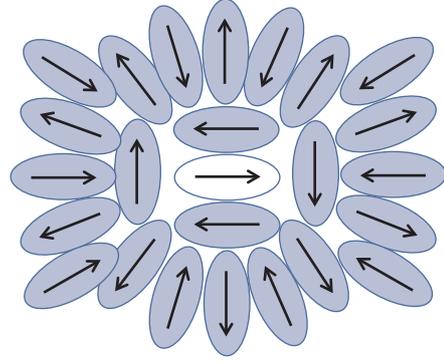

$$q = \int \rho(\mathbf{r}) d^3\mathbf{r}, \quad (2.32)$$

where the integral is over all space. The higher moments of charge are then

$$\mathbf{p} = \int \mathbf{r} \rho(\mathbf{r}) d^3\mathbf{r}, \quad (\text{dipole}) \quad (2.33)$$

$$Q_{ij} = \int (3r_i r_j - r^2 \delta_{ij}) \rho(\mathbf{r}) d^3\mathbf{r}, \quad (\text{quadrupole}) \quad (2.34)$$

with increasingly complex expressions for higher order multipoles (Jackson, 1998). Here,  $r_i$  and  $r_j$  are relative coordinates within the charge distribution, and  $\delta_{ij}$  is the Kronecker delta. Now, the expansion of

**Figure 2.11** Polarization of the surrounding medium by the fixed dipole in the center. The tendency to polarize gives rise to the dielectric properties of the medium.

the electrical potential in a medium with relative dielectric constant,  $\epsilon_r$ , can be written

$$\Phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0\epsilon_r} \left[ \frac{q}{r} + \frac{\mathbf{p} \cdot \mathbf{r}}{r^3} + \frac{1}{2} \sum_{i,j} Q_{ij} \frac{r_i r_j}{r^5} + \dots \right], \quad (2.35)$$

with higher order multipoles decreasing more rapidly with increasing  $r$ . When we consider two dipoles due to adjacent molecules,  $\epsilon_r \approx 1$ . However, when placed in a medium containing other polarizable molecules, their collective response is a physical reorientation of the induced dipoles. This screens the local electric field at the original molecule, which by superposition alters the net electric field, as illustrated in Fig. 2.11. For a solution of mobile molecules, this is known as the *solvation effect*, or in a solid, the *solid-state solvation effect*, which is treated analytically in Section 3.6.7.

### 2.4.3.1 Interactions between fixed dipoles

Since the potential of the  $n$ th charge moment is proportional to  $1/r^{n+1}$ , it is generally not useful to consider multipole orders higher than four due to their rapid decrease with distance. Indeed, in many practical cases, only the zeroth and first order moments are required. For the remainder of this treatment, we will only consider the effects of charges and their first moment. For neutral molecules,  $q=0$ , leaving only the first, or ground state dipole moment contributing significantly beyond the first nearest neighboring molecule in a crystal. Hence, we write

$$\Phi(\mathbf{r}) \cong \frac{\mathbf{p} \cdot \mathbf{r}}{4\pi\epsilon_0\epsilon_r r^3} \quad (2.36)$$

for the dipole potential of a neutral molecule. Poisson's equation gives the electric field:  $\mathbf{F}(\mathbf{r}) = -\Delta\Phi(\mathbf{r})$ . Then, Eq. 2.36 yields (Jackson, 1998)

$$\mathbf{F}(\mathbf{r}) = \frac{3\hat{\mathbf{n}}(\mathbf{p} \cdot \hat{\mathbf{n}}) - \mathbf{p}}{4\pi\epsilon_0\epsilon_r r^3}, \quad (2.37)$$

where  $\hat{\mathbf{n}}$  is the unit vector in the direction from the center of the dipole to the point,  $\mathbf{r}$ .

Now, the dipole energy is given by

$$U(\mathbf{r}) = -\mathbf{p} \cdot \mathbf{F}(\mathbf{r}). \quad (2.38)$$

Then the interaction energy between two fixed dipoles,  $\mathbf{p}_1$  and  $\mathbf{p}_2$  separated by distance  $r_{12}$  oriented in the direction  $\hat{\mathbf{n}}_{12}$  (i.e.  $\mathbf{r}_{12} = r_{12}\hat{\mathbf{n}}_{12}$ ; see Fig. 2.12) is

$$U(r_{12}) = \frac{\mathbf{p}_1 \cdot \mathbf{p}_2 - 3(\hat{\mathbf{n}}_{12} \cdot \mathbf{p}_1)(\hat{\mathbf{n}}_{12} \cdot \mathbf{p}_2)}{4\pi\epsilon_0\epsilon_r r_{12}^3}. \quad (2.39)$$

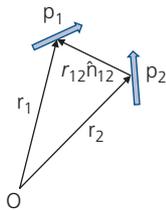

While calculating the dipole interaction energy in a solid can be complicated due to its dependence on relative orientation, it is clear that the energy decreases rapidly as  $1/r^3$  compared to  $1/r$  for a point charge,  $q$ . Hence, the dipole–dipole interaction is short range; vanishing rapidly beyond nearest neighbor interactions in a lattice.

Assuming that two in-plane dipoles are anti-parallel (corresponding to the lowest energy configuration), with  $r_{12}$  at angle  $\theta$  relative to the dipole axes, Eq. 2.39 can be written

$$U_{12}(r_{12}) = -\frac{p_1 p_2}{4\pi\epsilon_0\epsilon_r r_{12}^3} (1 - 3\cos^2\theta) = -\frac{p_1 p_2}{4\pi\epsilon_0\epsilon_r r_{12}^3} f(\theta), \quad (2.40)$$

where we have replaced the dipole vectors with their scalar magnitudes,  $p_1$  and  $p_2$ .

To calculate two randomly oriented dipoles (at angles  $\theta_1$  and  $\theta_2$  relative to  $\hat{\mathbf{n}}_{12}$ , and rotated by azimuthal angle,  $\phi$  relative to each other), we must use the full expression for the fixed dipole interaction, Eq. 2.39. As noted above, the lowest energy of the system is when  $\mathbf{p}_1$  and  $\mathbf{p}_2$  are anti-parallel (and hence  $U(r_{12}) < 0$ ), and is highest when they are parallel. Hence, the most probable orientation in an ensemble of dipoles is the one that achieves the lowest energy, requiring that we weight each orientation by a Boltzmann factor,  $\exp(-U(r_{12})/k_B T)$ . Here,  $k_B$  is Boltzmann's constant.

**Figure 2.12** Two dipoles and positions,  $\mathbf{r}_1$ ,  $\mathbf{r}_2$ , relative to the observation point,  $O$ .

The *potential distribution theorem* then gives a spatially averaged value for the energy according to (Beck et al., 2006)

$$e^{-U(\mathbf{r}_{12})/k_B T} = \frac{\int e^{-U(\mathbf{r}_{12}, \theta_1, \theta_2, \phi)/k_B T} d\Omega_{12}}{\int d\Omega_{12}}, \quad (2.41)$$

where  $d\Omega_{12} = \sin\theta_1 \sin\theta_2 d\theta_1 d\theta_2 d\phi$ . Then the denominator is equal to  $8\pi$ , and the fixed dipole energy can be solved when  $U(\mathbf{r}_{12}) < k_B T$ . Expanding the exponential gives

$$\langle e^{-U(\mathbf{r}_{12})/k_B T} \rangle = \left\langle 1 - \frac{U(\mathbf{r}_{12})}{k_B T} + \frac{1}{2} \left( \frac{U(\mathbf{r}_{12})}{k_B T} \right)^2 - \dots \right\rangle. \quad (2.42)$$

Writing the spatial average in terms of the expansion in  $U(r_{12})$  we obtain

$$\begin{aligned} e^{-U(\mathbf{r}_{12})/k_B T} &= 1 - \frac{U(\mathbf{r}_{12})}{k_B T} + \frac{1}{2} \left( \frac{U(\mathbf{r}_{12})}{k_B T} \right)^2 - \dots \\ &= \left\langle 1 - \frac{U(\mathbf{r}_{12})}{k_B T} + \frac{1}{2} \left( \frac{U(\mathbf{r}_{12})}{k_B T} \right)^2 - \dots \right\rangle. \end{aligned} \quad (2.43)$$

Solving this to first order, we get

$$\frac{U(\mathbf{r}_{12})}{k_B T} = \left\langle \frac{U(\mathbf{r}_{12})}{k_B T} + \frac{1}{2} \left( \frac{U(\mathbf{r}_{12})}{k_B T} \right)^2 - \dots \right\rangle. \quad (2.44)$$

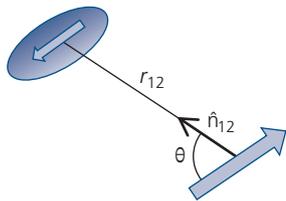

The final step is to integrate over all angles using the relative dipole orientation function  $f(\theta, \phi) = 2\cos\theta_1 \cos\theta_2 - \sin\theta_1 \sin\theta_2 \cos\phi$ , where  $-2 \leq f(\theta, \phi) \leq 2$ . Using the expression for the dipole energy in Eq. 2.40, this finally gives the *Keesom interaction* between fixed dipoles:

$$U(r_{12}) = -\frac{2p_1^2 p_2^2}{3(4\pi\epsilon_0\epsilon_r)^2 k_B T r_{12}^6} = -\frac{A_{DD}}{r_{12}^6}. \quad (2.45)$$

This expression has the rapidly decaying  $1/r^6$  dependence characteristic of all dipole interactions. Furthermore, by superposition, the potential is additive to other molecular attractive energies such as dipole–induced dipole and induced dipole–induced dipole interactions to be discussed below.

### 2.4.3.2 Dipole–induced dipole interactions

Since a fixed dipole induces a dipole in a neighboring molecule, the pair will orient in the lowest energy, anti-parallel, position. The geometry of the system is illustrated in Fig. 2.13. The polarization of the electron

**Figure 2.13** Fixed dipole (large arrow) inducing a dipole (small arrow) in the charge distribution of an adjacent molecule.

system of the molecule leads, to first order, to an induced dipole moment whose magnitude is proportional to the electric field:

$$\mathbf{p}_{ind}(\mathbf{r}) = \alpha \mathbf{F}(\mathbf{r}), \quad (2.46)$$

where  $\alpha$  is the molecular polarizability. Generally,  $\alpha$  is a tensor ( $\vec{\alpha}$ ) although in this treatment we take it as a scalar for simplicity. The molecules have a linear polarizability that depends on the extent of the conjugated  $\pi$ -electron system and the molecular structure. That is, planar, conjugated molecules such as anthracene, tetracene, and pentacene (consisting of 3, 4, and 5 fused carbon rings, respectively) can have a very large  $\alpha$ , whereas molecules that are smaller or have higher symmetry (e.g.  $\text{Alq}_3$  used in electroluminescent devices) have a considerably smaller polarizability.

We can write Eq. 2.46 for a pair of point charges separated by distance  $d$ , using the scalar relationship  $p_{ind} = qd = \alpha F$ . Since  $F = q/4\pi\epsilon_0 d^2$  in vacuum, we have  $\alpha = 4\pi\epsilon_0 d^3$ ; that is the molecular polarizability increases as the third power of the charge separation. The units of  $p$  are Debye (D), where  $1 \text{ D} = 3.336 \times 10^{-30} \text{ C m}$ . Hence, a molecule that supports a full electron charge across its length of 1 nm has  $p = 4.8 \text{ D}$ .

Using Eq. 2.37, we calculate the field at distance  $r_{12}$  from the dipole for the system in Fig. 2.13:

$$\mathbf{F}(r_{12}) = \frac{p_1}{4\pi\epsilon_0\epsilon_r r_{12}^3} \left( 2\cos\theta \hat{\mathbf{n}}_{12} + \sin\theta \hat{\boldsymbol{\theta}} \right), \quad (2.47)$$

which has a magnitude of

$$F(r_{12}) = \frac{p_1}{4\pi\epsilon_0\epsilon_r r_{12}^3} (1 + 3\cos^2\theta)^{1/2}. \quad (2.48)$$

Induction leads to a displacement of the charge in adjacent molecules, exerting a force,  $\mathcal{F}$ , due to electric field,  $\mathbf{F}$ . Hence, the free energy of the system is given by

$$U(r_{12}) = - \int \mathcal{F}(r_{12}) \cdot d^3 \mathbf{r} = -q \int \mathbf{F}(r_{12}) \cdot d^3 \mathbf{r}. \quad (2.49)$$

Averaging over all angles,  $\theta$ , we are left with the radial component of the electric field:

$$F_r(r_{12}) = \frac{2p_1}{4\pi\epsilon_0\epsilon_r r_{12}^3}. \quad (2.50)$$

Substituting  $p_{ind} = p_1$ , we thus obtain for the induced field:

$$F_{ind}(r_{12}) = - \frac{2a}{4\pi\epsilon_0\epsilon_r r_{12}^3} F_r = - \frac{2a q}{(4\pi\epsilon_0\epsilon_r)^2 r_{12}^5}. \quad (2.51)$$

Finally, integrating over  $r$  we arrive at the energy of an induced dipole for a polarizable molecule of

$$U(r_{12}) = - \frac{a q^2}{2(4\pi\epsilon_0\epsilon_r)^2 r_{12}^4} = \frac{1}{2} a F_{ind}^2. \quad (2.52)$$

The factor of  $1/2$  on the right hand side comes from the energy expended in inducing the dipole in the neighboring molecule. Using this relationship along with Eq. 2.48, we obtain the energy for the fixed dipole-induced dipole interaction:

$$U(r_{12}) = - \frac{a p_1^2}{2(4\pi\epsilon_0\epsilon_r)^2 r_{12}^6} (1 + 3\cos^2\theta). \quad (2.53)$$

Finally, taking the spatial average of  $\langle \cos^2\theta \rangle = 1/3$ , we arrive at the dipole-induced dipole interaction energy that once more is a function of  $1/r^6$ :

$$U(r_{12}) = - \frac{a p_1^2}{(4\pi\epsilon_0\epsilon_r)^2 r_{12}^6} = - \frac{A_{D-ind}}{r_{12}^6}. \quad (2.54)$$

### 2.4.3.3 Induced dipole-induced dipole (London) interactions

The exact derivation of induced dipole-induced dipole interactions (also known as London or dispersion interactions) is considerably more difficult than the cases of fixed dipoles since its origin is inherently quantum mechanical. Its first derivation by London was based on perturbation theory (London, 1930), where the instantaneous formation of a dipole or higher order multipole in the delocalized electron distribution of one molecule generates an electric field that induces a dipole pointing in the opposite direction in a neighboring molecule. This instantaneous multipole arises from perturbations of the electrons that can occur at  $T = 0 \text{ K}$  due to zero point fluctuations, or at higher temperatures due to thermally excited molecular vibrations, or phonons.

The fluctuating charge distribution in a molecule induces net attractive responses in all of the surrounding molecules. Due to the short range of the dipole

interaction—we have seen that dipolar interactions decrease as  $1/r^6$ —the charge distributions of only the nearest neighbors oscillate in phase to the molecule at the origin. Since the zero point energy cannot be dissipated, the induction process is non-radiative. Clearly this electrostatic attraction between many neighbors depends on the lattice type and basis, and becomes increasingly complex for molecular structures that are non-planar or otherwise lack inversion symmetry.

Induced multipole forces exist between all molecules and atoms, independent of other binding forces that may exist. However, due to their relatively short range, these bonds are often considerably weaker than, and are thus dominated by covalent or ionic forces when they coexist in a solid. Complications arise where there are many neighboring molecules, all responding to the initial fluctuation and hence creating an instantaneous response as illustrated in Fig. 2.11.

Induced dipole effects are extremely important in determining the optical, electronic and structural properties of organic solids. That is, they comprise the dominant binding forces between neutral, non-polar molecules, and they also participate in energy and electron transfer between molecules. Importantly, since they are far weaker than ionic or covalent bonds, the sublimation temperatures of molecular solids ( $\sim 100^\circ\text{C}$  to  $500^\circ\text{C}$ ) tend to be far lower than for materials bonded by Coulombic attraction ( $\sim 600^\circ\text{C}$  to  $1500^\circ\text{C}$ ).

London has shown that the quantum *dispersion interaction* can be described using second order perturbation theory (London, 1930, 1937):

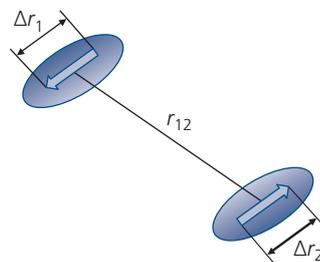

$$U(r_{12}) = -\frac{A_{disp}}{r_{12}^6}, \quad (2.55)$$

where

$$A_{disp} = \frac{2}{3} \sum_{f_1} \sum_{f_2}' \frac{|\langle i_1 | p_1 | f_1 \rangle|^2 |\langle i_2 | p_2 | f_2 \rangle|^2}{(E_{f_1} + E_{f_2}) - (E_{i_1} + E_{i_2})}. \quad (2.56)$$

Here, the initial and final states of molecules 1, 2 are  $|i_1\rangle, |i_2\rangle$  and  $|f_1\rangle, |f_2\rangle$ , respectively, with corresponding energies  $E_{i_1}, E_{i_2}$  and  $E_{f_1}, E_{f_2}$ . The sums are over all final states, excluding those states where  $|i\rangle = |f\rangle$ .

Deriving and then calculating Eq. 2.56 is complicated and adds little insight to our understanding of the dispersion interaction. A simple approximation based on the polarizability of a pair of coupled dipoles shown in Fig. 2.14 can be illustrative of

**Figure 2.14** Configuration of two induced dipoles. The electron distributions around molecules 1 and 2 are illustrated by ellipses, and the instantaneous dipole moments are shown by arrows.

induction effects. For this calculation, consider the zero point motion of the electron distribution around a neutral atom or molecule as a simple harmonic oscillator. The dipoles have lengths,  $\Delta r_1$  and  $\Delta r_2$ , which are much smaller than their separation distance,  $r_{12}$ . The individual dipoles are parallel since they each exist in response to anti-parallel fluctuations in the charge of their neighbor. The total state Hamiltonian of the system is then written

$$H = -\frac{\hbar}{2m_0} (\nabla_1^2 + \nabla_2^2) + \frac{1}{2} k_0 (\Delta r_1^2 + \Delta r_2^2) + V(r_{12}, \Delta r_1, \Delta r_2), \quad (2.57)$$

where the first two terms are for the two independent oscillators, and the third term is the interaction potential.

The restoring force is related to the normal mode vibrational frequency of the electron density,  $\omega_0$ , via  $k_0 = m_0 \omega_0^2$ , and  $m_0$  is the electron mass. The intermolecular coupling is then given by the electrostatic potentials between the various charges:

$$V(r_{12}, \Delta r_1, \Delta r_2) = \frac{q^2}{4\pi \epsilon_0 \epsilon_r} \left( \frac{1}{r_{12}} + \frac{1}{r_{12} + \Delta r_1 - \Delta r_2} - \frac{1}{r_{12} + \Delta r_1} - \frac{1}{r_{12} - \Delta r_2} \right), \quad (2.58)$$

where the signs for the dipole displacements arise from the oppositely directed dipole vectors,  $\hat{\mathbf{p}}_1 = -\hat{\mathbf{p}}_2$ . Now, in the far-field approximation, we have  $\Delta r_1, \Delta r_2 \ll r_{12}$ , in which case expansion of Eq. 2.58 to second order yields

$$V(r_{12}, \Delta r_1, \Delta r_2) = -\frac{q^2 \Delta r_1 \Delta r_2}{4\pi \epsilon_0 \epsilon_r r_{12}^3}. \quad (2.59)$$

Schrodinger's equation is solved by substituting the symmetric and antisymmetric momentum and position vectors into Eq. 2.58 and 2.59:

$$\Delta r_{\pm} = \frac{1}{\sqrt{2}}(\Delta r_1 \pm \Delta r_2)$$

$$\text{and } \nabla_{\pm}^2 = \frac{1}{\sqrt{2}}(\nabla_1^2 \pm \nabla_2^2). \quad (2.60)$$

Then Eq. 2.57 becomes:

$$H = -\frac{\hbar}{2m_0}(\nabla_+^2 + \nabla_-^2) + \frac{1}{2} \left( \left[ k_0 - \frac{2q^2}{4\pi\epsilon_0\epsilon_r r_{12}^3} \right] \Delta r_+^2 + \left[ k_0 + \frac{2q^2}{4\pi\epsilon_0\epsilon_r r_{12}^3} \right] \Delta r_-^2 \right). \quad (2.61)$$

By comparing Eq. 2.57 and 2.61, we find that the normal mode dipole oscillation frequency,  $\omega_0$  is now broken into two symmetric harmonics:

$$\omega_{\pm} = \sqrt{\frac{k_0 \pm 2q^2/r_{12}^3}{m}}$$

$$\simeq \omega_0 \left( 1 \pm \left( \frac{q^2}{4\pi\epsilon_0\epsilon_r k_0 r_{12}^3} \right) - \frac{1}{2} \left( \frac{q^2}{4\pi\epsilon_0\epsilon_r k_0 r_{12}^3} \right)^2 \pm \dots \right). \quad (2.62)$$

The lowest energy of the normal mode of a quantum oscillator is  $\frac{1}{2}\hbar\omega_0$ . Thus, the induced dipole interactions shift this zero-point energy by the amount:

$$\Delta U(r_{12}) = \frac{1}{2}\hbar(\omega_+ + \omega_-) = -\frac{1}{2}\hbar\omega_0 \left( \frac{q^2}{4\pi\epsilon_0\epsilon_r k_0 r_{12}^3} \right)^2. \quad (2.63)$$

Equating the Lorentz force ( $\mathcal{F} = q\mathbf{E}$ ) to the restoring force of a harmonic oscillator, we find  $k_0 = q^2/a$ . Then, we finally arrive at the dispersion interaction energy for the induced dipole-induced dipole energy:

$$\Delta U(r_{12}) = -\frac{1}{2}\hbar\omega_0 \left( \frac{a}{4\pi\epsilon_0\epsilon_r} \right)^2 \frac{1}{r_{12}^6} = -\frac{A_{disp}}{r_{12}^6}. \quad (2.64)$$

Since the magnitude of the energy decrease is proportional to  $\hbar$ , this is a purely quantum mechanical effect, whereby the zero-point energy is lowered by the dipole-dipole interaction.

Another, intuitive approach suggested by London (1937) is to take  $\hbar\omega_0$  as the ionization energy of the atom (e.g. He, Ar, Ne, etc.). Generalizing this to a molecule, the electron that occupies the highest occupied molecular orbital (HOMO) can be removed with energy equal to its *ionization potential* ( $IP$ ). Given that the induction between two molecules follows a relationship similar to that used to derive Eq. 2.45, and recognizing that induced dipole energies can be superposed, the

following simplified approximate relationship for Eqs. 2.54 is:

$$U(r_{12}) \approx -\frac{3}{2} \frac{a_1 a_2}{(4\pi\epsilon_0\epsilon_r)^2} \frac{IP_1 IP_2}{IP_1 + IP_2} \left( \frac{1}{r_{12}^6} \right). \quad (2.65)$$

By inspection,  $\hbar\omega_0 \approx \frac{3}{2}IP$ , where we assume identical molecules as in Eq. 2.64 such that  $a_1 = a_2$  and  $IP = IP_1 = IP_2$ . In fact these expressions are identical since Eq. 2.64 is solved for a one dimensional coordinate system, whereas Eq. 2.65 more realistically assumes each molecule has three degrees of freedom.

Up to this point, we have only considered the attractive binding forces from fixed electronic multipoles due to molecules that contain electron donating or withdrawing groups, or are spontaneously induced by zero-point and/or thermal fluctuations of the electronic distribution within a molecule. The total potential due to attractive dipole moments that includes nuclear core repulsion is thus given by

$$U(r_{12}) = \frac{A_{core}}{r_{12}^{12}} - \frac{A_{disp}}{r_{12}^6}. \quad (2.66)$$

Equation 2.66 is known as the *Lennard-Jones 6-12 potential*. As in the case of ionic bonds (Eq. 2.17), the repulsive power law of  $1/r^{12}$  is chosen for convenience. The very large power reflects the steep and short range of core-core repulsion potentials. An alternative form is known as the *Buckingham potential* (Buckingham, 1938):

$$U(r_{12}) = a_{12} \exp(-\beta_{12} r_{12}) - \frac{A_{disp}}{r_{12}^6}. \quad (2.67)$$

In the following discussion, we will use the 6-12 potential in its common, simplified form:

$$U(r_{12}) = 4\epsilon_{12} \left[ \left( \frac{\sigma_{12}}{r_{12}} \right)^{12} - \left( \frac{\sigma_{12}}{r_{12}} \right)^6 \right], \quad (2.68)$$

where  $\epsilon_{12} = (A_{disp}^2/4A_{core})$  and  $\sigma_{12} = (A_{core}/A_{disp})^{1/6}$  are empirical constants obtained from pairwise interactions of atoms and/or molecules in the gas phase (Vargasa et al., 2001). That is, they are obtained by measuring deviations of atomic species from the ideal gas law,  $PV = Nk_B T$ , where  $P$  is the pressure,  $V$  is the volume, and  $N$  is the number of atoms or molecules. The deviations from this expression as a function of gas density are quantified by the *virial coefficients* which are related to many-particle interactions in the gas. These coefficients then provide the equilibrium

interatomic distances and energies used to calculate their interaction energies in Eq. 2.68.

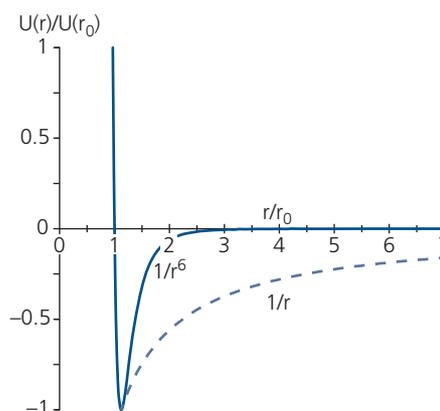

Now the equilibrium separation,  $r_{0,12}$ , of the molecules is found using Eq. 2.18 which gives  $r_{0,12} = \sqrt[6]{2}\sigma_{12} = 1.12\sigma_{12}$ , and  $U(r_0) = -\epsilon_{12}$ . Here,  $r_{0,12}$  is known as the *van der Waals radius*, which is the distance of closest approach of adjacent molecules. A list of Lennard-Jones coefficients for several common interatomic interactions is provided in Table 2.5. The Lennard-Jones potential and the definition of the equilibrium values for  $U$  and  $r$  are shown in Fig. 2.15. The short-range nature of the van der Waals energy (solid line) is compared with that of the longer-range Coulomb energy (dashed line).

The elastic constant,  $k$ , for a van der Waals solid is (cf. Eq. 2.21):

$$k = \left. \frac{\partial^2 U(r)}{\partial r^2} \right|_{r=r_0} = \frac{72 \epsilon}{\sqrt[3]{2}\sigma^2} = 57.16 \frac{\epsilon}{\sigma^2}. \quad (2.69)$$

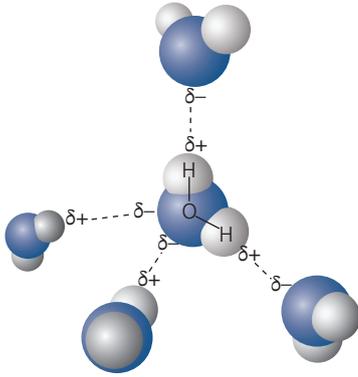

#### 2.4.4 Hydrogen bonds

Hydrogen bonds exist between molecules when a hydrogen atom is covalently bonded to an electronegative atom. The classic case of an H-bonded substance is water where neighboring molecules align due to interactions between an H atom on one dipolar H<sub>2</sub>O molecule with the O atom on an adjacent molecule, as illustrated in Fig. 2.16. The hydrogen bond is represented by the dashed line: H $\cdots$ O—H. Here, the covalent O—H bond distance is 1 Å, whereas the

**Figure 2.15** Van der Waals energy vs. molecular separation normalized to their values at equilibrium ( $U(r_0)$  and  $r_0$ , respectively). The short range van der Waals energy (which depends on  $1/r^6$ ) is compared to the longer range Coulomb potential ( $\sim 1/r$ ).

H $\cdots$ O distance is 1.76 Å since it is considerably weaker than the former bond. Hydrogen bonds not only exist between H and O, but also are found with N, F, and Cl. The bond strength depends on the electronegativity of the atom bonded to the H atom. The H bond results from Coulombic attraction between an H atom bound to one molecule and the nearby molecule with which it coordinates. It arises from electrostatic dipole–dipole interactions whose bond strengths can be considerably larger and more directional than van der Waals bonds. Hydrogen bonds owe their properties to a limited but nevertheless significant covalent content between the electron on

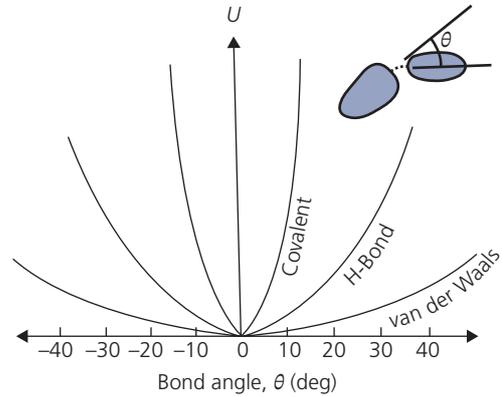

**Figure 2.16** Five  $\text{H}_2\text{O}$  molecules coordinated through H bonds denoted by dashed lines. The oxygen atoms (large spheres) have 8 valence electrons. The increase (decrease) in charge density is denoted by (+).

the H atom shared with the electronegative atom on the adjacent molecule. This leaves the H atom with a slight positive charge that increases the electronegativity of the adjacent molecule (Jeffrey, 1997).

The H-bond strength and directionality leads to the high boiling points of polar liquids as  $\text{H}_2\text{O}$ , and can play a significant role in the bonding of molecular crystals, and between polymers where H atoms are suitably positioned on each monomer along the molecular backbone. Importantly, H-bonding is primarily responsible for the double helix structure of DNA, providing the attractive force between base pairs on the two strands that comprise the molecule.

The directionality and strength of the bond that leads to the complex structures of DNA, proteins and other molecular species is qualitatively illustrated in the plot of  $U(\theta)$  in Fig. 2.17, where  $\theta$  is the angle between the two bonded molecules (inset). The H-bond is more directional than the van der Waals interaction, but is far less directional than are covalent bonds. The bond reaches a minimum energy at  $\theta = 0$ . This forces it to be as linear as steric constraints between the molecules allow. Otherwise, in the example of  $\text{H}_2\text{O}$ , the O—O repulsion would dominate over the  $\text{H}\cdots\text{O}$  attraction, considerably reducing surface tension and all of the other unique properties of this substance.

The larger directionality of the H bond compared with that of the van der Waals bond suggests that its influence attenuates less rapidly than  $1/r^6$ . Indeed, the bond can be modeled by Coulomb attraction from an extended (molecular) charge distribution of dipole moment,  $p$ , at angle,  $\theta$ , and distance,  $r$ , from a point charge. This yields an attractive energy (Israelachvili, 2011):

**Figure 2.17** The directionality of the hydrogen bond lies between the highly directional covalent bond and the non-directional induced dipolar van der Waals bond, sharing characteristics of both. Inset: The angle between molecules bonded by H interactions (Israelachvili, 2011).

$$U(r, \theta) = -\delta^+ \frac{qp \cos \theta}{r^2}. \quad (2.70)$$

Here,  $\delta^+$  is the fraction of a charge transferred from the H atom to the neighboring molecule. Note that while Eq. 2.70 is approximate, it provides the essential details of directionality and relatively slowly decreasing energy with distance of the H bond. As in the case of other bonding mechanisms, the hard nuclear core repulsion becomes dominant as the distance between molecules approaches their van der Waals radii.

### 2.4.5 Comparison of bond strengths

Ionic, covalent, van der Waals, and hydrogen bonds are all found to play a role in determining the structure of organic materials, including molecular crystalline solids and polymers. The strength of the bonds determines the hardness (elastic strength), as well as melting and boiling points of the solid. A sampling of materials bonded by these different forces is provided in Table 2.6, along with some of their physical characteristics. We note that in general, the higher the bond energy, the higher the sublimation or melting point, and the density of the solid (i.e. higher bond strengths lead to tighter packing within the crystal). A seeming exception to this rule in Table 2.6 is the van der Waals bond. However, examination of the energies in Table 2.5 shows that van der Waals bonds are roughly 0.2 kcal/mol *per bond between atomic species*. This is in contrast to the molecular compounds in Table 2.6 that consist of 20 or more atoms. To obtain the total molecular bond strength, we show in Section 2.5 that energies from each atom within the molecule must

**Table 2.6** Example materials, their bond types and physical properties

Bond type	Material	Melting point (°C)	Boiling point (°C)	Sublimation point <sup>a</sup> (°C)	Density <sup>b</sup> (g/cm <sup>3</sup> ) STP	Bond energy <sup>a</sup> (kJ/mol)

<sup>a</sup> Approximate values are given for sublimation points and several bond energies.

<sup>b</sup> STP = standard temperature and pressure, s = solid, l = liquid.

be summed to result in the total molecular bond energies. Then, these are only slightly less than covalent bond energies between individual Si or Ge atoms. As a rule of thumb, we find that van der Waals bond energies are  $\sim k_B T$  at room temperature, compared with  $10k_B T$  for H bonds,  $100k_B T$  for covalent bonds, and perhaps 5–10 times higher still for ionic bonds.

## 2.5 Equilibrium crystal structures

Using the interaction energy between two induced dipoles, in principle it is straightforward to determine the energy of an ensemble of molecules to determine the minimum energy that determines the equilibrium crystal structure. In practice, Eq. 2.68 is solved to determine simple, pairwise interatomic interactions. It can, however, also be extended to molecular binding as inferred from our discussion in Section 2.4.3, although the determination of the Lennard-Jones coefficients,  $\epsilon$  and  $\sigma$ , is more complex and is unavailable for most molecules. Recall that these coefficients are determined from deviations at high density from the ideal gas law for atomic species. Such data rarely exist for molecules, and hence a different approach is required.

Let us assume that the interaction energies are  $U(R_{ij})$  for individual molecules,  $i, j$  separated by a distance  $R_{ij} = |\mathbf{R}_i - \mathbf{R}_j|$  are known. Then we can write the total crystal energy as the sum of the individual molecule–molecule binding energies, which are expected to have

a form similar to Eq. 2.68. The total crystal energy is given by the sum over all molecule–molecule interactions in a manner identical to that used between atoms, viz.

$$U_{crystal} = \frac{1}{2} \sum_{i \neq j} U(R_{ij}). \quad (2.71)$$

The minimum free energy of a solid is then obtained by taking the first derivative of  $U_{crystal}$  relative to position,  $R_{ij}$  and then setting this derivative to zero to find the equilibrium intermolecular separation,  $R_0$ .

In this discussion we have implicitly assumed that the minimum energy is achieved in a crystal structure, rather than in an amorphous collection of molecules. However, often conditions do not exist to kinetically drive the molecules into the energy structure minimum. Also, some solids comprising heterogeneous mixtures of molecular isomers (e.g. both *cis* and *trans* isomers), or more than a single compound, may not have a well-defined structure with a distinct minimum energy. In these instances, *metastable* crystalline phases corresponding to a *local* energy minimum, or even amorphous solids can result, depending on the conditions used to achieve crystal growth. It is important to emphasize, however, that growth kinetics notwithstanding, the minimum energy structure of a homogeneous material is crystalline whereby neighboring molecules achieve the closest possible equilibrium packing habit, as discussed in Section 2.2.

While in principle the determination of the minimum energy structure is straightforward, in practice the process generally consumes extraordinary amounts of computer resources. The absence of data for molecular van der Waals coefficients requires that the energy calculation includes all pairwise interactions between *atoms* comprising the interacting molecules. Then, their energy contributions are determined using Eq. 2.68 with the help of the coefficients in Table 2.5, summed using Eq. 2.71, and then minimized. This calculation must be done for each molecule with respect to all others in the ensemble, and for all possible orientations for each molecule relative to all others in the neighborhood that extends until the contributions from more distant molecules becomes negligible. To accomplish this for almost any crystal structure, the number of degrees of freedom rapidly leads to an intractably large computational challenge. However, there are several simplifications that can be safely applied to many molecular solids that can provide a reasonably accurate estimation of the lattice energy and structure.

The process of reducing the molecule to its atomic constituents, and then summing over all the pairwise interactions between atoms to calculate their individual bond energies is known as the *atom–atom potential method*. In this case, the energy between molecules  $i, j$  is

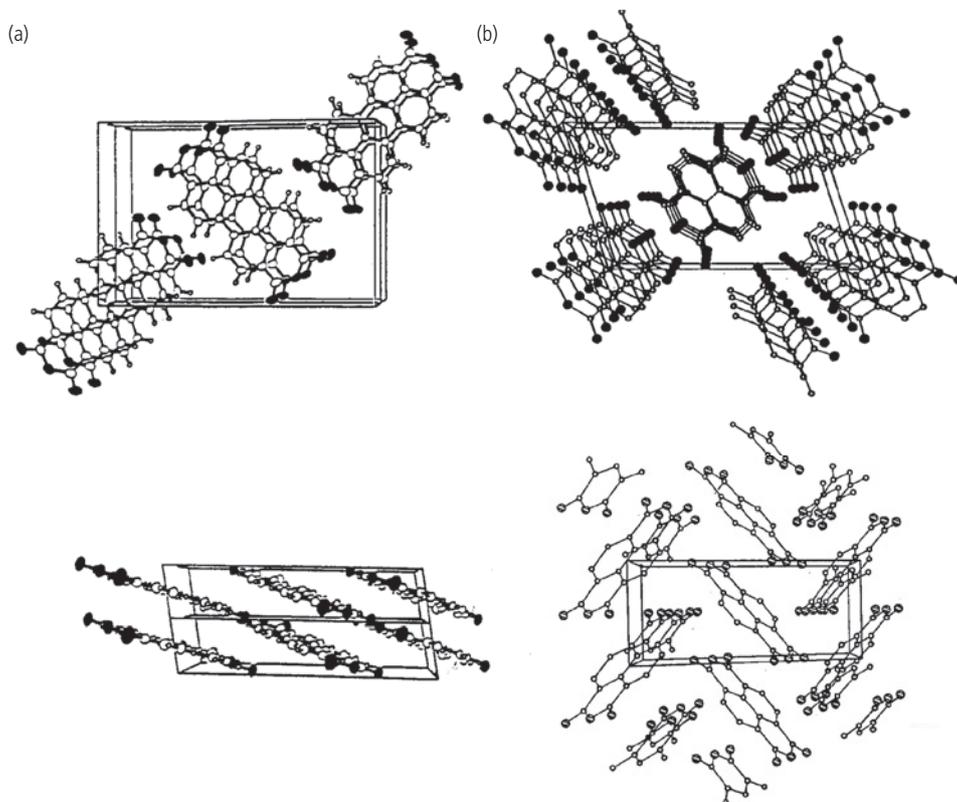

$$U(R_{ij}) = \frac{1}{2} \sum_{m,n} U(r_{mn}), \quad (2.72)$$

where  $m, n$  are atoms in different molecules,  $i, j$ , whose potential is given by Eq. 2.68. The validity of this approach is based on several assumptions: (i) The calculation applies to equilibrium at  $T = 0$  K, and hence it cannot predict dynamic growth processes, nor does it consider vibrational contributions or phase changes that may occur at  $T > 0$  K. Thus, the model is static. (ii) The van der Waals forces between atoms on neighboring molecules are isotropic, and are not significantly perturbed by the molecular structure in which they reside. (iii) The molecules are rigid, that is, there are no internal degrees of freedom where they might flex or twist when placed in proximity to another molecule. In effect, the ground state configuration of the isolated molecule is unaffected by its environment. This constraint is quite limiting since there are many molecules that have extended, linear structures that do indeed conform to the forces exerted by their neighbors. (iv) There is no significant contribution to the intermolecular energy arising from Coulombic forces, hydrogen bonds, higher

order multipoles, etc. Hence, intermolecular charge transfer is ignored. In principle, these forces can be added although their long-range nature extends the neighborhood of molecules that must be included, and hence can greatly increase calculational intensity. On the other hand, the calculation can be simplified by eliminating configurations prohibited by crystal symmetry or unlikely molecular orientations. For example, we can start the structural calculations by assuming either a monoclinic or triclinic lattice with the adjacent molecules stacked in either a lamellar or herringbone configuration, which captures a large majority of organic structures (see Table 2.1). Previous calculations for planar, nonpolar molecules such as anthracene and coronene have shown that the assumptions used in the atom–atom potential calculations generally lead to accurate, first-order estimations of equilibrium structures (Kitaigorodsky, 1973).

The accuracy of the method has been tested by calculating the bulk crystal structures of NTCDA and PTCDA, and then comparing these results with crystallographic data (Forrest, 1997). Perspective views of the measured bulk PTCDA and NTCDA unit cells are provided in Fig. 2.18a and b, respectively (Forrest et al., 1987). Here, PTCDA and anthracene (Fig. 2.8) form lamellar structures, whereas NTCDA is in one of many possible herringbone arrangements. Table 2.7 provides the details of the lattice structures of both materials. In this table we see there are two possible structures of PTCDA (called the  $\alpha$  and  $\beta$  phases), and only one known *isomorph* of NTCDA. PTCDA is *polymorphic*; that is, it can take on several different stable or metastable forms, each one known as an isomorph. Polymorphism is a common attribute of molecular solids, with each isomorph achieved via a different kinetic route. Also, the unusually close intermolecular spacing of only 3.21 Å in  $\alpha$ -PTCDA leads to many of its remarkable physical as well as electronic properties, that will be discussed in the following chapters.

As noted above, tackling the full structure is a complex 3D problem involving numerous degrees of freedom between the several molecules in the cells. Hence, only limited aspects of the 3D structure are calculated to demonstrate the application and accuracy of the atom–atom potential method. In Fig. 2.19, the energy surfaces of two PTCDA molecules and two NTCDA molecules are stacked one above the other (forming physical dimers). The surfaces are obtained by calculating the total energies (Eq. 2.72) while translating the molecules along the glide plane normal to the stacking axis using the atomic van der Waals coefficients in Table 2.5.

**Figure 2.18** Views of the crystal structures of (a)  $\alpha$ -PTCDA and (b) NTCDA. PTCDA is a closely packed, monoclinic lamellar structure, with a minimum distance of 3.21 Å between stacked molecules. NTCDA forms a more open herringbone monoclinic lattice. The unit cells are shown by the frames. Carbon atoms are shown as open circles, O as closed circles, and H are the small circles at each outer vertex at the carbon rings. Adapted from Forrest (1997).

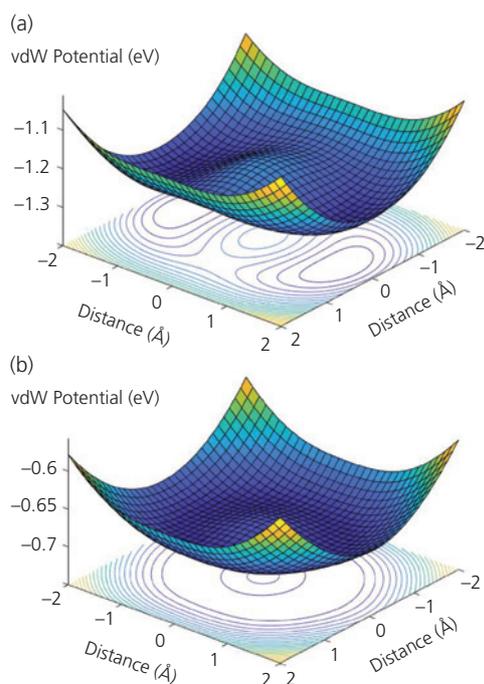

From these calculations, the equilibrium distances (i.e. the van der Waals radius) in the stacking direction are between 3.20 Å and 3.26 Å for these planar molecules. It has been assumed that the molecular planes of adjacent molecules are parallel, which is not the case for the herringbone structure of NTCDA. The binding energy of the PTCDA dimer is approximately  $-1.3$  eV, corresponding to 24 kcal/mol (see Table 2.7). This value is consistent with the sublimation energies of many aromatic molecules similar to PTCDA and NTCDA (Cox and Pilcher, 1970). Indeed, the sublimation temperatures or evaporation temperatures that range between 80°C and 500°C for most organic crystals (compared to 700°C to 2000°C characteristic of covalently bonded semiconductors) are a direct consequence of the bond strengths. Stronger bonds result in higher boiling or evaporation temperatures. Thus, van der Waals bonds are typically in the range of 1–10 meV/atom (Kitaigorodsky, 1973), leading to a binding energy/molecule  $\geq 1$  eV, whereas for covalent or ionic bonding, the energies

range from 100 meV to  $\sim 5$  eV/atom (Ashcroft and Mermin, 1976).

There are two minima located at  $\pm 1.1$  Å from the center of the PTCDA molecules forming the dimer, and  $\pm 1.0$  Å for NTCDA. The energy minima are displaced from the molecular centers of mass, and are located along the long molecular axis. The equilibrium offset is experimentally observed in the PTCDA bulk structure, resulting in the molecular lamella stacking along the (102) axis, forming a slip-stacked structure. That is, there is an 11° tilt of the molecular plane within the unit cell, which has been widely observed for PTCDA deposited on such insulating substrates as glass (Forrest et al., 1984b) and polymers (Taylor et al., 1995, 1997). Interestingly, this 11° tilt is not observed for PTCDA on conducting substrates such as Au or GaAs (Hirose et al., 1996), suggesting that more complex charge exchange interactions not included in the calculations may exist for these latter situations.

Already we have seen that the computational intensity of even these simple dimer structures involves

a considerable investment of computer time. As a simplification, the molecule can, in some cases be substituted by a proxy structure for the individual atoms. The proxy has a similar spatial symmetry of the actual molecule. For example, PTCDA and NTCDA have been replaced by ellipsoidal “atoms” whose effective van der Waals coefficients approximate the total intermolecular interactions (Forrest and Zhang, 1994). In the ellipsoidal approximation, all the atom–atom potentials between two planar molecules (e.g. PTCDA and NTCDA) are reduced to ellipsoidal potentials, one for each molecule, but where the

**Figure 2.19** Potential energy surfaces obtained by fixing the intermolecular spacing of (a) PTCDA and (b) NTCDA as the molecules are translated relative to each other in the dimer (Forrest and Zhang, 1994).

Buckingham coefficients,  $\alpha_{12}$ ,  $\beta_{12}$ , and  $A_{disp}$  in Eq. 2.67 are replaced by phenomenological constants that depend on angle and distance to the nearest neighbor molecule.

To account for more complex molecular shapes, the molecular structure can be broken into a limited set of interaction sites representing a cluster of atoms in a molecule, and spatially arranged to approximate the shape of the actual molecule. The Lennard-Jones potential is then used, along with “effective” atom–atom interaction coefficients derived for each site to calculate the lowest energy crystal structures. For example, the 54 atoms comprising the CuPc molecule are replaced by 13 spherically symmetric sites, thereby eliminating 95% of the pairwise calculations required to determine the interaction between two like molecules (Liu et al., 1996). The number and distribution of sites chosen is determined by a compromise between the requirement to accurately represent molecular geometry and symmetry, and the need to include as much of the interaction physics as possible without making the calculation impractically unwieldy.

Unfortunately, none of these potential approximations can be employed without some *a priori* experimental verification of their accuracy. Yet, obtaining such data (via, for example, examining the structure of the actual solid under study) can ultimately minimize or even eliminate the need for the calculation in the first place.

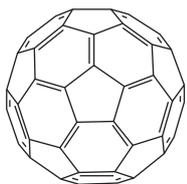

It is inevitable, therefore, that approximations must be employed to make structural calculations tractable, such as limiting the interactions to short range van der Waals forces, eliminating unlikely structures from the outset, or by replacing all the atom–atom potentials with a few effective potentials. Even with such approximations, the predicted structures may be difficult or even impossible to reach by conventional growth methods. Given these significant limitations,

**Table 2.7** Monoclinic unit cell parameters for PTCDA and NTCDA (from Forrest and Zhang, 1994 for  $\alpha$ -PTCDA and NTCDA, and Mobus et al., 1992 for  $\beta$ -PTCDA)

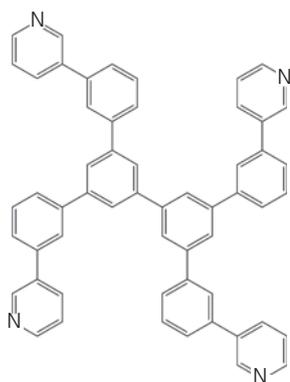

Parameter	$\alpha$ -PTCDA	$\beta$ -PTCDA	NTCDA
Formula	$C_{24}O_6H_8$	$C_{24}O_6H_8$	$C_{14}O_6H_4$

structures are often approximated using *molecular dynamics* (MD) methods, whereby a limited set of interactions for an ensemble of molecules are applied at a temperature,  $T > 0$  K. The non-zero temperature provides kinetic energy to the ensemble. The calculation of the structure is then carried out for a time sufficient for the molecules to reach an equilibrium, or near-equilibrium configuration. This is equivalent to structural *annealing*, whereby the individual molecules are jostled around to find an energetically favorable structure that may actually be reached under realistic laboratory conditions.

MD simulations, for example, have been used to understand the structure of an interface between films of  $C_{60}$  and BP4mPy and its evolution over time after its growth by *organic vapor phase deposition* (OVPD, see Section 5.4.2) (Baldo et al., 1998, Song and Forrest, 2016). The molecular structural formulas of  $C_{60}$  and BP4mPy are shown in Schemes 1 and 2, respectively.

**Scheme 1**  $C_{60}$

**Scheme 2** BP4mPy

In OVPD, organic molecules are volatilized by a hot inert carrier gas that transports them to a cold substrate where they are adsorbed (Shtein et al., 2001). The carrier gas imparts kinetic energy to adsorbate molecules to promote diffusion along the surface until the molecules find suitably low energy sites where they stabilize. In MD calculations, the annealing

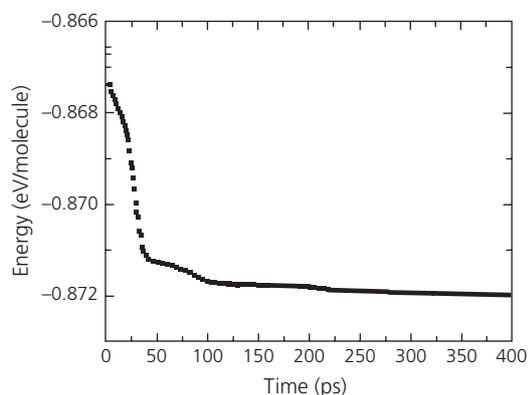

energy, however, is provided by the ambient temperature. For OVPD-based growth, the dependence of kinetic energy on pressure can be substituted by an equivalent small change in substrate temperature according to the ideal gas law. That is, if the temperature at pressure  $P_1$  is  $T_1$ , then at a different pressure,  $P$ , the incremental kinetic energy is given by the canonical relationship:

$$\begin{aligned} \delta E_{kin}(T, P) &= \frac{k_B(T_{eff} - T_1)}{k_B T_1} \delta E_{kin,0}(T_1, P_1) \\ + \delta E_{kin,0}(T_1, P_1) &= \left[ \frac{k_B T_1 (P/P_1 - 1)}{k_B T_1} + 1 \right] \delta E_{kin,0}(T_1, P_1), \end{aligned} \quad (2.73)$$

where  $T_{eff}$  is the equivalent substrate temperature that leads to the increased energy. Note that  $T_{eff}$  is not the actual temperature; it is the temperature needed to supply the same kinetic energy to the molecules as the change in pressure in the actual growth environment. The increase in carrier gas pressure allows molecules to find lower energy sites during the annealing process due to their larger kinetic energy. Equation 2.73 depends on the activation energy barrier,  $\delta E_{kin,0}$ , that must be overcome for a molecule to have sufficient surface mobility to seek a low energy site, rather than fixed at its point of initial incidence on the surface. For the system considered, nanocrystalline films formed at  $P_1 = 0.17$  torr, whereas in vacuum only amorphous films were grown. From these data, it was inferred that  $T_1 = 350$  K, from which the activation energy for crystallite formation was  $\delta E_{kin,0} = 4.5$  meV (Song and Forrest, 2016).

Molecular dynamic simulation results were obtained for an ensemble of 32  $C_{60}$  and 12 BP4mPy molecules that were initially segregated into amorphous regions bounded by an abrupt, planar interface. This is clearly a far more challenging problem than seeking the lowest energy of a homogeneous pair of flat, polyaromatic hydrocarbons. In this case, we are examining an inherently disordered structure comprised of 44 molecules with vastly different volumes, shapes and atomic distributions. Whereas  $C_{60}$  has spherical symmetry, BP4mPy is approximately planar, although its single C—C bonds between phenyl groups allows for numerous twisting and bending degrees of freedom, all of which are considered in the simulations. Molecular dynamic simulations based on a 6-12 Lennard-Jones potential, and that included simulated annealing for times up to 400 ps were performed using commercial software (Bovia Corp, 2016). Convergence toward structural equilibrium in  $<150$  ps is found for  $P_2 = 0.28$  torr (with an equivalent temperature of  $T_{eff} = 576$  K; see Fig. 2.20).

The simulation proceeds by allowing the ensemble of molecules to reach different equilibrium arrangements at each background pressure. At  $P_1$  ( $T_{eff} = 350$  K), Fig. 2.21a shows that there is minor reorganization within the  $C_{60}$  and BP4mPy regions with a slight intermixing at the interface. At  $P_2$

**Figure 2.20** Potential energy of the simulated molecular configuration annealed at  $T = 576$  K (corresponding to  $P_2 = 0.28$  torr) as a function of simulation time. The equilibrium structure is achieved after approximately 150 ps (Song and Forrest, 2016).

(corresponding to  $\delta E_{kin} = 7.4$  meV) in Fig. 2.21b,  $C_{60}$  molecules form into their characteristic, tight packed fcc lattice that limits interdiffusion of BP4mPy. As the growth pressure increases to  $P_3 = 0.49$  torr (corresponding to  $\delta E_{kin} = 13.0$  meV in Fig. 2.21c), the  $C_{60}$  region becomes more disordered, allowing BP4mPy molecules to interdiffuse across the interface. The molecules become completely blended in an amorphous mixture at the highest pressure,  $P_4 = 0.82$  torr ( $\delta E_{kin} = 21.7$  meV in Fig. 2.21d). The corresponding van der Waals energies of each configuration are  $-0.833$  eV/molecule at  $P_1$ ,  $-0.872$  eV/molecule at  $P_2$ ,  $-0.935$  eV/molecule at  $P_3$ , and  $-1.01$  eV/molecule at  $P_4$ . This implies that the ensemble energy decreases as the BP4mPy: $C_{60}$  blend becomes more intermixed. Increasing pressure (and hence kinetic energy) drives the morphology to an increasingly stabilized structure.

## 2.6 Molecular layer structures

### 2.6.1 Epitaxial growth modes

For practical applications, the optoelectronically active material is layered onto a supporting substrate. Unlike inorganic semiconductors, it is impractical or exceptionally difficult to grow molecular crystals of a size useful for studying and exploiting their properties in the bulk. Hence, almost all electronic devices

**Figure 2.21** Molecular dynamic simulation results of an ensemble of 12 BP4mPy and 32  $C_{60}$  molecules after simulated annealing with effective molecular kinetic energies of (a)  $\delta E_{kin} = 4.5$  meV, (b) 7.4 meV, (c) 13 meV, (d) 21.7 meV corresponding to OVPD growth pressures of 0.17 torr, 0.28 torr, 0.49 torr, 0.82 torr, respectively. The initial condition corresponds to (a) with  $C_{60}$  to the left and BP4mPy to the right of the interface in the center of the diagram. Note the ordered fcc  $C_{60}$  lattice in (b), and the almost complete intermixing of the equilibrium structure achieved at the highest pressure of 0.82 torr in (d) (Song and Forrest, 2016).

employ thin films of active materials grown onto a supporting substrate. Epitaxial growth, or *epitaxy*, is achieved when the lattice structure of the film matches that of the substrate, that is, when the lattice of the adlayer atoms or molecules is identical to that of the underlying substrate. When this condition is met, the substrate acts as a template on which to grow the layer. For materials bonded by strong and long range covalent and/or ionic forces (e.g. Si, GaAs, InP, etc.), lattice-matching between the substrate and epitaxial layer is essential in achieving a thin film free of dislocations or other defects that are generated to relieve lattice strain.

*Strain* is defined as the degree of lattice mismatch between two contacting layers. The lattice mismatch for a cubic structure is given by

$$\Delta a = |a_S - a_E|, \quad (2.74)$$

where  $a_S$  is the lattice constant of the substrate and  $a_E$  is that of the epitaxial layer. For example, due to the strong interatomic bonding of inorganic semiconductors, a close lattice-match (typically with strains of  $f = \Delta a/a_S < 10^{-3}$ ) is required when growing films thicker than a critical value beyond which a very high density of strain-energy relieving misfit dislocations are generated (Matthews and Blakeslee, 1974). While such mismatched epitaxy can occasionally be useful for device applications, the short carrier lifetimes and high junction leakage currents that accompany high defect densities are often unacceptable. This severely restricts the choice of materials available to the device engineer.

The *Matthews–Blakeslee thickness limit* is an estimate of the thickness at which a high density of dislocations is generated in an epitaxial layer. The critical Matthews–Blakeslee thickness is

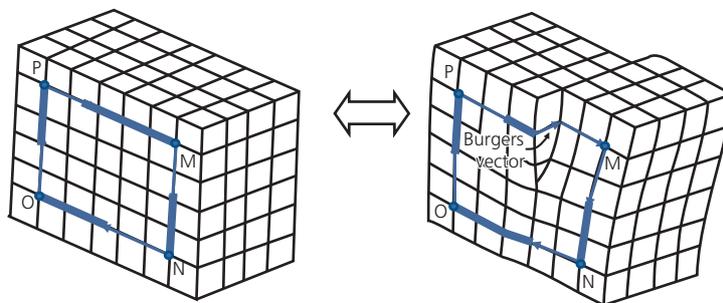

$$t_{crit} = \frac{\|\mathbf{a}\|(1 - \nu/4)}{4\sqrt{2}\pi f(1 + \nu)} \left( \log \left[ \frac{\sqrt{2}t_{crit}}{\|\mathbf{a}\|} \right] + 1 \right). \quad (2.75)$$

This is proportional to  $1/f$ , that is,  $t_{crit}$  decreases inversely with the degree of lattice mismatch between the epitaxial layer and the substrate. Also, it scales linearly with  $\|\mathbf{a}\|$ , the magnitude of the *Burgers vector* of the dislocation, which depends on both the magnitude and direction of the lattice distortion due to a lattice dislocation. The relationship between the Burgers vector and a dislocation is shown in Fig. 2.22. It points in the direction, and has the magnitude of the gap in a clockwise path originating and ending at the dislocation.

Ultimately, the tolerable strain is determined by how much distortion the lattice can withstand before a dislocation is formed. Distortion into the out-of-plane direction (i.e. normal to the substrate) relieves strain by attempting to maintain a constant unit cell volume, and hence maintaining its minimum lattice energy. In cubic lattices, this is known as *tetragonal distortion*, and is determined by the magnitude of the Poisson's ratio (Eq. 2.22). The effect of tetragonal distortion on a square lattice is illustrated in Fig. 2.23.

The substantially weaker cohesive forces exerted by van der Waals bonds between the adlayer and the substrate leads to a significantly reduced Poisson's ratio ( $\nu \sim 0.01$ ) compared to that for inorganic materials ( $\nu \sim 0.3-0.5$ ). The magnitude of the lattice distortion is correspondingly reduced, thereby resulting in an increase in the critical thickness. For strains of  $\sim 10^{-3}$  that are tolerable in covalently bonded materials, the critical thickness is  $\sim 100$  nm, whereas this value can be at least an order of magnitude larger for organics.

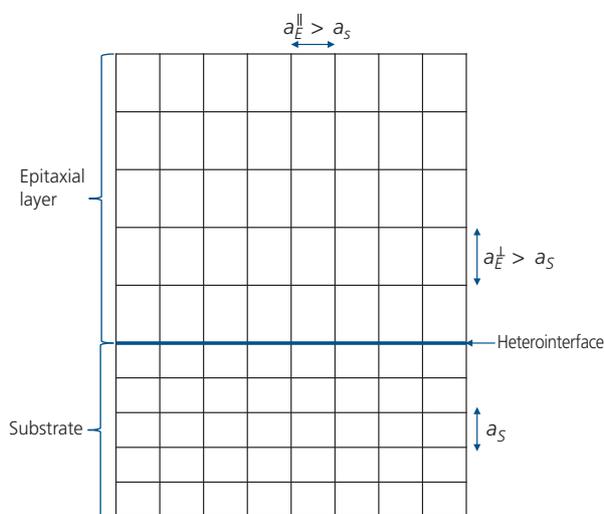

While the properties of organic molecular crystals have been studied for nearly 70 years, only recently has long range structural ordering of layers been achieved on a wide range of substrates (Forrest et al., 1984a, Hara et al., 1989, So et al., 1990, Umbach et al., 1998, Lunt et al., 2011). There has been both experimental and theoretical investigation of the

**Figure 2.22** An undistorted cubic lattice (left) and one with a dislocation (right). The Burgers vector extends from the start to the end of the clockwise path of MNOP.

conditions that lead to these ordered molecular thin films (Forrest and Zhang, 1994, Hillier and Ward, 1996, Yang and Forrest, 2008).

In the preceding discussion, we have emphasized the effects that the substrate lattice can have on the quality of subsequently grown layers, and the degree to which mismatch-induced strain can have on the quality of the epitaxy. To categorize the various types of structures, it is interesting to note that the etymology of the word *epitaxy* is a combination of the Greek *epi* for “upon”, plus *taxis* for “arrangement” or “in the form of.” Several such overlayer arrangements are shown in Fig. 2.24, where the deposited layer is shown by the grid with black circles, and the substrate with open circles. A conventional epitaxial

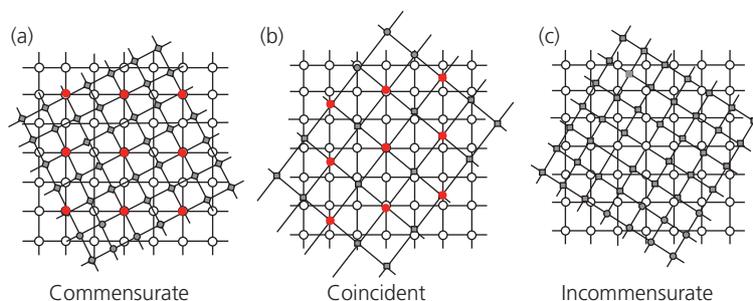

**Figure 2.23** An epitaxial layer whose lattice constant,  $a_E$ , is slightly larger than that of the substrate,  $a_s$ . The strain energy is relieved in the layer by tetragonal distortion to maintain the original unit cell volume. In this case, the lattice constant perpendicular to the substrate plane,  $a_E^\perp$ , is enlarged relative to that parallel to the substrate, where  $a_E^\parallel = a_s$ .

layer is both *commensurate* with the underlying lattice (i.e. both lattices precisely fit), and is aligned to it. An epitaxial layer therefore has a lattice with an identical symmetry as the substrate, as well as a lattice constant that is an integer multiple (usually no larger than 2) of the substrate. This motif results in an unstrained layer since there are no periodic mismatches between the upper and lower lattices. Thus, analogous to Fig. 2.24a, the lattice sites in the upper layer lie directly on top of those in the lower layer. In this example, the epitaxial layer is tilted such that its lattice points match every second substrate lattice point in both the  $x$  and  $y$  directions. This is known as a  $2 \times 2$  surface reconstruction.

If such a registry is not possible, the *coincident* layer illustrated in Fig. 2.24b may be achieved. The particular configuration shown is known as *point-on-line coincidence*. Notice that the epitaxial lattice is registered along each column of lattice sites on the substrate. This registration minimizes misfit strain, although it is not entirely eliminated. Coincident structures find “magic angles” of alignment to produce the minimum energy structure. Coincidence occurs for lattices with similar, but not identical symmetries (in the diagram a rectangular layer is registered with a square substrate lattice), and the lattice constants are related by a simple, rational fraction or integer multiple of each other. For example, if the substrate has a square lattice with lattice constant  $a$ , the overlayer can find a coincident registration if it is a rectangular lattice with lattice constants  $a, \frac{3}{2}a$ .

Finally, the most common situation found in organics is the nearly total lack of periodicity between the upper and lower layers. This results in an incommensurate registration between the lattices. *Incommensurate lattices* have both different symmetries and lattice constants. Since there is no perfect fit, the lattice constants differ by irrational numbers.

**Figure 2.24** Three possible layer schemes of a misfit lattice on a substrate. (a) Commensurate, (b) coincident, and (c) incommensurate. The square substrate lattice is shown by open circles and the overlayer structure is shown by filled circles. Coincidence in (a) and (b) is highlighted by red points.

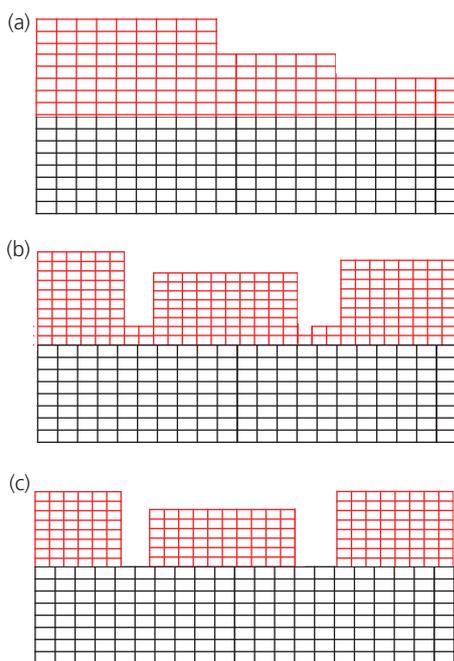

Such a layer will always be strained, although as shown below, it can nevertheless find a preferred alignment with the substrate that can produce long-range order. Indeed, given the highly elastic nature of van der Waals solids, incommensurability does not necessarily result in structural defects, as it would surely do in covalent or ionically bonded materials.

To distinguish these possible relationships between the layer and the substrate, van der Waals film growth has been identified by various terms including epitaxy (Hara et al., 1989), quasiepitaxy (So and Forrest, 1991) and epitaxy (Koma, 1992), depending on the degree of strain or morphology of the resulting film. Here, we will clarify this terminology as well as identify the primary characteristics of molecular films grown on a variety of substrates.

In conventional epitaxy, the molecules are chemisorbed onto the substrate surface through the relatively high energy covalent bond, whereas in van der Waals epitaxy adhesion to the substrate is through purely electrostatic bonds (Burrows et al., 1992). Inevitable mismatches between the substrate and film lattices result in strained layer growth that promotes three different surface morphologies illustrated in Fig. 2.25. In order of decreasing strain between the adsorbate and the substrate, the growth mode is

(Smith, 1995): (i) layer-by-layer, or *Frank–van der Merwe growth* (Fig. 2.25a), (ii) wetting layer-plus-island, or *Stranski–Krastanov growth* (Fig. 2.25b), and (iii) island, or *Volmer–Weber growth* (Fig. 2.25c).

In the absence of significant strain, epitaxial growth occurs layer-by-layer, with each layer lattice matched to the one beneath. In this case, the Matthews–Blakeslee critical thickness is substantially larger than the total layer thickness. The surface morphology is either flat or terraced. If the strain is large (i.e. the epitaxial lattice is significantly mismatched to, or incommensurate with the substrate lattice), only a few molecular layers (“wetting layers”) can grow before  $t_{crit}$  is exceeded. The strain in subsequent layers exceeds the elastic limit of the material, and hence the strain energy is released by the formation of defects. The defects separate strain-relaxed islands that nucleate on the wetting layers. Finally, for the most highly strained layers, the growth commences by isolated island nucleation on the substrate surface. The size of the islands is determined by the degree of strain; the mean island diameter decreases with increasing lattice mismatch. As the layer thickness is increased, the islands grow in both height and width in a layer-by-layer mode, eventually merging into a highly disrupted and often discontinuous, polycrystalline layer with grain boundaries separating each island. The process of island nucleation and increasing size with thickness is known as *Ostwald ripening* (Ratke and Voorhees, 2002). The rate and scale of island growth are determined by the wetting properties of the nucleation sites on the substrate (i.e. the mismatch in surface energies between substrate and adsorbate), and the available thermal energy that promotes molecular migration across the surface to the growing islands.

**Figure 2.25** Growth modes of epitaxial layers. (a) Layer-by-layer (Frank–van der Merwe), (b) layer-plus-island (Stranski–Krastanov), and (c) island (Volmer–Weber) growth. The substrate lattice is in black, and the epitaxy is in red.

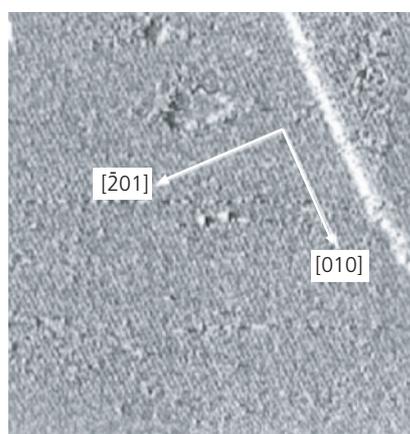

## 2.6.2 van der Waals epitaxy and quasiepitaxy

Perhaps the most “classical” example of a van der Waals bonded solid is graphite. The carbon atoms within a layer are covalently bonded into graphene sheets, yet the forces bonding the sheets together to form a three dimensional solid are by the weaker van der Waals interaction. Like mica, graphite is a layered material whose individual sheets can easily be separated. This gives graphite a significant asymmetry in tensile strength along these orthogonal axes.

As noted in the previous section, it is difficult to find commensurate molecular crystal/substrate combinations leading to unstrained van der Waals epitaxy. Thus, Stranski–Krastanov growth tends to be the most frequently observed mode, albeit with a

wetting layer that is considerably thicker than found in inorganic semiconductor materials combinations. Somewhat compensating the lack of a matching substrate is the large number of degrees of freedom that the adlayer molecules can assume due to their large size and complex structure. For example, with appropriate substrate surface preparation, the molecules can assume various configurations that compensate for strain, such as standing on edge, or lying flat on the substrate plane (Shtein et al., 2002, Lassiter et al., 2010, Yook et al., 2011). As a result, all of the modes in Fig. 2.25 have been realized in crystalline organic layers. The mode that develops depends on the kinetic conditions present during growth (i.e. substrate lattice mismatch to the equilibrium film structure, bonding energy between molecules and between molecules and substrate, rate of film growth, substrate temperature, background pressure in the case of vapor phase deposition, etc.).

Examples of different growth modes of organic films on various substrates are given in Figs. 2.26–2.28. Figure 2.26 shows the surface of a PTCDA film grown on highly oriented pyrolytic graphite (HOPG). The growth is by thermal evaporation in ultrahigh vacuum. This is an example of layer-by-layer, Frank-van der Merwe growth, with a monolayer at the bottom left, and a terrace leading to an additional layer, forming a bilayer, at the upper right. The crystalline molecular planes are clearly visible and oriented relative to the graphite substrate. Also, a few defects appear in the monolayer toward the top center of the image. These are apparently holes in the film

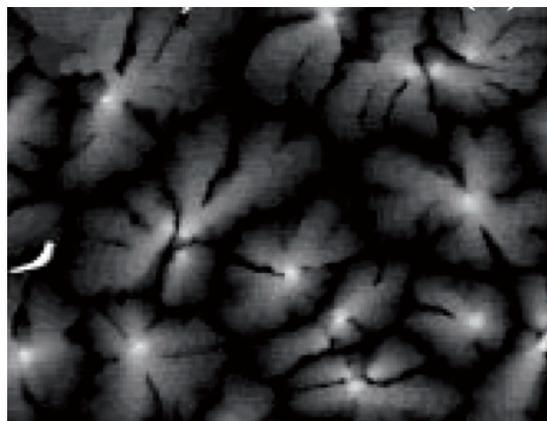

**Figure 2.26** Scanning tunneling microscope image of layer-by-layer growth of PTCDA on graphite. Note the molecular planes and the step edge of the second layer. Also indicated are the crystal plane directions of PTCDA. The image size is approximately  $(150 \text{ nm})^2$  (Kendrick et al., 1996).

where PTCDA molecules are absent, exposing the underlying HOPG substrate.

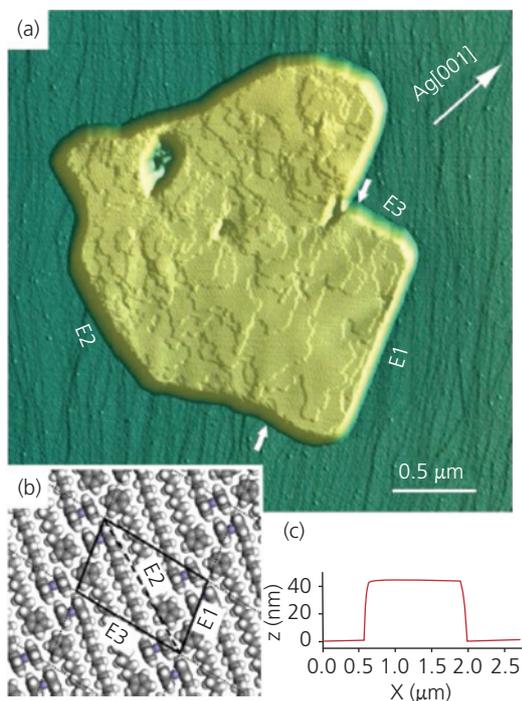

Figure 2.27 shows Stranski–Krastanov, layer-plus-island growth of pentacene on an amorphous polyimide substrate. The polyimide does not have the structure to provide a growth template. Thus, the first layer of thermally deposited pentacene molecules in high vacuum form randomly distributed nucleation sites on the substrate. As subsequent molecules arrive, they migrate to those sites leading to the formation of nanocrystalline islands. The islands continue to grow until they contact a neighboring island, eventually covering the entire substrate area. Further growth only increases the island thicknesses, but the deep fissures between the islands remain. These fissures (the darkest regions in the image) are grain boundaries that possibly extend all the way to the wetting layer. The crystallinity of the islands themselves is inferred from the fern-like, dendritic appearance that radiates from a central location corresponding to the original nucleation site.

Finally, Fig. 2.28 shows an isolated island oligoethylene-bridged ferrocene grown by thermal deposition in ultrahigh vacuum on the surface of Ag (110). This is an example of Volmer–Weber, or island growth. The island has a mesa-like morphology, that is, it is a multilayer structure that rises above the substrate. Growth within the island itself is layer-by-layer, since the island is sufficiently small such that dislocations and grain boundaries are absent. The terraced features characteristic of layer-by-layer growth are clearly apparent across the island surface.

**Figure 2.27** Stranski–Krastanov growth of pentacene on polyimide. Note the deep fissures and rough morphology formed by the islands. Approximate dimension of the image is  $4 \times 3 \mu\text{m}$  (Yang et al., 2005).

**Figure 2.28** (a) Image of an island of oligoethylene-bridged ferrocene grown in ultrahigh vacuum on Ag (110). The terraces on the island show layer-by-layer growth. (b) Faceting of the island denoted by E1, E2, E3 correspond to the (0,1), (1,1), and (1,0) directions in the (211) plane, respectively. (c) Thickness profile of the island taken along a line between the short arrows. It is roughly 2  $\mu\text{m}$  at its widest point (Zhong et al., 2008).

As in the other growth processes, nucleation on the substrate is random. Once an island is nucleated, subsequently deposited molecules migrate toward those nucleation sites, growing the size and height of the islands. Insufficient material has been deposited for the separate islands to grow together in what would undoubtedly be a very uneven surface with many grain boundaries. The absence of a nearby island in this image, in spite of its multilayer thickness of 40 nm and edge faceting, suggests that the binding energy of the molecules to themselves (i.e. to the island) is significantly larger than the binding energy to the Ag surface. Thus, molecules can migrate relatively large distances until they find an island on which to attach. The substrate temperature of 300 K is sufficiently high to promote this long-distance molecular migration. The energy available to molecular surface motion increases with substrate temperature. Thus, the island thickness is understandably temperature dependent, ranging from 38 nm at 250 K to 51 nm at 350 K.

*Quasiepitaxy* (QE) has been used to describe, and understand how ordered films can be grown on

incommensurate substrates. That is, quasiepitaxial ordering appears to be a unique feature of highly elastic van der Waals solids, where large crystal domains (sometimes extending across entire substrates) can be grown, even though there is no clear integer relationship between the dimensions of the unit cells of the adlayer (called *unit meshes*) and substrate (Fenter et al., 1995, Sellam et al., 2001, Kilian et al., 2006).

The epitaxial relationship between lattices is expressed using a 2D vector:

$$\begin{pmatrix} \mathbf{a}' \\ \mathbf{b}' \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12} \\ b_{21} & b_{22} \end{pmatrix} \begin{pmatrix} \mathbf{a} \\ \mathbf{b} \end{pmatrix} = \mathbf{T}_{\mathbf{a},\mathbf{b}} \begin{pmatrix} \mathbf{a} \\ \mathbf{b} \end{pmatrix}, \quad (2.76)$$

where  $\mathbf{T}_{\mathbf{a},\mathbf{b}}$  is the spatial transform matrix. The matrix elements,  $a_{ij}$ ,  $b_{ij}$  ( $i, j = 1, 2$ ) are rational numbers that transform the substrate lattice unit mesh with primitive vector,  $(\mathbf{a}, \mathbf{b})$ , into the adlayer lattice vector,  $(\mathbf{a}', \mathbf{b}')$ . Even in lattice-mismatched QE growth, however, there remains an orientational relationship between the film and substrate that results in a defined azimuthal orientation between the lattices. Residual stress can develop in the film as it “attempts” to conform to the substrate lattice; this is known as strained QE. Strained QE films can be distorted from their bulk lattice structure, although there is no significant relaxation of this distortion with film thickness. It has been suggested that strain relaxation in QE films results from local periodic variations in molecular density of the adsorbate molecules along the substrate surface. That is, the unit cells are distorted, similar to tetragonal distortion in the vertical growth direction, with the compression of cells in one region followed by expansion farther along the surface. This results in an oscillating energy strain along the surface that is insufficient to generate dislocations (Zhang and Forrest, 1993). Periodic longitudinal lattice distortions, known as *mass density waves*, have been proposed as a strain-limiting mechanism in Ar adsorbed on graphite (McTague and Novaco, 1979).

The ability of van der Waals-bonded molecular crystals to accommodate strain over large distances is due to their small elastic constants. In contrast to van der Waals epitaxy that results in relaxed and often highly disordered systems, QE is often achieved under non-equilibrium growth conditions, that is, on cold substrates or at high growth rates. Since strain relief can occur without inducing defects, Frank–van der Merwe as well as Stranski–Krastanov QE growth modes have been observed.

The primary requirement for QE is that there exists a range over which a surface molecule can

be translated relative to the substrate without a significant change in energy. If the total potential between molecules within a layer is  $U_{intra}$ , and between molecules in different layers is  $U_{inter}$  then this condition met when the relative magnitudes of the inter- and intralayer compressibilities follow

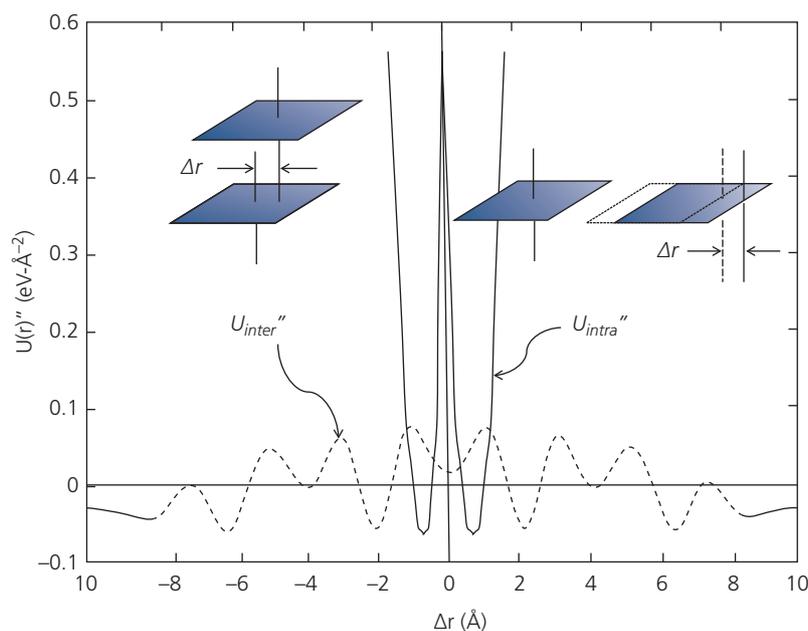

$$\frac{\partial^2 U_{intra}(r)}{\partial r^2} \gg \frac{\partial^2 U_{inter}(r)}{\partial r^2}. \quad (2.77)$$

This is the governing condition for QE growth. In this admittedly “static” model, the condition for QE is relatively independent of the absolute magnitudes of the energies themselves. As in many cases involving large planar molecules,  $U_{inter} > U_{intra}$  even though the inequality of the elastic constants in Eq. 2.77 is reversed.

The QE condition highlights an inherent difference with “orientational epitaxy” of inert gas atoms bonded to surfaces whose periodicities are similar (Itoh et al., 1988). In QE growth, large molecules are often bound to an inorganic substrate with a considerably smaller lattice constant than the adsorbed layer. Hence, the molecule can “sample” many substrate atoms to find its minimum energy position, which is not the case for adsorbed inert gas atoms.

The condition for QE can be understood from the plot of elastic constants for a pair PTCDA molecules shown in Fig. 2.29, where the elastic constant within a layer (proportional to the second derivative,  $U_{intra}''$ , as in Eq. 2.77) is clearly larger than the elastic shear constant (proportional to  $U_{inter}''$ ) near the equilibrium molecular separation corresponding to a displacement of  $\Delta r = 0$ . Indeed, attempting to compress the molecules in the plane even further (at  $\Delta r \rightarrow 1 \text{ \AA}$ ) results in a dramatic increase in lattice stiffness for separations less than the van der Waals radius.

Thus, the QE condition implies that the surface mesh of the overlayer is only slightly distorted when deposited onto a substrate. This small lateral compressibility allows for minor but important adjustments of the layer orientation relative to the substrate. The potential surface of the molecule-substrate interaction has a relatively broad minimum (leading to a small  $U_{inter}''$ ), allowing for the orientational conformation between lattices without a large expense of strain energy. Rafts of large molecules thus have a range of energy-equivalent positions, and therefore can form (under appropriate growth conditions) an incommensurate overlayer with only a small interfacial strain energy. These assumptions suggest that a QE thin film is a rigid overlayer that is largely undistorted when contacting the incommensurate

**Figure 2.29** Calculated elastic constants of two PTCDA molecules that are positioned perpendicular to the molecular plane (with a second spatial derivative of  $U_{inter}''$ ), and in-plane ( $U_{intra}''$ ) as a function of relative molecular displacements,  $\Delta r$  defined in the insets. For calculating  $U_{inter}''$ , the “test molecule” is located at an equilibrium molecular distance of  $r_0 = 3.2 \text{ \AA}$  over an infinite, 1D lattice of substrate molecules. The calculation of  $U_{intra}''$  corresponds to that of two adjacent, co-planar molecules. The equilibrium molecular distance within the plane is calculated to be  $r_0 \sim 0.7 \text{ \AA}$ . Adapted from Forrest and Burrows (1997).

substrate lattice. Since the overlayer has a very low spatial periodicity as compared with the substrate, strain may be relieved through modifications of the internal degrees of freedom within the larger, adsorbed molecular lattice. The elastic distortion of the film does not appear to relax even in the thickest films studied. The details of QE structures are considerably more complex than predicted by the model discussed here, although their general features can be predicted by the somewhat simplified assumptions used to make the calculations both intuitively useful and tractable.

In many respects, the conditions leading to QE are similar to those responsible for self-assembly of materials, a topic we discuss further in Section 2.7 and in Part II. Self-assembly is the process by which the forces between atoms or molecules are sufficiently high that an equilibrium structure, whether it is a colloidal particle, an island grown on a substrate, or even a complete and macroscopically thick layer, is achieved largely independent of its energetic environment, although such assembly is often driven by forces between the layer and the substrate that can serve as a growth template. Hence, crystalline QE layers are essentially self-assembled films grown in their native equilibrium crystal habit on a substrate whose own structure may influence their relative orientation or the degree of strain within the adlayer. The internal organization of the film (i.e. its assembly into its equilibrium structure) arises from strong internal molecular forces that are greater than the adhesive forces to the substrate itself.

### 2.6.3 Modeling and growth of ordered layers

In previous sections we introduced methods for finding equilibrium structures of bulk molecular crystals. We now turn to methods that can predict the structures of epitaxial layers whose lattices might have significant misfits with the substrate. In particular, we need to develop an understanding of the factors that determine the relative axial orientation of incommensurate lattices. The QE condition explains how strain is accommodated by the asymmetric stiffness between and within a layer, but it does not provide a predictive model for the film structure itself. Several models have been advanced to understand epitaxial growth of covalent/ionic bonded epitaxial layers that can provide a foundation for understanding van der Waals bonded systems (Reiss, 1968, van der Merwe, 1982). The growth dynamics, and indeed the various growth modes achieved are the same for these apparently different systems, although the energies (and

hence the temperatures) involved in growth are a function of the different bond strengths. Epitaxial growth is typically modeled using a harmonic potential for the atomic cores, with a period equal to the atomic spacing of the substrate (van der Merwe, 1982). This is different for incommensurate lattices whose potential between overlayer and substrate is anharmonic. Hence, the analytical solutions attained for epitaxial systems must be modified using often impractically computationally intensive methods. One approach is to employ the atom-atom potential calculation simplified using one or more of the following strategies:

1. If we consider a set of  $n$  atoms in the epitaxial layer and  $m$  atoms in the substrate, the total number of atomic pairwise interactions is  $\frac{1}{2}nm$ . To make these calculations more efficient, we recognize that van der Waals interactions decrease as  $1/r^6$ . Hence, only nearest and next-nearest neighbor interactions need to be considered.
2. Extending the model to include molecules where long-range (but weak) intra- and interlayer Coulomb binding plays a role (e.g. where charge transfer between molecules does not occur) can significantly complicate the problem, and to our knowledge has not been treated in detail. However, the calculational methods employed for van der Waals solids can, in principle, be extended to include other, long-range bonding forces. When such interactions are dominant, conventional epitaxy results, and a harmonic potential can be employed. In this case, *intralayer* interactions between molecules need not be included, and the equilibrium configuration of the first monolayer is accurately determined by the single molecule/substrate binding interactions (Hashimoto et al., 1995).
3. Since the number of degrees of freedom within and between the molecules is large, an accurate and predictive calculation must include minimization of total energy with respect to all degrees of freedom. Where possible, therefore, it is essential to limit the degrees of freedom. For example, molecules can be restricted to lie within the substrate plane, and the molecules and substrate are both assumed to be rigid. This is known as the *rigid lattice approximation*. Whether or not it is an accurate representation of reality depends on the details of both the molecular and substrate structures.

Whatever assumptions are made, the calculations must include sufficient physics to lead to an accurate, equilibrium lattice configuration. Example

simplifications are to assume that there is an approximate lattice match, or to recognize and exploit symmetries common to both the substrate and the adlayer. Then there are a very limited number of preferred alignments that lead to a minimum energy configuration.

An example of this is to find directions where there is an apparent “fit” between substrate and adlayer. It would then seem logical that this orientation should lead to a minimum energy configuration. For example, for a given situation there may be an angle that results in point-on-line coincidence (Hoshino et al., 1994, 1995), where the lattice points of the adlayer are aligned along a primary (i.e. low Miller index) direction of the substrate, as illustrated in Fig. 2.24b. Coincidence models have also been proposed whereby a large epitaxial “super cell” consisting of many unit cells is found that achieves approximate coincidence along a particular substrate direction (Hillier and Ward, 1996). While these simple coincidence models are appealing, they simply seek “geometric” fits between substrate and supercell. This approach may provide intuitive insights, although it is not based on a rigorous energy minimization that seeks the equilibrium crystal structure. Indeed, point-on-line and super cell approaches can result in several equivalent orientations of the adlayer with the substrate, but they do not distinguish between those with higher or lower energy.

In contrast to coincidence models, energy minimizations employing simplified molecular structures have also been attempted. That is, the full, atom–atom potential summation between two complex molecules can be replaced by an ellipsoidal, site specific, or other potential approximations discussed in Section 2.5. These simplifications reduce the massive computational challenge required in modeling layers consisting of a sufficient number of molecules to approximate actual physical systems, although they have the shortcomings of being applicable to only specific molecular types or substrate-layer morphologies. Hence, they lack a clearly predictive quality of molecular combinations that lead to a particular structure.

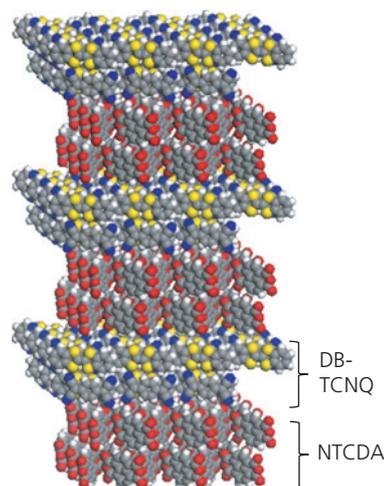

In the context of this discussion, the validity of the atom–atom potential method has been directly compared to coincidence models to understand the long range, and perfect QE ordering of multilayer stacks of NTCDA and the neutral charge transfer complex, DB-TCNQ grown by OVPD on KBr substrates (Lunt et al., 2011). Figure 2.30 shows the molecular structural formulae for NTCDA, DB-TCNQ, and KBr. The multilayers were grown on crystalline substrates via OVPD (see Chapter 5). Sustained ordering of NTCDA/DB-

TCNQ pairs initiated on a KBr substrate was maintained for several periods, with a clear quasiepitaxial relationship between adjacent, 5 nm thick layers in the stacks.

Figure 2.31 illustrates the multilayer stack along with structural models of the molecules within each layer. The structure was monitored *in situ* during growth using reflection high energy electron diffraction (RHEED) whereby a beam of electrons incident at 1–2° from the surface plane is scattered by the surface mesh of the growing layer. The shallow e-beam incidence angle results only in surface scattering since the electron beam penetration into the film is only ~10 Å. A flat surface results in diffraction streaks whose spacing gives the Bragg spacings of  $d_{xy}$  from the  $(x, y)$  surface mesh. The pattern for a single crystal appears only when the Bragg condition of

**Figure 2.30** Molecular structures of the molecules used in the multilayer stacks in Fig. 2.31. The KBr substrate is an ionic crystal, NTCDA is a neutral molecule and DB-TCNQ is a charge transfer salt. K = red, Br = purple spheres. In NTCDA, C = gray, O = red and H = white. In DB-TCNQ the color code is the same as for NTCDA with S = yellow (in DB) and N = blue.

**Figure 2.31** Schematic of a three-period stack of bilayers of NTCDA and DB-TCNQ. In the actual structures, the layer in the period is 5 nm thick, which is roughly 10 monolayers thick. From Lunt et al. (2011).

$$m\lambda = 2d_{xy}\sin\theta \quad (2.78)$$

is met. Here,  $\lambda$  is the electron wavelength ( $= hc/E_{RHEED}$  where  $E_{RHEED}$  is the electron beam energy),  $m = 0, 1, 2, \dots$  is the diffraction order, and  $\theta$  is the angle between diffraction streaks.

The growth of the multilayer stack commenced with the NTCDA deposited onto KBr. The diffraction streaks were continuous, indicating a flat surface, and their intensities varied along different azimuthal angles corresponding to different crystal directions in the NTCDA lattice. This indicated single crystalline, layer-by-layer growth across the entire  $2 \times 2 \text{ cm}^2$  substrate covered by the glancing incidence beam (Lunt et al., 2011). The bulk lattice of NTCDA(100) has unit mesh dimensions of  $a_1 = 0.531 \text{ nm}$ ,  $a_2 = 1.257 \text{ nm}$ , and  $\beta = 90^\circ$ , which is slightly different than the reconstructed values measured for the first layer. The in-plane NTCDA lattice constants were not found to vary for thicknesses up to 100 nm, suggesting that although the lattice is reconstructed differently than in the bulk, the maximum strain of  $\Delta a/a = 6.4\%$  accumulated even in the thick layers is insufficient to generate dislocations. Note that this amount of strain is more than an order of magnitude larger than can be accommodated in covalently bound crystals without inducing a high density of misfit dislocations, attesting to the elasticity inherent in the van der Waals bond.

The epitaxial relationship between the KBr and NTCDA lattices is  $\mathbf{T}_{\text{KBr,NTCDA}} = \begin{pmatrix} 1.99 & 0.009 \\ 0.01 & 0.753 \end{pmatrix}$  (cf. Eq. 2.76), where the NTCDA molecules contact the KBr substrate in its characteristic herringbone structure. Hence, an approximately coincident structure is observed within the error of the measured surface mesh, as shown in Fig. 2.32.

**Figure 2.32** Measured orientations of the surface unit meshes of DB-TCNQ and NTCDA on KBr (atoms shown as circles) (Lunt et al., 2011).

The lattice surface mesh of DB-TCNQ(001) on KBr is  $a_1 = 0.922 \text{ nm}$ ,  $a_2 = 1.064 \text{ nm}$ , and  $\beta = 67.66^\circ$ , which is similar to its bulk dimensions. Remarkably, although DB and TCNQ molecules were deposited from separate sources in the OVPD system, a 1:1 concentration of these two constituents is achieved in the layer. This is an example of *congruent growth* where the layer has the same stoichiometric composition as the bulk. This implies that excess DB or TCNQ is not incorporated into the lattice and hence is removed by the carrier gas in the growth chamber. Similar congruent growth is observed in binary inorganic compounds such as GaAs and InP reinforcing the conclusion that the growth of organics is similar in almost all ways to that of inorganic compounds once the different binding energies are taken into account.

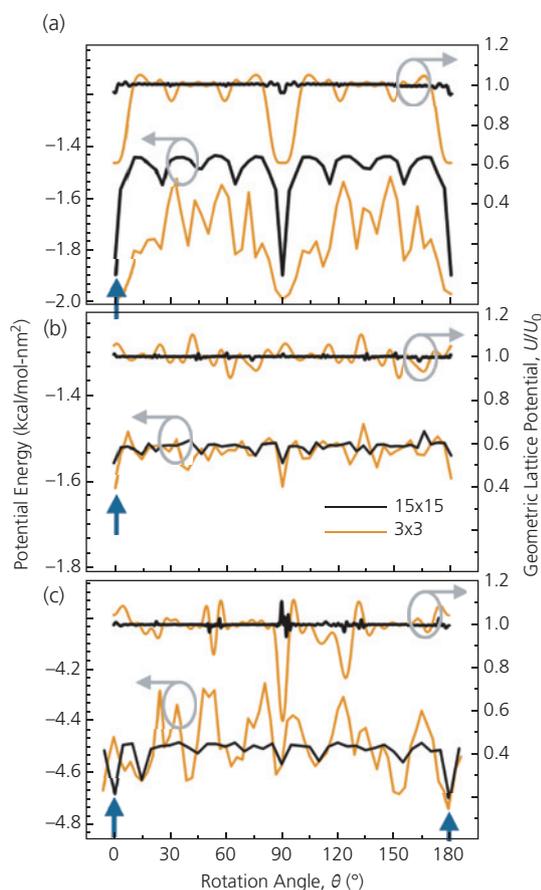

Finally, the transform matrix between the DB-TCNQ and NTCDA lattices is  $\mathbf{T}_{\text{NTCDA,TCNQ}} = \begin{pmatrix} 0.70 & 0.02 \\ 0.32 & 1.96 \end{pmatrix}$ . The absence of simple fractions shows that there is no apparent epitaxial relationship (corresponding to exact coincidence or commensurality) between these two molecular structures. The existence of a 5 nm thick, strained single crystal DB-TCNQ layer covering the NTCDA layer with a well-defined orientation even though the lattices are incommensurate provides a compelling example of strained, QE growth. The crystalline alignment, single crystallinity of all layers, and surface flatness are maintained by alternating 5 nm thick NTCDA followed by 5 nm thick DB-TCNQ layers for up to at least five periods (Lunt et al., 2011).

The geometric lattice potential (Hillier and Ward, 1996) that follows (in one dimension) the form  $U(r)/U_0 = \cos(2\pi r/a)$ , was compared to atom-atom potential calculations as a function of angle between lattice directions. In the geometric approach,  $(U/U_0)$  vs. relative lattice angles of the overlayer and substrate can describe the degree of lattice commensurality. For example, if  $U(\theta)/U_0 = 1.0$  for all relative lattice orientations,  $\theta$ , the lattices are incommensurate and there is no preferred direction. However if  $U(\theta)/U_0 = 0.0$  at a symmetry equivalent orientations, the lattices are fully commensurate.

The atom-atom potential calculations have to account for charge transfer between the anion and cation pair of DB and TCNQ, respectively, which makes the calculations considerably more complicated. Nevertheless, by only including van der Waals forces in the simulations confirmed that the

intermolecular distances between DB and TCNQ, and between DB-TCNQ pairs of 3.29 Å and 3.27 Å, respectively, were similar to their experimental values, indicating that charge transfer contributions were small and could be ignored.

Structural simulations using the geometric lattice and the full atomistic van der Waals potential energy between the substrate and the adlayer as a function of substrate–adlayer azimuthal rotation angle,  $\theta$ , are compared in Fig. 2.33a. The geometric potential tends toward coincidence (with a minimum  $U(\theta)/U_0 \sim 0.6$ ) at the symmetry equivalent angles of  $0^\circ$ ,  $90^\circ$ , and  $180^\circ$  for NTCDA lattices comprising  $3 \times 3$  unit cells on KBr. For larger overlayer cell meshes ( $15 \times 15$  cells) the coincidence becomes less pronounced, with only a shallow minimum of  $U(\theta)/U_0 \sim 0.95$  at  $\theta = 0^\circ$ . In contrast,

**Figure 2.33** Lattice potential energy (via the atom–atom potential method and via the coincident geometric method) for different lattice combinations. (a) NTCDA on KBr, (b) DB-TCNQ on KBr, and (c) DB-TCNQ on NTCDA. The orange line is for a  $3 \times 3$ , whereas the black line is for a  $15 \times 15$  surface lattice. Arrows indicate measured rotation angles,  $\theta$  (Lunt et al., 2011).

the atom–atom energy calculations indicate an energy minimum (baseline minus bottom of potential well) of approximately  $-0.3$  kcal/mol nm<sup>2</sup> at  $\theta = 0^\circ$  that grows deeper and narrower with increasing cell size. The depth of the energy well for a  $3 \times 3$  surface mesh is 75meV, or  $\sim 3k_B T$  at room temperature where growth proceeds. This suggests the route taken to achieve ordered growth. As the NTCDA nucleates, the first monolayer samples the energy landscape to find a preferred geometric alignment. As the grain grows, the alignment becomes fixed since the energy cost for rotation increases.

The preferred alignments predicted by both models are consistent with electron diffraction data. A significant difference between the approaches, however, is that the atom–atom potential calculation predicts that the total binding energy increases with the area of the film, whereas the coincidence model suggests that the energy decreases under this circumstance. This latter result is both unintuitive and unphysical.

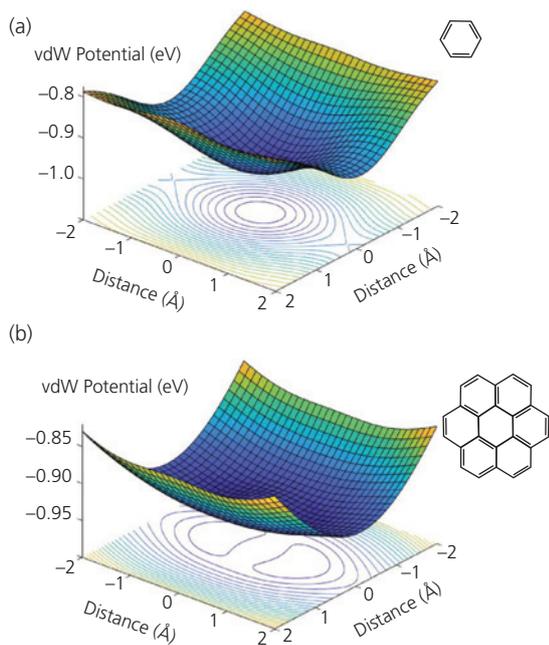

For DB-TCNQ grown on KBr (see Fig. 2.33b), the geometric model fails to predict the existence of any preferred angle, that is, it suggests an incommensurate lattice at every rotation,  $U(\theta)/U_0 \sim 1$ . On the other hand, the potential calculations exhibit minima at  $0^\circ$  and  $90^\circ$  consistent with the experimental data. As the lattice size increases, the potential well depth decreases while the minima remain at the same angles. The depth of the well is  $\sim 0.1$  kcal/mol nm<sup>2</sup>, which is smaller than for NTCDA on KBr, indicating a weaker driving force for alignment. For DB-TCNQ deposited on NTCDA in Fig. 2.23c, the geometric model predicts one coincident ( $U(\theta)/U_0 \sim 0.6$ ) alignment at  $\theta = 90.5^\circ$  ( $a_1(\text{DB-TCNQ}) \parallel a_2(\text{NTCDA})$ ) for small cells that disappear for larger surface meshes. In contrast, the atom–atom potential calculations indicate several energy minima for small domain sizes, with the deepest energy minimum at  $180^\circ$ . For the larger  $15 \times 15$  unit cell domains, the preferred alignments are at  $\theta = 0^\circ$  and  $180^\circ$  ( $a_1(\text{DB-TCNQ}) \parallel a_1(\text{NTCDA})$ ) with a well depth similar to NTCDA of  $\sim 0.2$  kcal/mol nm<sup>2</sup>. The  $0^\circ$  and  $180^\circ$  orientations are experimentally observed.

The energy-based calculations predict that preferred alignments can be observed for entirely incommensurate organic lattices, which are absent in purely geometric (i.e. coincidence or periodic potential) approximations. This highlights the importance of molecular structure over lattice geometry in determining the lowest energy layer-to-substrate orientations.

### 2.6.4 Dependence of strain on molecular size and shape

Meeting the QE condition of  $U_{inter} \ll U_{intra}$  depends on many different factors, including details of the molecular size and shape, the symmetry match between substrate and adlayer, substrate lattice structure and surface morphology, etc. Molecular size, for example, strongly influences the shear forces between molecules. For example, the energy surfaces calculated for a (small) benzene ( $C_6H_6$ ) and a much larger planar coronene ( $C_{24}H_{12}$ ) molecule on a PTCDA substrate lattice are shown in Fig. 2.34. Unsurprisingly, the energy minimum of the larger molecule is broad and flat as compared to that of benzene. Hence, the intermolecular shear stress ( $U_{inter}$ ) at the coronene/PTCDA interface is therefore much smaller than that of benzene, which should enhance the probability for long range QE ordering of this materials combination.

Molecular symmetry also plays a role in determining strain between layers. Figure 2.35 plots the minimum energies of adhesion on PTCDA for the linear polyacene series that includes benzene, naphthalene, anthracene, tetracene and pentacene, with 1, 2, 3, 4, and 5 fused rings, respectively. The shear stress

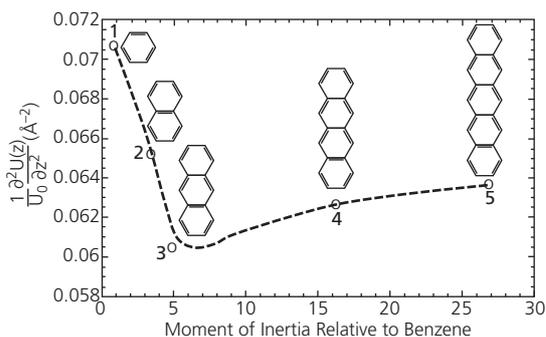

**Figure 2.34** Potential energy surfaces calculated for (a) benzene and (b) coronene molecules positioned  $3.2 \text{ \AA}$  above a PTCDA molecule. Notice the broad, flat minimum for the larger coronene, indicating a lower shear stress compared to benzene. Molecular formulas for the ad molecules are shown. Adapted from Forrest and Zhang (1994).

decreases monotonically for the three smallest molecules, and then it increases with a further increase in molecular length. Since the perylene core of PTCDA extends to only three fused rings, longer molecules (e.g. tetracene and pentacene) extend beyond the central molecule in the PTCDA surface cell over the carboxyl end groups, thus increasing the resistance to shear.

From the foregoing, it is apparent that the shear stress normalized to the equilibrium energies between layers decreases monotonically with increasing molecular size, or number of carbon rings. Hence, we expect that the ability to grow ordered QE layers increases as we progress from smaller (benzene) to larger, “rounder” molecules (coronene). As in all epitaxial growths, QE is favored when both the molecular shape and size of the substrate and overlayer molecules are approximately matched.

We once more emphasize that while the energy calculations predict the favored, or minimum energy configuration of the grown layers, the degree and extent of layer ordering that is actually achieved depends critically on the non-equilibrium thermodynamic conditions under which growth occurs. Static models do not predict these conditions. However, we find that certain low-energy thresholds between theoretically predicted structural isomorphs imply that growth at low substrate temperatures is favored for achieving uniform crystalline order, as has often been experimentally observed. Nevertheless, molecular dynamic models that consider the kinetic energy available during deposition are required to find the preferred crystal structures. In Part II we will describe how such dynamic simulations can be

**Figure 2.35** Normalized shear stress vs. “molecular shape” (as defined as the moment of inertia of a molecule rotated about an axis centered in the molecule and perpendicular to the molecular plane). The series of linear polyacenes are (1) benzene, (2) naphthalene, (3) anthracene, (4) tetracene, and (5) pentacene. Adapted from Forrest and Zhang (1994).

useful in describing and predicting the charge and energy transport characteristics of a range of molecular structures that are employed in high performance organic devices.

## 2.7 Self-assembly

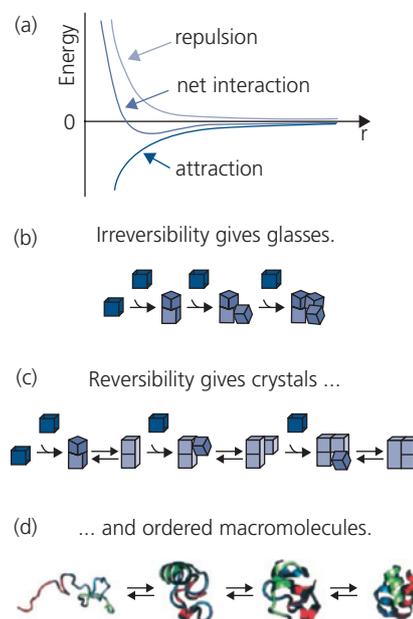

*Self-assembly* is the process by which the structure of a solid is guided by the cohesive energy and symmetry of its components. Self-assembly can spontaneously occur at several length scales, from the atomic or molecular, to the nano-, all the way to the macro-scale. Indeed, self-assembly of solids can span all of these scales, resulting in what is often termed *multi-scale assembly* (Whitesides and Boncheva, 2002). Self-assembly occurs ubiquitously in nature, driving the structure from cells to entire organisms. A classic example of self-assembly is the growth of hoarfrost. Water molecules nucleate into crystallites on dust or other imperfections on a cold window pane. As further molecules are adsorbed, the crystal grows into fern-like, self-assembled dendritic structures. Similarly, QE ordering is partially driven by self-assembly of the adsorbed film: the structure of the film is ultimately determined by strong intermolecular cohesion within a layer, with lesser adhesive forces binding the layer to the substrate. Self-assembly has been observed almost independent of the method used in structural formation, and has been achieved by growth in the vapor phase as well as in solution.

Molecular materials are particularly suited to layer formation by self-assembly due to weak intermolecular forces that allows for adjustment of molecules to form near-perfect structures even at room temperature. In Part II we will describe numerous high performance device structures that rely on self-assembled mono- and multilayers to achieve desired film morphologies. Self-assembly has been found particularly useful in solar cells, transistors and in limited-dimensional devices (Chapter 7–9).

Self-assembly relies on molecules or molecular sub-units that interact with each other with sufficient strength to form a stable structure. As we have seen in Section 2.4, the subunits must interact with an appropriate balance of attraction and repulsion. If the molecules adhere with excessively high binding forces, a glassy structure results. However, if the binding is on the order of the thermal energy, then the molecules can adjust to find the most energetically favorable configuration, which as we have seen, is often a crystal structure with order that extends over considerable

distances. In this sense, the assembly process must be reversible, where errors can be rapidly corrected before the structural defects become embedded in an imperfect assembly. This emphasizes the importance of supplying external energy (most probably, thermal) to allow for structural annealing and mass transport. The formation of self-assembled structures with different degrees of order, depending on the balance of attractive and repulsive forces between units, is illustrated in Fig. 2.36.

Self-assembly plays an important role in the structural organization of organic thin films and crystals, whether they are based on monomers, oligomers, dendrimers, or polymers. The most elemental and commonly used form of self-assembly in organic electronics is where molecules are designed and synthesized that have functional groups, steric properties or employ other strategies that force the assembly of molecules into large-scale structures. The adhesive forces between constituents are rarely covalent due to the strength of the bond, but rather are assembled via electrostatic Coulomb, van der Waals, or hydrogen bonds.

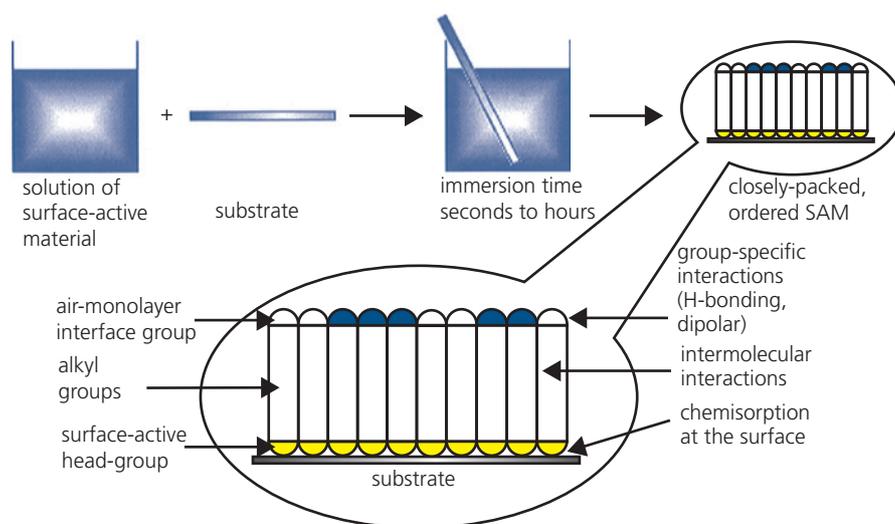

**Figure 2.36** (a) A balance of repulsive and attractive forces between structural elements is required for self-assembly. For example (b) shows that when the attractive forces are large, a disordered glass is formed, whereas (c) when thermal energy is available for weakly bonded elements, they can adjust to find the lowest energy configuration to form a crystal. (d) Likewise, large macromolecules such as proteins or cells can assemble with an appropriate balance of repulsive and attractive interactions (Whitesides and Boncheva, 2002).

A particularly useful electronic application of self-assembly is substrate space filling via deposition of *self-assembled monolayers* (SAMs). Alkanes with sulfur end groups (known as alkane thiols) can attach to Au substrates. Organosilicon groups can also attach to appropriately prepared surfaces (Ullman, 1996). A functionalized, space-filling layer pre-assembled on a substrate can serve as a template for the ordered growth of a subsequently deposited active organic molecular species (see Fig. 2.37). This strategy has been used to initiate ordered growth of pentacene channel layers on pre-deposited octadecyltrichlorosilane (OTS) SAMs to achieve high mobility organic thin film transistors (Section 8.6.1) (Shtein et al., 2002). Numerous strategies for using SAMs to create a function or to prevent metallic particles from sticking to each other on contact have been employed in the design of materials and structures to suit a particular application need.

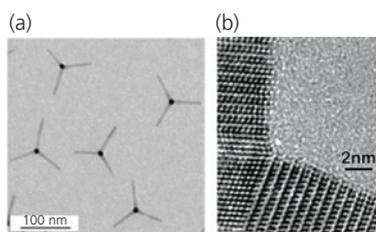

Beyond molecular assemblies, structures several nanometers in size have been demonstrated to exhibit interesting optoelectronic as well as mechanical properties. For example, composites consisting of an organic matrix where semiconductor or metallic quantum dots, nanorods, tripods, tetrapods and other more complex structures are embedded have applications to organic light emission, photodetection, and solar energy harvesting (Murray et al., 1993, Coe et al., 2002, Gur et al., 2007). An example of a population of CdS tetrapod nanoparticles grown from solution from

CdSe seeds in Fig. 2.38 illustrates the control that can be obtained in creating self-assembled structures driven by the chemical composition of the individual constituents comprising the whole. Indeed, using self-assembled structures in colloidal solids has become an area of intense investigation from both a practical as well as a fundamental materials science perspective. Their application to organic photodetectors, memories and light emitting devices is found in Part II of this volume.

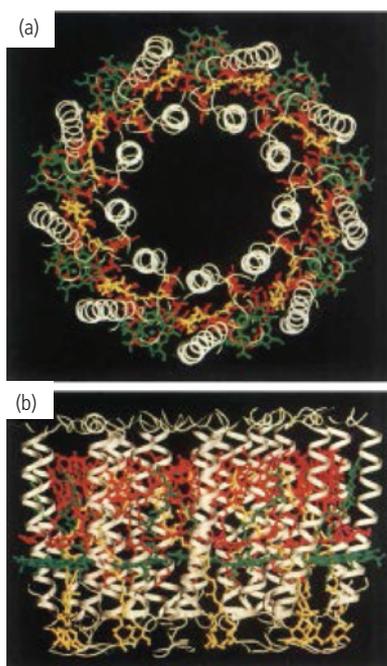

Beyond their optoelectronic properties, self-assembled structures can serve as nano-scaffolds on which larger, ordered mesoscopic structures can be built. For example, highly complex assemblies based on folded proteins are responsible for such varied structures as molecular motors, photosynthetic complexes and artificial materials with a wide range of mechanical properties. An example of a natural self-assembled structure is *the light harvesting complex*, LH2, shown in Fig. 2.39. This is a nine-fold symmetric system of two concentric cylinders supported by protein coils that optimize the photogeneration of charge in the bacteria, *Rhodospseudomonas acidophila*. The total volume of the assembly is  $4287 \text{ nm}^3$ . Indeed, cells found in all organisms, from the most primitive to the most complex are, in themselves examples of complex, mesoscopic self-assembled units with volumes  $10^6$  times larger than LH2. These units feature many diverse components, each providing a specific function to the living organism

**Figure 2.37** Illustration of the formation of a self-assembled monolayer onto a substrate. In this case, an alkyl chain is functionalized on one end to allow for chemical bonding to the substrate atoms, whereas the opposite end is functionalized to accommodate a different molecule that is later deposited, or that prevents the continued deposition of more than a single monolayer (Ullman, 1996).

**Figure 2.38** (a) Tetrapods consisting of a CdSe seed with three, radiating CdS arms. (b) Transmission electron microscope image showing the zincblende structure of the seed (upper right) and the wurtzite structure of two arms (Nelson et al., 2007).

**Figure 2.39** Two views of the photosynthetic light harvesting complex, LH2 showing the incredible complexity and diversity of this mesoscopic biological, self-assembled system. The white coils are the protein scaffolds, with other colors representing smaller molecular units active in the charge generating process. (a) Top view of the nine-segment complex, (b) side view. The dimensions of the unit cell are  $a = b = 120.3 \text{ \AA}$ ,  $c = 296.2 \text{ \AA}$  (McDermott et al., 1995).

as a whole. Considerable research has been done over the years to mimic (largely without success) various aspects of biological systems using self-assembly.

The process of self-organization of a macrostructure based on the function and composition of its microscopic components has been taken beyond the molecular, nano-, and mesoscopic scales discussed above, to realize large-scale mechanical systems. For example small multifaceted objects and even robots

can be programmed to self-replicate and then organize into a larger system (Gross and Dorigo, 2008). While this type of self-assembly is beyond the scope of this book, it is nevertheless illustrative of the power and versatility of multiscale self-assembly, where building blocks at the nanoscale create sub-assemblies at the microscale. These, in turn assemble into larger functional systems at the millimeter and centimeter scales. This is, in fact known as a *biomimetic* approach, whereby cells build to substructures that assemble into organs, and ultimately into a fully functional living organism. Self-assembly similarly provides a route to creating a very diverse range of functions in organic optoelectronics. It owes its usefulness and consequent nearly ubiquitous adaptation in molecular devices to the comparatively weak van der Waals bonds that allows for facile adjustment of structure and properties during the assembly process.

## 2.8 Summing up

In this chapter we have considered the important role that structure plays in determining the properties of organic (and all other) materials. We found that materials can be bonded by a variety of forces whose strengths range over many orders of magnitude. All of these forces are electrostatic, but their strengths depend on whether the electrons are shared between atoms as in the strongest covalent, metallic or ionic bonds, or whether the attractive forces are based on relatively weak dipolar or higher multipole forces, as in van der Waals and hydrogen bonds.

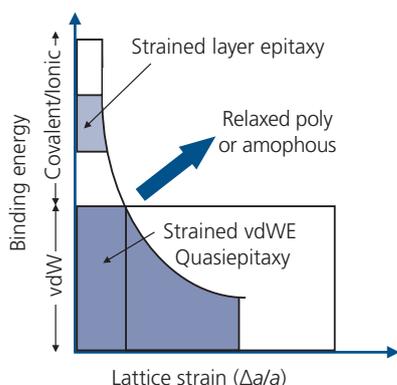

Based on our understanding of the cohesive forces, we showed that molecular materials are bonded primarily by van der Waals attraction. The equilibrium crystal structures are found, to first order, using atom–atom potential calculations, although this static model does not have the capability for predicting the thermodynamic conditions that are needed to achieve a given structure. More comprehensive (and necessarily complex) MD simulations are required to achieve this goal. Ultimately, the materials scientist is challenged to use a combination of intuition backed by deep knowledge and experience to grow high quality molecular layers useful for both scientific as well as technological applications. We will discuss the methods used to achieve such crystals and films in Chapter 5.

A particular attribute of weak van der Waals forces is the ability to achieve long range order in layers grown onto substrates where there is substantial strain between the contacting lattices. Even

incommensurate layers with strains approaching 10% can be grown without incurring a high density of defects. Such a large strain accommodation is unheard of in covalent and ionically bonded inorganic semiconductors. Thus, van der Waals solids avail themselves to applications that are inaccessible to conventional semiconductors, enabling one of the most attractive features of organic electronics: the ability to achieve very high thin film device performance without regard to lattice matching constraints with the substrate.

A qualitative summary of the growth modes of materials with different interlayer binding energies is shown in Fig. 2.40. Covalent and ionically bonded structure can accommodate very small strains (typically  $< 10^{-3}$ ). Use of strained layer epitaxy, whereby alternating layers with strains of opposite signs can increase the strain tolerance, allows for relaxation of the Matthews–Blakeslee thickness limit. However, strain balance requires the use of layers of different compositions which may not be desirable for all applications. In contrast, van der Waals structures have bonding strengths at least an order of magnitude smaller than inorganic semiconductors, allowing them to accommodate a significantly larger strain energy. The growth modes for this class of materials are variously termed van der Waals epitaxy, strained van der Waals epitaxy, and quasiepitaxy. The illustration attempts to distinguish these different modes, although the terminology is often used interchangeably in the literature. Finally, for all solids, excessive strain results in relaxed polycrystalline or amorphous structure. We will find in subsequent chapters that the vast majority of organic devices exploit this class of film structure.

We also found that self-assembly of molecules can be used to drive structural organization of a higher

**Figure 2.40** A qualitative plot of the binding energy (which spans several decades) vs. lattice strain, and the resulting possible growth modes over this range of parameters.

order, macroscopic structure. Indeed, the process of quasiepitaxy has many features common to self-assembled systems. Quasiepitaxial layers are those whose lattices are incommensurate, or have large lattice mismatches with the substrate lattice, yet they can exhibit long-range order and a well-defined orientation with the substrate. This structural organization is attributed to the pronounced asymmetry of bonding forces within the layer, and between the layer and the substrate. Self-assembly is found to play a significant role in the organization of molecular and polymeric solids, and it is the governing principle that drives the formation of mesoscopic biological assemblies such as proteins, and functional biological complexes. It is responsible for such fundamental processes as photosynthesis and even the functioning of cells and entire organisms. Indeed, self-assembly appears to be one of the most fundamental principles governing the form and function of all biological systems. As a result, biomimicry provides a foundation on which many concepts in organic electronics are built.

## Problems

1. Crystal symmetry groups.
  - (a) What is the symmetry group of the diamond lattice?
  - (b) What is its coordination number?

- (c) What is the symmetry group of the zincblende lattice?  
 (d) Calculate the  $d_{444}$  spacing for a zincblende structure with lattice constant,  $a$ .  
 (e) Answer (a) and (c) for graphite.
2. For the crystal structures in Table 2.2,  
 (a) Derive the packing fractions.  
 (b) What are the coordination numbers of the lattices considered?  
 (c) The wurtzite structure is a lattice with hexagonal symmetry and a basis of  $Z = 2$ , as shown in Fig. P2.2. Do parts (a) and (b) for a wurtzite structure.

**Figure P2.2** Wurtzite structure consisting of a basis of two atoms (gray and yellow) (M. Khaksar, et al., 2015).

3. Assume that a charge transfer molecular pair form a hexagonal close-packed structure with dimensions  $a$  and  $c = 2a$ . Assume that one of the pair of molecules is positioned in the center of the unit cell, that is, the basis is  $Z = 2$ , and that  $\delta = 0.6q$  is transferred between the anion to the cation.  
 (a) Calculate the first five terms of the Madelung constant for this structure.  
 (b) Assuming that only ionic forces are important, calculate the total crystal energy using the result in part (a).  
 (c) Calculate the bulk modulus of the crystal assuming uniaxial compression along the  $c$ -axis.
4. (a) Fill in the missing steps leading to the derivations of the expressions for the fixed dipole-fixed dipole (Keesom) and fixed dipole-induced dipole interaction energies in Eqs. 2.45 and 2.54, respectively.  
 (b) The quantum mechanical treatment leading to the dispersion energy in Eq. 2.64 is based on a one dimensional interaction between dipoles. Extend this to three dimensions and compare with the London equation in Eq. 2.65.
5. The “self-energy” of a molecule in a medium is the energy equal to the sum of all of its interactions with its neighbors (see Fig. 2.11).  
 (a) By integrating the attractive energy over all space, show that this self-energy of an isolated molecule approximated as a hard sphere of radius,  $R$ , in a medium of density,  $\rho$ , consisting of induced dipoles with an attractive pair potential  $u(r) = -A/r^6$  at  $r > 2R$  is  $U_{self} = -\pi A \rho / 6R^3$ .

- (b) If a spherical molecule is placed into a close-packed medium, it will have 12 nearest neighbors. Show that by placing the molecule into its own medium, the total energy change is  $U_{self} = 6u(2R)$ .  
 (c) From (a), show that  $U_{self} = -4u(2R)$ .  
 (d) What is the source of the difference between (b) and (c)?
6. Assume that two benzene molecules ( $C_6H_6$ ) form a face-to-face dimer. Using the atom-atom potential method, calculate:  
 (a) the equilibrium distance between the molecules forming the dimer;  
 (b) the equilibrium energy;  
 (c) the elastic constant;  
 (d) the bulk modulus.  
 (e) Estimate the boiling point of benzene from this result.
7. Atomic lattice potentials can be approximated by a periodic potential of the form (in one dimension):

$$U(r) = U_0 \cos(2\pi r/a)$$

where  $U_0$  is the strength of the interatomic potential,  $r$  is the displacement, and  $a$  is the substrate (1D) lattice constant.

- (a) Write the generalized 2D geometric potential.  
 (b) Defining the transformation matrix,  $T$ , which depends on the relative azimuthal relationship between the adsorbed layer and the substrate lattice, show that:

$$T = \begin{pmatrix} b_1 \sin(a - \theta) / a_1 \sin(\alpha) & b_1 \sin(\theta) / a_2 \sin(\alpha) \\ b_2 \sin(a - \theta - \beta) / a_1 \sin(\alpha) & b_2 \sin(\theta + \beta) / a_2 \sin(\alpha) \end{pmatrix}$$

where  $i, j$  are the lattice sites of the adsorbed layers, and  $a_{1,2}, \alpha$  and  $b_{1,2}, \beta$  are the primitive vectors and angles of the substrate and adlayer unit meshes, respectively, and  $\theta$  is the angle between principal lattice directions in the two lattices.

- (c) Show that  $U(\theta)/U_0 = 0$  at all symmetry equivalent angles corresponds to the case of perfect commensurality, whereas complete incommensurality corresponds to  $U/U_0 = 1$  at all angles.
8. (a) Calculate the zero point energies of Ar and anthracene.  
 (b) How does this compare to the van der Waals energy and the thermal energy (at room temperature) of these two species?
9. (a) Solve Eq. 2.30 and 2.31 for the  $H_2^+$  ion and show that the result for the two lowest energy levels is given in Fig. 2.9. *Hint:* This solution requires a transformation to elliptical coordinates.  
 (b) What is the expectation value of the Hamiltonian,  $H$ ? How does this compare with literature values for the energies of  $H_2^+$ ?

# Optical properties of organic semiconductors

---

*"Light brings us news of the Universe."*

Sir William Bragg, *The Universe of Light*, 1933

The optical properties of organic semiconductors have their origins in the generation of a fundamental excitation known as the *exciton*. Excitons are mobile molecular excited states that consist of a tightly bound electron and hole pair. The large binding energies of molecular excitons are stable due to the low dielectric constants characteristic of organics which, in turn, is a consequence of the absence of chemical bonds between molecules. The excitonic nature of organic semiconductors leads to their exceptionally rich, complex and ultimately useful optical properties. They can be extremely strong light absorbers whose absorption coefficients can be comparable to individual atoms, and they also often can reach 100% luminescent quantum yields. The understanding of organic semiconductors, therefore, begins by understanding their optical properties. It is the purpose of this chapter to introduce the reader to the many interesting optical phenomena of organics, beginning with a discussion of the origins of light absorption and emission that arise from the energy level structure of individual molecules. A fascinating aspect of organics is that the optical properties of individual molecules are replicated, often with little modification, by their collective properties in the solid state. That is, collective phenomena do not entirely overwhelm and mask the properties of the molecules themselves. Indeed, molecular materials provide an ideal system whereby we can study the transitions between isolated species and their behavior in ordered and disordered solids. We will find that properties emerging from interactions of just a few molecules, such as excimer and exciplex emission, provide insights into molecular characteristics that can be exploited in practical device applications.

Unlike conventional semiconductors where bonds lead to degeneracy of the electronic states, the spin multiplicity of excited states in organic materials, that is, whether the exciton is a singlet, triplet or a higher order multiplet state, plays a defining role in its characteristics. We, therefore, make an effort to clarify the origins and properties of both singlets and triplets, and the electronic transitions that lead to their absorption and emission spectra. Within this discussion, we will find that other transitions between vibronic (i.e. phonon) states and non-radiative transfer between spin states within an electronic manifold also influence in the optical characteristics of organic materials.

Next, we discuss the quantum mechanical origin of energy transfer between molecules. Transfer can occur by *electron exchange* (also known as *Dexter transfer*) from one molecule to the next, or by longer-range electrostatic interactions between molecules due to *Förster* or *radiative* processes. Exciton transfer is intimately related to exciton–exciton interactions such as annihilation, fusion and fission. Long range transfer that consists of a series of individual steps is called *energy migration* (or *exciton diffusion*). We include in this treatment a discussion of the optical (i.e. excitonic) properties of very thin multilayer, and even "multiple

quantum wells” consisting of alternating films of different composition, each only a few monolayers thick. Excited states in such thin layers provide information about their spatial extent.

Our treatment is necessarily based on several quantum mechanical principles. We introduce each phenomenon starting with the wavefunction of electrons comprising molecular bonds, and extending this to the understanding collective phenomena in the solid state. The interested reader should be able to follow all of the discussion, although some of the more involved derivations are left to the problems at the end of the chapter. For those only seeking to use important results in analyzing their data, relevant expressions are highlighted by shading throughout the chapter, as is the custom throughout this book.

To paraphrase Sir William Bragg, we will see that the optical properties of organics do indeed bring us news of their universe!

### 3.1 The electronic structure of molecules

In the following three sections, we describe increasingly accurate approaches to calculate the electronic structure of complex molecular species. The principal objective of the calculations is to derive the energy levels from which emerge many rich and diverse optical properties. Indeed, the molecular spectra are exploited in all photonic applications ranging from light emission to detection. The molecular energetics are essential to computing molecular conformations (e.g. rotational and vibrational modes), and even transition energies leading to intermolecular reactions. Understanding their fundamental origins ultimately enables rational molecular design based on sound physical principles. For this reason, a great deal of effort has been dedicated over many decades to accurately calculate the energetics of molecular and polymeric systems. The discussion of energy fundamentals in Sections 3.2 and 3.3 will be followed in Section 3.4 by a brief introduction to computational approaches used to approximate electronic energies of individual molecules, extended to include to those of ensembles of interacting molecules in the solid state.

### 3.2 The Born–Oppenheimer approximation and the Franck–Condon principle

In Section 2.4.2, we calculated the electron distribution, and its role in forming covalent bonds in the simplest of all molecular species, the  $\text{H}_2^+$  cation. This molecule is, in fact, the most complex situation that can be solved analytically. As more atoms and valence electrons are added, the solutions become increasingly approximate and unreliable, and require considerable computational resources to solve. We start by describing the physical principles leading to estimations of the energies of multi-electron molecular systems.

The molecular wavefunction has three components: electronic, nuclear, spatial and electron spin. These

components can be decomposed into the product of the individual wavefunctions. The total wavefunction for a molecule with  $N$  electrons is given by

$$\Psi_t(\{\mathbf{r}_i\}, \{\mathbf{R}_I\}; \{S_i\}) = \Phi(\{\mathbf{r}_i\}, \{\mathbf{R}_I\})\sigma(\{S_i\}), \quad (3.1)$$

where  $\mathbf{r}_i$  represents the position of the  $i$ th electron, and the brackets,  $\{\}$ , represent all  $N$  position vectors,  $\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N$ ,  $\{\mathbf{R}_I\}$  are the nuclear coordinates,  $\{S_i\}$  are the electron spins,  $\Phi$  is the spatial wavefunction, and  $\sigma$  is the electronic spin wavefunction. Nuclear spins are ignored since coupling to the electron spin gives rise to the *hyperfine interaction* that does not play a significant role in determining the electronic properties of the molecule.

The *Pauli Exclusion Principle* demands that the entire wavefunction be antisymmetric under the exchange of two electrons. For electrons at  $\mathbf{r}_1$  and  $\mathbf{r}_2$  with total spin quantum number,  $S$ , and its projection along the  $z$ -axis,  $m_S$ , the total electronic wavefunctions are given by  $\psi(\mathbf{r}_1, \mathbf{r}_2; S, m_S)$ . Thus, if the spatial wavefunction is symmetric, then the spin function must be antisymmetric, and vice versa. For the  $S = 0$  state,  $m_S = 0$ . This results in a single, totally antisymmetric function:

$$\psi(\mathbf{r}_1, \mathbf{r}_2; 0, 0) = \frac{1}{\sqrt{2}}(\phi_a(\mathbf{r}_1)\phi_b(\mathbf{r}_2) + \phi_a(\mathbf{r}_2)\phi_b(\mathbf{r}_1)) \times (a_1\beta_2 - a_2\beta_1). \quad (3.2)$$

Here,  $\phi_i(\mathbf{r}_k)$  is the spatial wavefunction of an electron in atomic or molecular orbital  $i$  at position  $\mathbf{r}_k$ , and  $\alpha$  corresponds to a spin with  $m_S = +\frac{1}{2}$  (also denoted as  $\alpha = |\uparrow\rangle$ ) and  $\beta$  corresponds to  $m_S = -\frac{1}{2}$  (i.e.  $\beta = |\downarrow\rangle$ ) for electrons 1 and 2. The factor of  $\frac{1}{2}$  normalizes the wavefunctions.

Similarly, the antisymmetric spatial wavefunction,  $S=1$  results in three possible spin states corresponding to  $m_S = 1, 0$ , and  $-1$ :

$$\psi(\mathbf{r}_1, \mathbf{r}_2; 1, 1) = \frac{1}{\sqrt{2}}(\phi_a(\mathbf{r}_1)\phi_b(\mathbf{r}_2) - \phi_a(\mathbf{r}_2)\phi_b(\mathbf{r}_1))\alpha_1\alpha_2, \quad (3.3a)$$

$$\psi(\mathbf{r}_1, \mathbf{r}_2; 1, 0) = \frac{1}{\sqrt{2}}(\phi_a(\mathbf{r}_1)\phi_b(\mathbf{r}_2) - \phi_a(\mathbf{r}_2)\phi_b(\mathbf{r}_1)) \times (\alpha_1\beta_2 + \alpha_2\beta_1), \quad (3.3b)$$

and

$$\psi(\mathbf{r}_1, \mathbf{r}_2; 1, -1) = \frac{1}{\sqrt{2}}(\phi_a(\mathbf{r}_1)\phi_b(\mathbf{r}_2) - \phi_a(\mathbf{r}_2)\phi_b(\mathbf{r}_1))\beta_1\beta_2. \quad (3.3c)$$

For convenience, we replace the combined spatial and spin functions with a *spinorbital function*,  $\Phi^\sigma(\mathbf{r}; S, m_S) = \phi(\mathbf{r})\sigma(S, m_S)$ . For example, we write  $\Phi^\uparrow(\mathbf{r}_1) = \phi(\mathbf{r}_1)\alpha_1$ . The total wavefunction asymmetry can then be expressed using a determinant for the two particle system:

$$\psi(\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{\sqrt{2}} \det \begin{vmatrix} \Phi^\uparrow(\mathbf{r}_1) & \Phi^\downarrow(\mathbf{r}_1) \\ \Phi^\uparrow(\mathbf{r}_2) & \Phi^\downarrow(\mathbf{r}_2) \end{vmatrix}. \quad (3.4)$$

Extending this to an  $N$ -electron system we can write the asymmetric wavefunction in terms of an  $N$ -dimensional *Slater determinant*:

$$\psi(\{\mathbf{r}_i\}) = \frac{1}{\sqrt{N!}} \det \begin{vmatrix} \Phi^a(\mathbf{r}_1) & \Phi^b(\mathbf{r}_1) & \dots & \dots & \Phi^z(\mathbf{r}_1) \\ \Phi^a(\mathbf{r}_2) & \Phi^b(\mathbf{r}_2) & \dots & \dots & \Phi^z(\mathbf{r}_2) \\ \dots & \dots & \dots & \dots & \dots \\ \Phi^a(\mathbf{r}_N) & \Phi^b(\mathbf{r}_N) & \dots & \dots & \Phi^z(\mathbf{r}_N) \end{vmatrix}. \quad (3.5)$$

The Pauli Exclusion Principle is clearly expressed by this formulation since if any two rows are the same, which corresponds to two electrons in identical states, then the determinant, and hence  $\psi(\{\mathbf{r}_i\})$ , vanishes.

The lone antisymmetric spin state in Fig. 3.1 is called the *singlet state* (corresponding to  $S = 0$ ,  $m_S = 0$ ), and the three symmetric combinations of spin under exchange in Eq. 3.3 comprise the *triplet state*. The two electron spin quantum states are

visualized by their vector representations in Fig. 3.1. Here,  $S$  is the vector sum of the two separate spins whose projections along the  $z$ -axis give their quantum numbers  $m_S$ . The two *coupled* spins for a given state precess in phase. For the singlet state, the individual spins are at  $180^\circ$  relative to each other while they precess about the  $z$ -axis to give  $S = 0$ , which is equal to  $m_S = \frac{1}{2} - \frac{1}{2} = 0$ . Interchange of the spins results in a  $\pi$ -phase change, resulting in its antisymmetric property. In contrast, the three triplet states require no phase change on spin exchange, and hence they are spin symmetric. Nevertheless, the spin precession must be coupled to result in  $S=1$  in all three cases. Note that for  $m_S = 0$ , the total spin vector rotates within the  $x$ - $y$  plane, thereby lacking a projection along  $z$ , as required.

We will return to the spin wavefunction and symmetry, which play vital roles in the optical properties of molecules, in Section 3.5. Since spin and spatial wavefunctions are separable, we will first treat the spatial wavefunction to determine the electronic distribution across the molecule.

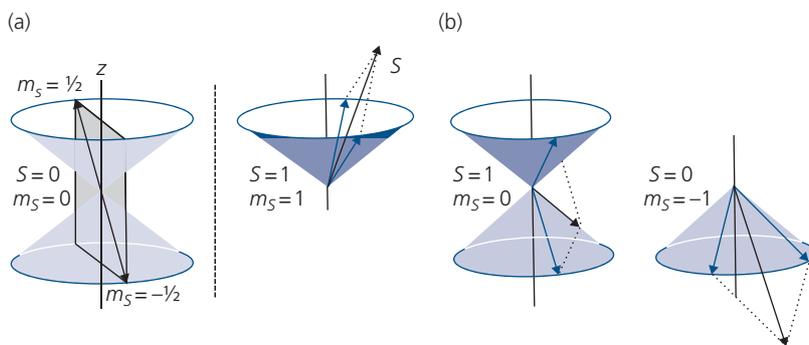

The time independent Schrödinger's equation for the total system of energy,  $E_T$ , consisting of both nuclei and electrons is

$$H_T\Phi(\{\mathbf{r}_i\}, \{\mathbf{R}_I\}) = E_T\Phi(\{\mathbf{r}_i\}, \{\mathbf{R}_I\}), \quad (3.6)$$

where the Hamiltonian is:

$$H_T = -\frac{\hbar^2}{2m_e} \sum_i \nabla_{\mathbf{r}_i}^2 - \frac{\hbar^2}{2} \sum_I \frac{1}{m_{N_I}} \nabla_{\mathbf{R}_I}^2 + \frac{q^2}{4\pi\epsilon_0} \times \left( \sum_{i>j}^N \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} - \sum_{i,I}^{N,M} \frac{Z_I}{|\mathbf{r}_i - \mathbf{R}_I|} + \sum_{I>J}^M \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} \right) \quad (3.7)$$

(cf. Eqs. 2.25 and 2.28). Here,  $i$  and  $I$  are the indices of the  $i$ th electron and  $I$ th nucleus of atomic number  $Z_I$ ,

**Figure 3.1** Vector representation of states for two coupled spin  $\frac{1}{2}$  electrons. (a) Total spin quantum number  $S = 0$  singlet state, and (b) three  $S = 1$  triplet states.

and  $m_e$  ( $m_N$ ) is the electronic (nuclear) mass. The sums are over all electrons and nuclei in the molecule. Now, since  $m_N \gg m_e$ , we can neglect the kinetic energy of the nuclei. Solving this problem for  $N$  electrons and  $M$  nuclei has no analytical solutions for  $N > 1$ ,  $M > 2$ . To simplify the calculation, we apply the *Born–Oppenheimer approximation* where we assume that the electronic motion can be separated from that of the nuclei. Then, since the last term in Eq. 3.7 is independent of electron position, it can be eliminated to simplify an already complex problem. The nuclei thus contribute a constant additive energy term. Due to their orthogonality, we can then separate the nuclear,  $\phi_N(\{\mathbf{R}_I\})$ , and electronic,  $\phi_e(\{\mathbf{r}_i; \{\mathbf{R}_I\})$ , wavefunctions accordingly:

$$\Phi(\{\mathbf{r}_i; \{\mathbf{R}_I\}) = \phi_e(\{\mathbf{r}_i; \{\mathbf{R}_I\})\phi_N(\{\mathbf{R}_I\}). \quad (3.8)$$

The electronic contribution to the energy is thus

$$\begin{aligned} H_e \phi_e(\{\mathbf{r}_i; \{\mathbf{R}_I\}) &= \left[ -\frac{\hbar^2}{2m_e} \sum_i^N \nabla_{\mathbf{r}_i}^2 + \frac{q^2}{4\pi\epsilon_0} \right. \\ &\times \left. \left( \sum_{i>j}^N \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} - \sum_{i,I}^{N,M} \frac{Z_I}{|\mathbf{r}_i - \mathbf{R}_I|} \right) \right] \phi_e(\{\mathbf{r}_i; \{\mathbf{R}_I\}) \\ &= E_e \phi_e(\{\mathbf{r}_i; \{\mathbf{R}_I\}) \end{aligned} \quad (3.9)$$

where  $E_e$  is the total electronic energy.

The problem is further simplified if we write the electronic wavefunction,  $\phi_e(\mathbf{r}_i)$ , as the product of one-electron wavefunctions for the  $M$  atoms in the molecule, that is,

$$\phi_e^0(\{\mathbf{r}_i\}) = \prod_{i=1}^N \phi_{e,i}^0(\mathbf{r}_i). \quad (3.10)$$

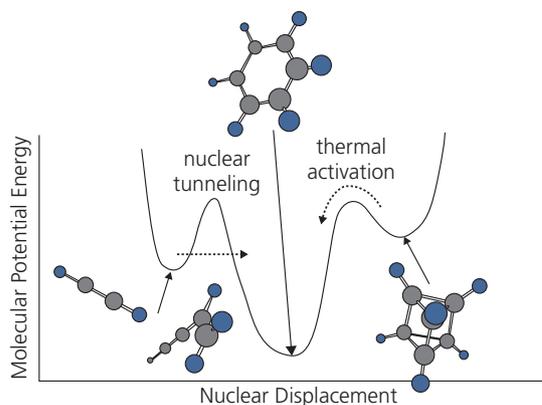

Here, the “0” superscript indicates that this is a first order approximation where the  $N$  electrons comprising the atomic systems of the  $M$  molecules are non-interacting. Once these electrons are shared within the molecule, the approximation of Eq. 3.10 must be adjusted to account for their interactions. The problem has now been simplified from the intractable situation of a single system consisting of  $N$  interacting electrons, to that of  $N$  single-electron systems perturbed by their interactions.

Even with this simplification, the solution to Eq. 3.9 cannot be found in a closed form, analytical approach. It must be solved for the entire electron system of all the atoms in the molecule, and minimized for each possible nuclear configuration. For this purpose, it is convenient to introduce the normal coordinates,  $Q_k$ , which represent a particular ( $k$ th) configuration of all the nuclei. This configuration has a corresponding electron energy,  $E_e(Q_k)$ , and wavefunction,  $\phi_e(\{\mathbf{r}_i; Q_k)$ . The

equilibrium electron energy is thus obtained by minimizing  $E_e$  for each  $Q_k$  and set of electronic coordinates,  $\{\mathbf{r}_i\}$ . That is, each set of nuclear coordinate configurations has an associated minimum electronic energy. However, this may only be a “local” minimum; the true or “global” minimum energy of both nuclear and electronic coordinates that defines the most stable molecular configuration can in fact be difficult to find for a complex molecule that can assume many equivalent configurations. This situation is shown graphically in Fig. 3.2 for a molecule with six carbon and six hydrogen atoms that is well known to have a global minimum configuration in the form of the cyclic benzene molecule.

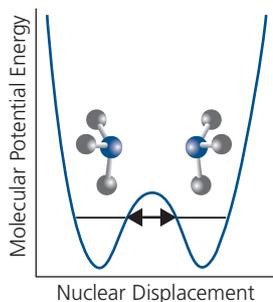

The various configurations that a compound can assume as it approaches its global minimum are called *geometric isomers*. When the same molecule can have different topologies (i.e. DNA where both helices and knots are possible), the differently shaped structures are referred to as *topological isomers*. It is also possible that two isomeric forms have identical energies: the classical example being the ammonia molecule that consists of a pyramidal structure formed by three equally spaced H atoms forming the base, and with the N atom at the apex. The symmetry of this configuration demands that the energy be equal whether the N atom is above or below the plane of H atoms, as shown in Fig. 3.3. The energy surface thus consists of two minima, where the N atom tunnels between the two. The isomers,  $\text{NH}_3$  and  $\text{H}_3\text{N}$ , are mirror symmetric, and are known as *inversion isomers*.

The general approach to finding a solution is to determine the energy surface corresponding to a

**Figure 3.2** Different configurations and their electronic energies for a combination of 6C + 6H atoms showing three example energy minima. The deepest, global minimum corresponds to the equilibrium configuration of the benzene molecule (Peumans, 2004).

Reprinted with permission.

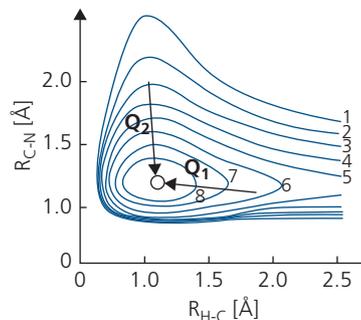

**Figure 3.3** Molecular potential energy vs. N atom displacement for the two inversion isomers of ammonia (N is shown in blue, H in brown). The ground state energy level of the atom is shown by the horizontal line, indicating identical energies for both isomers. The dashed arrow indicates isoenergetic tunneling between the coupled states that approximately form two harmonic oscillator potentials.

particular  $Q_k$ , and then incrementally changing the nuclear coordinates to seek yet a lower value of  $E_e$ . This application of the Born–Oppenheimer approximation continues until the lowest value of  $E_e$  is found (corresponding to  $E_e^0$ ). Without a guarantee that the absolute global minimum has been found, it is often necessary that a new starting configuration for the molecule be chosen and the procedure repeated once again.

The energy landscape of a simple linear molecule, HCN, serves to illustrate this approach in Fig. 3.4. Two different nuclear configurational “trajectories,”  $Q_1$  and  $Q_2$ , arrive at the same equilibrium energy. The shape of these curves follows that for a covalently bonded solid similar to that in Fig. 2.9. For example, the electronic potential surface along  $Q_1$  assumes a low attractive slope as the H–C separation distance is increased from equilibrium at  $R_{\text{H-C}} = 1.1 \text{ \AA}$ , but becomes steep and repulsive as the distance is reduced from that same point (indicated by “bunching” of the contours for small  $R_{\text{H-C}}$  and  $R_{\text{C-N}}$ ).

The lowest energy attained by calculating the energy surface for each nuclear configuration corresponds to the ground state of the molecule. This problem is computationally challenging due to the nearly unlimited possible configurations that even the simplest molecule can assume. For a molecule consisting of  $M$  nuclei, there are  $3M - 6$  degrees of freedom, where three translational and three rotational dimensions are eliminated. The energy is invariant under translation, and, in general, rotational mode energies are small compared to those associated with nuclear displacements and are ignored. Even the simple benzene molecule with 12 nuclei presents a daunting calculational challenge with its 30 independent nuclear configurations. To simplify the problem, efficient calculations of molecular orbital

**Figure 3.4** Ground state energy landscape for the HCN molecule whereby the bond lengths of H–C and C–N are varied. The contours correspond to energies of **1** =  $8 \times 10^4 \text{ cm}^{-1}$ , **2** =  $7 \times 10^4 \text{ cm}^{-1}$ , **3** =  $6 \times 10^4 \text{ cm}^{-1}$  ... **8** =  $1 \times 10^4 \text{ cm}^{-1}$ . Two possible nuclear configurations,  $Q_1$  and  $Q_2$  are also shown to indicate how the minimum is found (Peumans, 2004).

Reprinted with permission.

energies start by only considering known stable isomers of a molecule, thereby confining the calculations to a realistic set of configurations.

We now write the nuclear coordinates in terms of the relative coordinate,  $Q$ , that is,  $\phi_e(r, Q) = \phi(\{\mathbf{r}_i\}, \{Q_i\})$ . Then, Eq. 3.7 becomes

$$H_T = T_e(r) + T_N(Q) + V_e(r) + V_{eN}(r, Q) + V_N(Q), \quad (3.11)$$

where  $T$  and  $V$  are the kinetic and potential energy operators, respectively. It is further convenient to write integrals in terms of bracket vectors to arrive at the full solution to Eq. 3.6 as follows:

$$E_T = \langle \phi_e \phi_N | T_e(r) + T_N(Q) + V_e(r) + V_{eN}(r, Q) + V_N(Q) | \phi_N \phi_e \rangle \quad (3.12a)$$

or

$$E_T = \langle \phi_N | T_N(Q) + V_N(Q) + E_e(Q) | \phi_N \rangle, \quad (3.12b)$$

where

$$\langle \phi_N | E_e(Q) | \phi_N \rangle = \langle \phi_e \phi_N | T_e(r) + V_e(r) + V_{eN}(r, Q) | \phi_N \phi_e \rangle \quad (3.13)$$

is the electronic energy corresponding to the nuclear configuration,  $Q$ .

Since we have already selected the configuration near equilibrium, the total system energy can be expressed as a small deviation from its minimum at  $E_e(0) + V_N(0)$ , giving:

$$E_T = E_e(0) + V_N(0) + \Delta E_e(Q) + \Delta V_N(Q). \quad (3.14)$$

As discussed above, different molecular isomers result in different energy surfaces, each defined by a

separate equation with the form of Eq. 3.14. If the energy surfaces of two isomers intersect, they are degenerate at the value of  $Q$  where the intersection appears. In most cases, the degeneracy occurs at large deviations from equilibrium, in which case there is a significant activation energy barrier separating the isomers, as represented by the tunneling barriers in Figs. 3.2 and 3.3. Transformations between such energetically isolated isomers are difficult, making them independent and chemically distinct. Hence, one does not influence the energetic environment of the other.

As in Figs. 2.9 and 3.3, the Coulomb attraction between neighboring nuclei forms an approximately parabolic surface near their equilibrium separation. Thus, the nuclear vibration about equilibrium results in a new set of quantum states defined by  $E_N = \Delta E_e(Q) + \Delta V_N(Q)$  in Eq. 3.14. These vibrational modes, or *vibronics*, form discrete levels. Since the potential well near its minimum is approximately parabolic, the total vibronic energy in level  $j$  follows the well-known solutions for a simple harmonic oscillator (SHO):

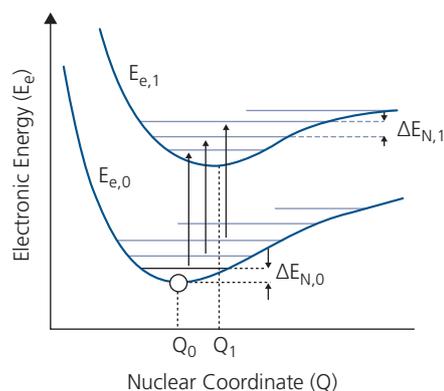

$$E_{N,j} = \hbar \sum_{l=1}^{3M-6} \omega_l(E_{e,j}) \left[ n_l(E_{e,j}) + \frac{1}{2} \right]. \quad (3.15)$$

Here,  $n_l = 0, 1, 2, \dots$  is the quantum number of the  $n$ th vibronic state of the  $l$ th normal nuclear mode in a molecule consisting of  $M$  atoms. Each electronic state, itself, is defined by  $E_{e,j}$  (where  $j = 0, 1, 2, \dots$ ) and has its own associated set of vibronic sub-levels. Since the nuclear masses are much larger than the electron mass, we infer that  $E_N \ll E_e$ ; that is, the vibronic states are much closer spaced than the electronic states, as illustrated in Fig. 3.5.

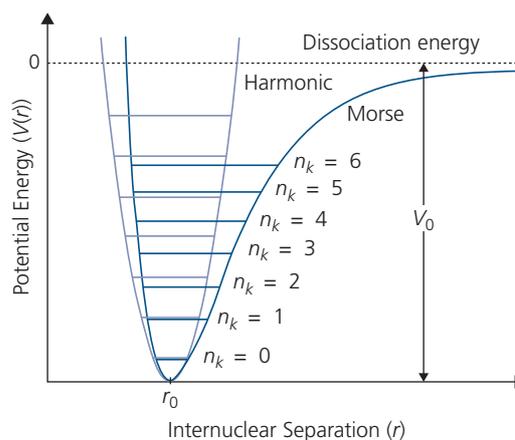

The actual interatomic potential including nuclear repulsion is not well approximated by the infinite parabolic potential of a SHO with its equal spacing of an unlimited number of vibronic modes in Eq. 3.15. The anharmonicity of the potential is more accurately represented by the *Morse potential* that was first applied to approximate the potential of a diatomic molecule. This is given by

$$V(r) = V_0(1 - \exp[-\alpha(r - r_0)])^2, \quad (3.16)$$

where  $r_0$  is the equilibrium interatomic spacing, and  $V_0 = V(\infty) - V(r_0)$  is the well depth. Since the reference energy is arbitrary, it is convenient to set  $V(\infty) = 0$ , in which case  $V_0 < 0$ . Finally,  $\alpha = \sqrt{k_0/2V_0}$ , where  $k_0$  is the force constant in the limit of  $r \rightarrow r_0$  (see Eq. 2.21). A comparison of the Morse potential to a SHO in an infinite potential well is shown in Fig. 3.6.

**Figure 3.5** Energy minima for the two lowest electronic states ( $E_{e,0}$  and  $E_{e,1}$ ) of a polyatomic molecule, showing the vibronic modes within each level with spacing  $\Delta E_N \ll E_{e,1} - E_{e,0}$  due to the much larger nuclear vs. electronic mass. The minimum energy configurations corresponding to the nuclear coordinates  $Q_0$  and  $Q_1$  are shown. The three vertical arrows represent transitions between similar vibronic states within the two corresponding electronic states.

**Figure 3.6** Comparison of the harmonic and Morse potentials. The vibronic quantum numbers for the  $k$ th normal modes,  $n_k$  are shown. Note the compression of levels in the Morse potential as  $V \rightarrow 0$ .

Solving Schrodinger's equation for  $V(r)$  in the Morse approximation gives the energy eigenvalues for the  $j$ th electronic state:

$$E_{N,j} = \hbar \sum_{l=1}^{3M-6} \omega_l(E_{e,j}) \left[ \left\{ n_l(E_{e,j}) + \frac{1}{2} \right\} - \left\{ \frac{1}{4V_0} \hbar \omega_l(E_{e,j}) \left( n_l(E_{e,j}) + \frac{1}{2} \right)^2 \right\} \right], \quad (3.17)$$

where the  $l$ th normal mode frequency is

$$\omega_l = \frac{\alpha}{2\pi} \sqrt{\frac{2V_0}{m_e}}. \quad (3.18)$$

Note that the energy eigenvalues are the same as those predicted in Eq. 3.15 for the SHO, modified by a second order term in  $\hbar\omega_l$  that becomes increasingly important with increasing  $n_l$ . This difference arises since the Morse potential widens as  $V \rightarrow 0$ , resulting in compression of the spacing between the modes, which contrasts with the equally spaced vibronics of the SHO. The energy between two adjacent vibronics in the Morse potential approximation is

$$\Delta E_l = E(n_{l+1}) - E(n_l) = \hbar\omega_l \left( 1 - \frac{\hbar\omega_l(n_l + 1)}{2V_0} \right). \quad (3.19)$$

This expression is valid until we reach the highest bound state at  $n_{l,max}$  near  $V = 0$ , corresponding to

$$n_{l,max} = \frac{2V_0 - \hbar\omega_l}{\hbar\omega_l}. \quad (3.20)$$

While the Morse potential more accurately represents the anharmonicity of the interatomic potential, it remains insufficient to accurately predict the spectral characteristics of most multi-atom systems. To accommodate this inaccuracy, Eq. 3.16 has been further adjusted using the Morse long-range potential that improves agreement with measured spectra (LeRoy et al., 2009).

The approximations in Eqs. 3.15 and 3.17 are only valid if the electronic states have an energy minimum. We will find in Section 3.5 that this is not always the case. For example, an *excimer* is a state shared between two neighboring molecules that is bound only when excited. Since there is no bound ground state, the vibronic progression is absent.

The equilibrium coordinate  $Q_1$  in Fig. 3.5 is depicted at a different location than  $Q_0$ . This indicates that when the electronic state changes, the nuclear configuration of the molecule must also adjust. Often, excited states have a larger separation between nuclei than in the ground state since the size of electronic orbitals generally increases with quantum number (i.e. d-orbitals tend to be larger than p-orbitals, which in turn are larger than s-orbitals). Because of the larger mass of the nuclei compared to that of the electron, the reconfiguration of the nuclear positions takes place on a time scale much longer than that of the electrons, which is known as the *Franck-Condon principle*. Like the Born-Oppenheimer approximation, application of this principle greatly simplifies calculations and the interpretation of absorption and emission spectra since it implies that the molecular structure relaxes into its new equilibrium state *after* the electronic transition has occurred.

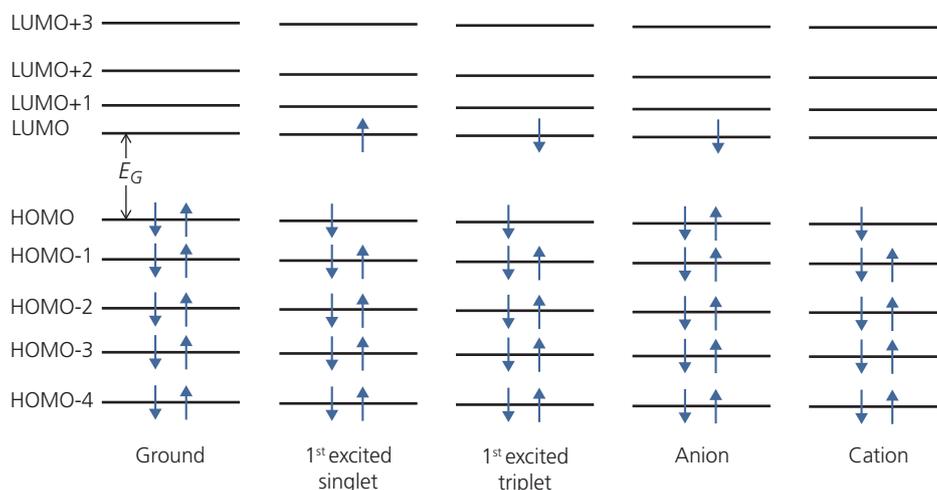

### 3.3 Linear combination of atomic orbitals, hybridization, and the aufbau principle

In the previous section we described a model to understand the absorption and emission spectra of molecules consisting of  $M$  nuclei and  $N$  electrons based on the quantum mechanical nature of the individual electronic states. While that treatment was based on first principles, it is not obvious how to extend it to an understanding of more complex molecules, where the electronic system is distributed over many atoms. In particular, as we build up the electrons from the deepest atomic orbitals to those at the highest (least tightly bound) valence states, the electrons find themselves sharing valences among several nearby and symmetrically equivalent atoms. These shared valence states are called *hybrid orbitals*. The most energetic bound state and the lowest energy excited state that were treated in Section 3.2 are known as the *frontier molecular orbital energies* between which the dominant optical transitions occur. Calculation of these energies forms the basis of molecular orbital theory.

The frontier energies are established using the *aufbau principle* (or “building up” principle). This is based on the Pauli Exclusion Principle whereby no two electrons can simultaneously occupy the same state. Since there are two possible spin states ( $|a\rangle$  and  $|\beta\rangle$ ) for fermions, each molecular orbital can be occupied by two electrons, resulting in the five possible configurations illustrated in Fig. 3.7. In the ground state, the electrons fill each orbital until the highest occupied molecular orbital (HOMO) energy is reached. The LUMO is the lowest unoccupied molecular orbital energy level. State filling up to the LUMO is characteristic of closed shell systems that consist of an even number,  $N$ , of electrons that fill the  $N/2$  lowest energy orbitals. In open shell systems, a single unpaired electron exists in the HOMO (and perhaps one or more HOMO  $- i$  levels, with  $i = 1, 2, 3 \dots$ ). A singlet spin state consists of one electron promoted from the HOMO to the LUMO. Following excited state nuclear positional relaxation, the state can emit light as the electron transitions back into the HOMO, or ground state. Electrons promoted from deeper occupied molecular orbitals (HOMO  $- i$ ) to higher unoccupied electronic manifolds (LUMO  $+ i$ ) can also be observed under the appropriate excitation conditions.

The difference in energy between the HOMO and LUMO is called the *energy gap*, that is,

$$E_G = E_{LUMO} - E_{HOMO}. \quad (3.21)$$

**Figure 3.7** Several possible electronic state configurations of the frontier orbitals of a molecule.  $E_G$  is the energy gap.

If the excited electron in the LUMO has the same spin as the electron remaining in the HOMO, the state is a spin-symmetric triplet state,  $|\beta_1\beta_2\rangle$ . A molecule with one additional electron is a negatively charged anion, whereas a positively charged cationic molecule is missing an electron. In the solid state, *anions* and *cations* are also known as negatively and positively charged *polareons*, respectively. When these species move from molecule to molecule, they result in the conductivity of organic materials, as discussed in Chapter 4. If a charge is transferred from one molecule to its neighbor, the resulting state is a cation-anion pair, also known as a *charge transfer state* or *polaron pair*.

In Section 3.2 the Schrödinger equation comprised of both the electronic and nuclear potentials was introduced. We now extend this formalism to calculate the full molecular orbital structure. A common starting point is using the *linear combination of atomic orbitals* (LCAO) method. Here, the molecule is assumed to be comprised of atoms whose orbitals are only slightly perturbed from their individual atomic states. This allows us to choose a basis set of electronic orbitals that have already been calculated for the individual atomic constituents, and then to correct them based on small perturbations that occur when they are combined in the molecule itself.

The  $i$ th orbital of a molecule consisting of  $L$  atoms obtained from a sum over all  $M$  atomic orbitals is expressed via:

$$\psi_i(\mathbf{r}_i) = \sum_{j=1}^M \sum_{k=1}^L c_{ijk} \phi_{jk}(\mathbf{r}_i - \mathbf{R}_j). \quad (3.22)$$

Here, the individual orbital wavefunctions,  $\phi_{ij}$ , are defined for an electron at position  $\mathbf{r}_i$  relative to an atom

whose nucleus is at position  $\mathbf{R}_j$ . The coefficients  $c_{ijk}$  weight the functions according to their contributions to  $\psi_i$ . This is precisely the method used in Chapter 2 to calculate the solutions to the  $\text{H}_2^+$  molecular ion. Unfortunately, even a calculation of the atomic orbitals using the Slater determinant in Eq. 3.5 can be daunting.

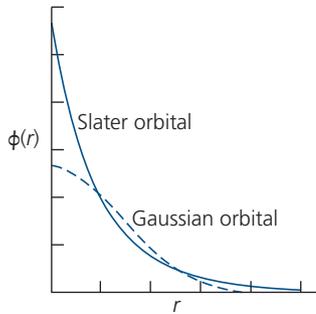

To make the calculations tractable, it is convenient to choose approximate basis set functions that lead to relatively rapid solutions that arrive at the wavefunctions,  $\psi_i(\mathbf{r}_i)$ . One example basis set is comprised of Gaussian orbitals, which in Cartesian coordinates take the form (Leach, 1996):

$$\phi(r) = Ax^a y^b z^c \exp(-ar^2), \quad (3.23)$$

where  $a$  is the rate of decay of the wavefunction with distance that is proportional to the atomic number,  $Z$ , and the exponents  $a$ ,  $b$ , and  $c$  express the orbital symmetry (i.e. s- or p-orbital) such that  $a + b + c$  equals 0, 1, or 2. Also,  $A$  is a normalizing constant. Alternatively, the Slater basis set has a form similar to that of the atomic hydrogen state with quantum numbers  $n$ ,  $l$ ,  $m$ :

$$\begin{aligned} \phi(r, \theta, \varphi) &= R_{nl}(r) Y_{lm}(\theta, \varphi) \\ &= A(2a)^{n+\frac{1}{2}} r^{n-1} \exp(-ar) Y_{lm}(\theta, \varphi). \end{aligned} \quad (3.24)$$

Here,  $R_{nl}(r)$  is the radial wavefunction component, and  $Y_{lm}(\theta, \varphi)$  are the spherical harmonics describing the angular distribution of the wavefunction. Hence, the 1s state is simply  $\phi(r) = 2Aa^{3/2} \exp(-ar)$ . A plot of the 1s Gaussian and Slater functions is shown in Fig. 3.8. A single Gaussian function does not accurately reproduce the tail at large  $r$ , nor does it provide an adequate probability amplitude near the origin.

**Figure 3.8** Calculated 1s states based on Gaussian or Slater wavefunctions.

These problems can be partially fixed by summing over several higher order Gaussian functions. There are many other basis sets and useful variants that are even more accurate than those in Eqs. 3.23 and 3.24 (see *Further reading* and Leach, 1996, for example).

We now simplify Eq. 3.22 by invoking the Born–Oppenheimer approximation, whereby the nuclear coordinates (and interactions between nuclei) can be ignored. Then:

$$\psi_i(\mathbf{r}_i) = \sum_{r=1}^M c_{ir} \phi'_r(\mathbf{r}_i), \quad (3.25)$$

where  $c_{ir}$  are the coefficients with respect to the electronic coordinates  $\mathbf{r}_i$  and  $\phi'_r(\mathbf{r}_i)$  comprise the new electronic orbital basis set. From time-dependent perturbation theory, the solution to Schrödinger's equation using Eq. 3.25 becomes (Atkins and de Paula, 2006):

$$\sum_{r=1}^M c_r (\langle \phi'_s | H_{int} | \phi'_r \rangle - E_i \langle \phi'_s | \phi'_r \rangle) = 0, \quad (3.26)$$

where  $H_{int}$  is the Coulombic interaction Hamiltonian in Eq. 3.9, and  $S_{rs} = \langle \phi'_s | \phi'_r \rangle$  is the *overlap integral* between orbitals  $r$  and  $s$ . Its magnitude depends on the relative proximity of the atomic orbitals: as the separation between two atoms increases,  $S_{rs}$  rapidly decreases. Hence, only nearest neighbor interactions are generally considered. The first term in Eq. 3.26 can be rewritten as  $H_{rs}$ . The diagonal matrix elements are  $H_{rr} = H_{ss}$ , known as the Coulomb integral that provides the kinetic and Coulomb potential energies due to attraction between all nuclei and electrons within a particular orbital. The off-diagonal term  $H_{rs} = H_{sr}$  ( $r \neq s$ ) is the resonance or bond integral that gives the electron energy in regions between atoms where the electron distributions overlap. As in the case of  $S_{rs}$ ,  $H_{rs}$  decreases as atoms become

increasingly separated, and hence only nearest neighbor interactions need be considered.

The solution to the eigenvalue Eq. 3.46 for the  $i$ th electronic state is found by requiring the determinant to vanish, viz.

$$\det[\mathbf{H} - E_i \mathbf{S}] = 0, \quad (3.27)$$

where  $\mathbf{H}$  and  $\mathbf{S}$  represent the matrices consisting of elements  $H_{rs}$  and  $S_{rs}$ , respectively. The solutions to Eq. 3.27 are computationally intensive for even the simplest molecules (Atkins and Friedman, 1997). Indeed, finding a suitable basis set  $|\phi'_r\rangle$  is in itself a complicated undertaking and is usually approached via the *Hartree–Fock approximation* (Callaway, 1974, Konishi and Paffuti, 2009) that builds up the atom starting with hydrogen. The interested reader is referred to the extensive literature on this subject for further detail.

It is instructive to return to the simple problem of the  $\text{H}_2^+$  molecule that we encountered in Section 2.4.2, now solving the problem using the LCAO method. This will allow for us to build the theory for more complex and larger molecules. Assuming the separate H atoms are in their 1s states, we can explicitly obtain the matrix elements as follows (cf. Eq. 3.7):

$$H_{rr} = \langle \phi'_r | H | \phi'_r \rangle = E_{1s} - \frac{q^2}{4\pi\epsilon_0} \langle \phi'_r | \frac{1}{|\mathbf{r}_r - \mathbf{R}_s|} | \phi'_r \rangle + \frac{q^2}{4\pi\epsilon_0 |\mathbf{R}_r - \mathbf{R}_s|}. \quad (3.28)$$

Here,  $E_{1s}$  corresponds to the interaction of an electron with its own proton, which is simply the sum of the Coulombic attraction and kinetic energy of a 1s H atom. The second two terms are interactions of the electron with the other proton, and the repulsion of the two H nuclei. The second term in Eq. 3.28 is solved using the 1s H ground state wavefunction, which requires the use of elliptical coordinates (see Problem 3.2). We can rewrite Eq. 3.28 as:

$$H_{rr} = H_{ss} = E_{1s} - J + \frac{q^2}{4\pi\epsilon_0 |\mathbf{R}_r - \mathbf{R}_s|}. \quad (3.29)$$

where  $J$  is the *Coulomb integral*. The off-diagonal terms are:

$$H_{rs} = H_{sr} = \langle \phi'_r | H | \phi'_s \rangle = \left[ E_{1s} + \frac{q^2}{4\pi\epsilon_0 |\mathbf{R}_r - \mathbf{R}_s|} \right] S_{rs} - \frac{q^2}{4\pi\epsilon_0} \langle \phi'_r | \frac{1}{|\mathbf{r}_r - \mathbf{R}_s|} | \phi'_s \rangle \quad (3.30)$$

or

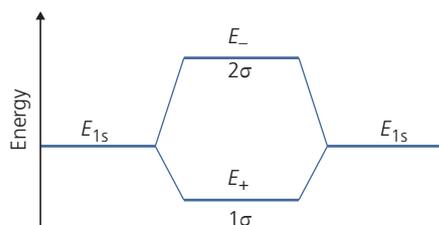

$$H_{rs} = H_{sr} = \left[ E_{1s} + \frac{q^2}{4\pi\epsilon_0 |\mathbf{R}_r - \mathbf{R}_s|} \right] S_{rs} - K, \quad (3.31)$$

where  $K$  originates from interactions of the overlap of the electronic wavefunctions in the states  $r$  and  $s$ . With these matrix elements in hand, we can solve the secular equation using the determinant, Eq. 3.27 to obtain the new eigenenergies for the  $\text{H}_2^+$  molecular ion:

$$E = \left[ E_{1s} + \frac{q^2}{4\pi\epsilon_0|\mathbf{R}_r - \mathbf{R}_s|} \right] \pm \frac{J \mp K}{1 \mp S_{rs}}. \quad (3.32)$$

Thus, the original  $1s$  states are now split into two new orbitals: the lower orbital is the  $1\sigma$  (corresponding to the linear combination  $\psi = \frac{1}{\sqrt{2}}(\phi'_r + \phi'_s)$ , where  $c_r = c_s = 1$  in Eq. 3.25) *bonding orbital* with energy  $E_+$ , and the upper  $2\sigma$  orbital (with  $\psi = \frac{1}{\sqrt{2}}(\phi'_r - \phi'_s)$  and  $c_r = 1 = -c_s$ ) is the *antibonding orbital* with energy  $E_-$ , as shown in Fig. 3.9. In Fig. 3.9, we show that the degeneracy between  $1\sigma$  and  $2\sigma$  at  $|\mathbf{R}_r - \mathbf{R}_s| \rightarrow \infty$  is lifted once this distance becomes comparable to the Bohr radius,  $a_0$ . At  $\sim 2a_0$ ,  $E_+$  reaches a minimum equal to the energy of the equilibrium bound state, and then both  $E_+$  and  $E_-$  become large and positive as the atomic spacing is further reduced due to electron repulsion. Also, from Fig. 3.9 we see that the antibonding  $2\sigma$  orbital has a higher energy than the  $1\sigma$  state due to repulsion of the electron densities away from the region between the nuclei, whereas the electron density for the  $1\sigma$  state is higher between the protons, resulting in a lower energy at all nuclear separation distances (c.f. Fig. 2.9). Hence, the names antibonding and bonding for these two different situations.

Moving to more complex organic molecules necessarily requires further approximations to allow for a reasonably tractable, yet predictive solution. The most important case in organic electronics is that of a conjugated electron system, which is a characteristic of both semiconducting polymer and small molecular weight compounds. Conjugated molecules allow for significant simplification by taking full advantage of molecular symmetry. We consider two atoms in a molecule to be computationally equivalent if under a symmetry operation they can be transformed into

**Figure 3.9** Bonding ( $1\sigma$ ) and antibonding ( $2\sigma$ ) orbital energies of the  $\text{H}_2^+$  molecular ion compared to H atom ground state energies,  $E_{1s}$ .

each other. For example, two atoms in their  $s$ -states are equivalent since their wavefunctions are spherically symmetric. Hence, any spatial transformation leaves such molecules unchanged. In contrast, higher order orbitals (e.g.  $p$  or  $d$ ) have a more restricted set of symmetry operations that are invariant under exchange. Linear combinations of atomic orbitals of adjacent but symmetrically equivalent atoms therefore results in an orbital whose symmetry is shared with that of the constituent atoms; these linear combinations are known as *hybrid atomic orbitals* (HAOs) that determine the physical, chemical and electronic properties of the molecules that they comprise.

An example of hybridization is the heteronuclear ethyne molecule, with the structure  $\text{HC} \equiv \text{CH}$ . In this case, each spherically symmetric C  $2s$  and  $2p_z$  orbital forms two hybrid  $sp$ -hybridized orbitals. The  $2p_z$ -orbital is not spherically symmetric since it changes sign when reflected at the  $x$ - $y$  plane, as shown in Fig. 3.10. The  $2p_z$ -orbital can have two equivalent phase configurations, whereas the  $s$ -orbital has only one (see the two left hand illustrations). When added, there is larger electron content where the phases are additive compared to when they are of opposite sign. When linearly superposed, the resulting  $sp_z$   $\pi$ -orbital (right hand illustration) is symmetrically disposed about the  $x$ - $y$  plane and oriented along the  $\hat{z}$  axis.

The hybrid orbitals from Eq. 3.25 are therefore comprised of linear combinations of the  $s$  and  $p_z$  states:

$$|\psi_1^H\rangle = c_{1s}|\phi_s\rangle + c_{1p}|\phi_{pz}\rangle \quad (3.33a)$$

and

$$|\psi_2^H\rangle = c_{2s}|\phi_s\rangle + c_{2p}|\phi_{pz}\rangle, \quad (3.33b)$$

where  $|\psi^H\rangle$  are the hybridized wavefunctions. These hybrids lie along the axis between the nuclei, and have the same symmetry as the  $p_z$ -orbitals of which they are comprised. Orthonormality of the individual AOs in Eq. 3.33 leads to the following conditions:

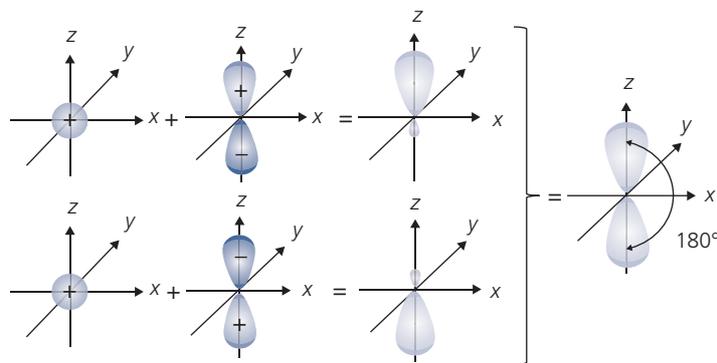

$$\langle\psi_1^H|\psi_2^H\rangle = c_{1s}c_{2s} + c_{1p}c_{2p} = 0 \quad (3.34a)$$

and

$$\langle\psi_{1,2}^H|\psi_{1,2}^H\rangle = c_{1s}^2 + c_{1p}^2 = c_{2s}^2 + c_{2p}^2 = 1. \quad (3.34b)$$

Furthermore, from symmetry:  $|\phi_s(z)\rangle = |\phi_s(-z)\rangle$  and  $|\phi_{pz}(z)\rangle = -|\phi_{pz}(-z)\rangle$ , from which we obtain  $c_{1s} = c_{2s}$  and  $c_{1p} = -c_{2p}$ . It then follows that the  $sp_z$ -orbitals are given by

$$|\psi_1^H\rangle = \frac{1}{\sqrt{2}}\left(|\phi_s\rangle + |\phi_{pz}\rangle\right) \quad (3.35a)$$

**Figure 3.10** Illustration of the hybridization of the  $s$  and  $p_z$  orbitals to form the symmetric  $sp$ -hybrid orbital on the right. The signs indicate the relative phases of the wavefunctions across the  $x$ - $y$  plane.

and

$$|\psi_2^H\rangle = \frac{1}{\sqrt{2}}(|\phi_s\rangle - |\phi_{pz}\rangle). \quad (3.35b)$$

These two hybrids are illustrated by the larger and smaller  $p$ -like orbitals in Fig. 3.10 whose orientations are along the internuclear ( $C \equiv C$ ) axis.

The next level of hybridization is formed by a superposition of an  $s$ -orbital and two  $p$ -orbitals ( $p_x$ ,  $p_y$ ), forming three  $sp^2$ -hybrid orbitals. An example molecule with this hybridization is ethene (also called ethylene),  $H_2C=CH_2$ . The molecule is planar with relative bond angles between the HCH and HCC atomic groups of  $120^\circ$ . The procedures for determining the hybrid wavefunctions is similar to that used for  $sp$ -hybridization, leading to:

$$|\psi_1^H\rangle = \frac{1}{\sqrt{3}}|\phi_s\rangle + \frac{2}{\sqrt{6}}|\phi_{px}\rangle, \quad (3.36a)$$

$$|\psi_2^H\rangle = \frac{1}{\sqrt{3}}|\phi_s\rangle - \frac{1}{\sqrt{6}}|\phi_{px}\rangle + \frac{1}{\sqrt{2}}|\phi_{py}\rangle, \quad (3.36b)$$

$$|\psi_3^H\rangle = \frac{1}{\sqrt{3}}|\phi_s\rangle - \frac{1}{\sqrt{6}}|\phi_{px}\rangle - \frac{1}{\sqrt{2}}|\phi_{py}\rangle. \quad (3.36c)$$

These three hybrids are formed from the two,  $2p$  electrons of the C atom. All of the H atoms are symmetrically equivalent. The orbitals lie in the  $x$ - $y$  (or  $\sigma^{(3)}$ ) plane between the two C nuclei, as shown in Fig. 3.11. The third electron in the  $2p_z$  orbital is excluded from the hybridization and lies perpendicular to the plane along the  $\hat{z}$ -axis. This electron pairs with that of the second carbon atom to form a cylindrical  $\pi$ -orbital in the  $\sigma^{(2)}$  ( $x$ - $z$ ) plane, holding the molecule rigid within its planar structure. As we will see below, the electrons occupying the  $\pi$ -orbitals contribute significantly toward the optical and electronic properties of conjugated molecules.

The final case is where the  $s$ -orbital electron hybridizes with all three  $p$ -electrons to form  $sp^3$  hybrid orbitals, characteristic of methane,  $CH_4$ . The four tetrahedrally oriented orbitals are linear combinations of the four valence  $2s$  orbitals with the three  $2p$ -orbitals of the C atom, viz.

$$|\psi_1^H\rangle = \frac{1}{2}|\phi_s\rangle + \frac{1}{2}|\phi_{px}\rangle + \frac{1}{2}|\phi_{py}\rangle + \frac{1}{2}|\phi_{pz}\rangle, \quad (3.37a)$$

$$|\psi_2^H\rangle = \frac{1}{2}|\phi_s\rangle - \frac{1}{2}|\phi_{px}\rangle - \frac{1}{2}|\phi_{py}\rangle + \frac{1}{2}|\phi_{pz}\rangle, \quad (3.37b)$$

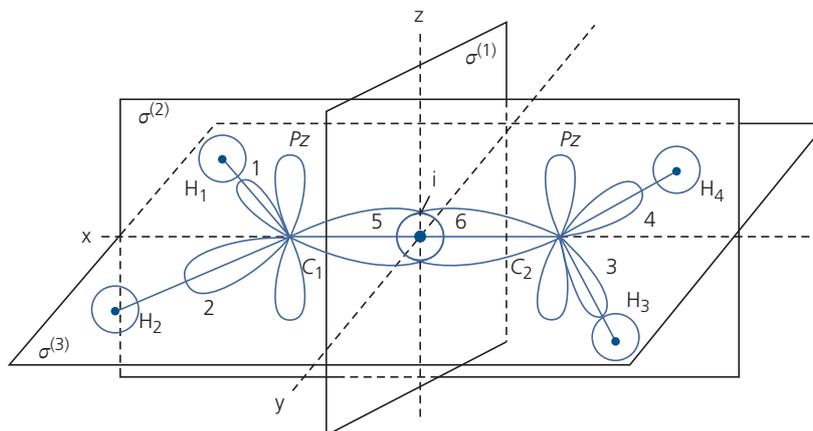

$$|\psi_3^H\rangle = \frac{1}{2}|\phi_s\rangle - \frac{1}{2}|\phi_{px}\rangle + \frac{1}{2}|\phi_{py}\rangle - \frac{1}{2}|\phi_{pz}\rangle, \quad (3.37c)$$

$$|\psi_4^H\rangle = \frac{1}{2}|\phi_s\rangle + \frac{1}{2}|\phi_{px}\rangle - \frac{1}{2}|\phi_{py}\rangle - \frac{1}{2}|\phi_{pz}\rangle. \quad (3.37d)$$

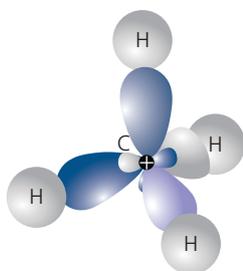

The C atom is at the vertex of the tetragon with the electron density shared in  $\sigma$ -bonds with the four H atoms, as shown in Fig. 3.12.

Given these symmetry arguments for arriving at the hybrid orbitals, we now can manage the general case of conjugated molecular systems that consist of alternating single and double bonds between adjacent atoms. This is referred to as  $\pi$ -orbital conjugation, whereby electrons within the hybridized  $\pi$ -system are distributed between atoms along the molecular plane. The calculations of the eigenfunctions and energies of such systems are enabled by using the simplifications of the *Hückel approximation* that takes full account of the molecular and bond symmetries between nearest neighbors as previously. The Hückel approximation assumes the following:

1. The different  $\sigma$ - and  $\pi$ -orbital symmetries allow for separation of their respective wavefunctions,  $\psi_\sigma$  and  $\psi_\pi$ , such that the total wavefunction is  $\psi_T = \psi_\sigma \psi_\pi$ .

**Figure 3.11** Orbital arrangements for ethene. The four H s-orbitals, four  $sp^2$  C orbitals (labeled 1-4) and two  $sp^2$  orbitals between the C atoms (5,6) are indicated. Also, the unhybridized  $p_z$ -orbitals lie in the  $\sigma^{(2)}$  plane, forming the molecular  $\pi$ -bond. The several symmetry planes of the molecule are indicated.

**Figure 3.12** Hybrid  $sp^3$  orbitals of methane.

- Nearest neighbor interactions are set equal to a constant. That is,  $H_{rr} = a$ , and  $H_{rs} = \beta$  for  $|r - s| = 1$ , otherwise  $H_{rs} = 0$ . Both  $a$  and  $\beta$  are negative (bonding) energies. Here,  $a$  is simply an energy offset, and  $\beta$  is the energy due to the hybridization of the orbitals themselves.
- The overlap integrals  $S_{rs} = \langle \phi'_s | \phi'_r \rangle = \delta_{rs}$ , where the Kronecker delta function has values of  $\delta_{rs} = 1$  when  $r = s$ ; and  $\delta_{rs} = 0$  otherwise. This is the most problematic of the assumptions since the overlap from adjacent orbitals can be substantial;  $\approx 0.2$  or larger in some cases.

With this approximation, the secular determinant in Eq. 3.27 now becomes:

$$\det|(\alpha - E)\mathbf{I} + \beta\mathbf{B}| = 0. \quad (3.38)$$

Here,  $\mathbf{I} = \delta_{rs}$  is the unity matrix, and  $\mathbf{B} = \delta_{r,r\pm 1}$ .

Benzene ( $C_6H_6$ ) provides a simple example of the utility of the Hückel approximation in estimating the energies of a conjugated system. Here, each C atom is  $sp^2$  hybridized with its neighbors, with its third  $p_z$ -orbital lying perpendicular to the molecular plane. As

in the case of ethene, the  $p_z$ -orbitals from adjacent C atoms overlap to form an extended  $\pi$ -system that maintains molecular planarity. For benzene, therefore, Eq. 3.38 becomes:

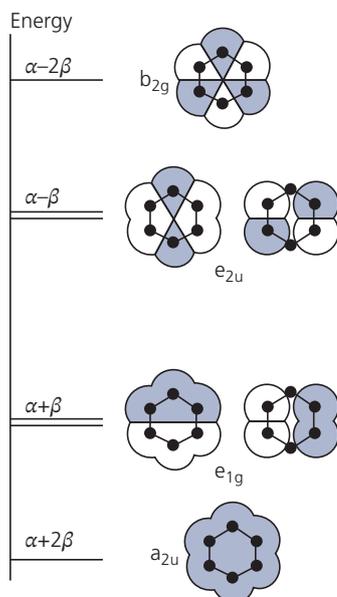

$$\det \begin{vmatrix} \alpha - E & \beta & 0 & 0 & 0 & \beta \\ \beta & \alpha - E & \beta & 0 & 0 & 0 \\ 0 & \beta & \alpha - E & \beta & 0 & 0 \\ 0 & 0 & \beta & \alpha - E & \beta & 0 \\ 0 & 0 & 0 & \beta & \alpha - E & \beta \\ \beta & 0 & 0 & 0 & \beta & \alpha - E \end{vmatrix} = 0. \quad (3.39)$$

The solutions to this equation give the following four energies of the six  $\pi$ -orbitals:

$$\begin{aligned} E(a_{2u}) &= a + 2\beta; \\ E(e_{1g}) &= a + \beta; \\ E(e_{2u}) &= a - \beta; \\ E(b_{2g}) &= a - 2\beta. \end{aligned} \quad (3.40)$$

Since both  $a$  and  $\beta$  are negative, the first two energy terms are the lowest bonding  $\pi$ -orbitals, and the second two are  $\pi^*$ -antibonding orbitals illustrated in Fig. 3.13. Note that there are two degenerate orbitals (labeled  $e_1$  and  $e_2$ ). Also, since  $a$  is a common additive energy offset, it is ignored.

The various symmetry states in Eq. 3.40 are identified by their spectroscopic nomenclatures based on group theory. The subscript  $g$  refers to states that have even symmetry, or *gerade* in German, under spatial inversion across the molecular plane. Even orbital symmetry (or *parity*) refers to the situation where the wavefunction is unchanged due to this symmetry operation, that is,  $\psi(\mathbf{r}) = \psi(-\mathbf{r})$ . On the other hand,  $u$  is *ungerade*, or odd symmetry under such an

**Figure 3.13** The  $\pi$ -orbitals of benzene and their relative energies. Light and dark shaded areas correspond to regions of opposite wavefunction phase. Note that both the  $e_1$  (bonding) and  $e_2$  (antibonding) orbitals are doubly degenerate (Atkins, 1983).

operation. The other notations,  $a$ ,  $e$ , and  $b$  refer to different point group symmetries whose details can be found elsewhere (see Chapter 2 as well as many texts on molecular spectroscopy, e.g. Harris and Bertolucci, 1989). Since there are six valence electrons, and two spin states per energy level, the ground state of the benzene molecule has the electronic configuration of  $a_{2u}^2 e_{1g}^4$ , which is called the  ${}^1A_{1g}$  state in the spectroscopic notation of Platt (1949). Thus, the  $a_{2u}$  state corresponds to the HOMO-1 state, whereas the frontier orbital, or HOMO, is the  $e_{1g}$  state with its four electrons. Similarly, the opposite (unoccupied) frontier orbital, or LUMO, corresponds to the  $e_{2u}$  state, and  $b_{2g}$  is the LUMO+1 orbital. In benzene, the spectroscopic nomenclature for the first excited state is  ${}^1B_u$  (Platt, 1949).

The total energy of six unhybridized electrons is  $6(a + \beta)$ . However, according to our LCAO calculation, the ground state energy of benzene is  $2(a + 2\beta) + 4(a + \beta) = 6a + 8\beta$ . Hence, the ground state benzene molecule has an energy  $2\beta$  lower than six individual C atoms. This difference is the *stabilization* or *delocalization* energy, and leads to the ground state benzene ring configuration. As we move to higher energies in the LUMO, the molecule becomes less stable since the orbitals are now antibonding.

An admittedly oversimplified but intuitive prediction of the  $\pi$ -system orbital energies of aromatic hydrocarbons can be found using *perimeter-free electron orbital* (PFEO) theory (Platt, 1949). The PFEO method

can be applied to the *catacondensed molecules* comprising  $N$  fused rings. For polyaromatic hydrocarbons with the formula  $C_{4n+2}H_{2n+4}$ , each ring contributes  $4n + 2$   $\pi$ -electrons. The basic premise is that  $\pi$ -electrons in the rings are completely decoupled from the inner  $\sigma$ -electrons, and are responsible for establishing the electronic ground and excited states of the molecule (Hückel approximation #1). Furthermore, the  $\pi$ -electrons contributed by each C atom in catacondensed molecules belong to no more than two rings and lie on the molecular periphery. The electron is free to move along the perimeter of length  $L = 2\pi r = (4n + 2)a_{CC}$ , which for the purposes of this approximation is distorted into a circle whose radius is  $r$ . Then  $L$  is equal to the number of C-C bonds of length,  $a_{CC}$ . Hence, the  $\pi$ -electron wavefunctions have periodic boundary conditions with the form:

$$\psi_l(\theta) = \frac{1}{\sqrt{2\pi}} \exp(il\theta), \quad (3.41)$$

where  $l = 0, \pm 1, \pm 2, \dots$  is the orbital angular momentum quantum number, and  $\theta$  is the azimuthal angle. The appropriate boundary condition is  $\psi_l(0) = \psi_l(2\pi)$ , as shown in Fig. 3.14.

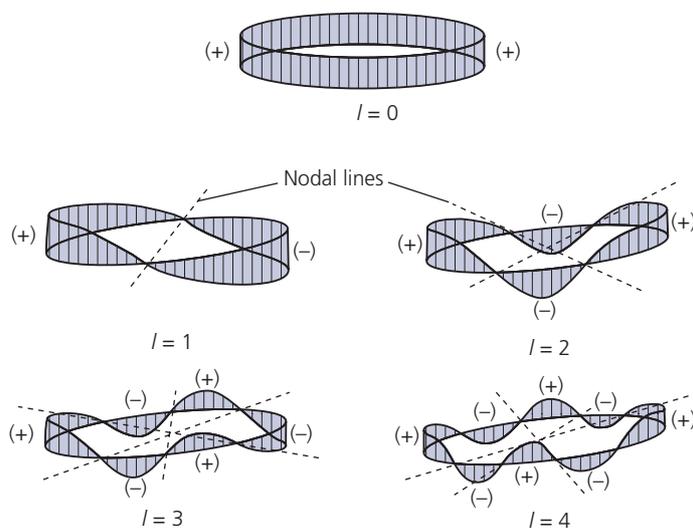

The wavefunction can be expressed using the LCAO formulation by summing over the basis set of  $p$ -atomic orbitals on  $N$  atoms (Moffitt, 1954):

$$\psi_l(\theta) = \frac{1}{\sqrt{2\pi N}} \sum_{k=0}^{N-1} \exp(ik\theta_l) \phi_k(\theta). \quad (3.42)$$

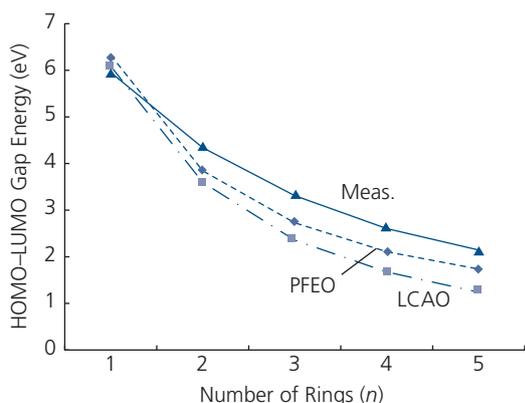

where  $\theta_l = 2\pi l/N$ . Solving Schrödinger's equation for the wavefunctions in Eq. 3.41 gives the PFEO eigenvalues:

$$E_l = a + \frac{\hbar^2}{2mr^2} l^2. \quad (3.43)$$

There are two degenerate counter propagating wavefunctions (e.g.  $l = \pm 1$ ) resulting in four electrons occupying each level, except for the  $l = 0$  state which is occupied by only two electrons following the aufbau principle. The energy gap is between the highest filled  $2n + 1$  orbital (the HOMO) and the orbital at  $2n + 2$  corresponding to the LUMO. In PFEO nomenclature, the highest filled level is called the "*f* state," with letters ascending (descending) through the alphabet with increasing (decreasing)  $l$ . This is consistent with the picture for benzene in Fig. 3.13 where the six  $\pi$ -electrons fill levels up to the HOMO energy corresponding to the  $e_{1g}$  orbitals. Unlike the more precise solution obtained via the Hückel approximation, however, the difference between energy levels

**Figure 3.14** Wavefunctions,  $\psi(\theta)$ , for the lowest five orbitals with angular momentum quantum numbers,  $l$ . The number of nodal lines is equal to  $l$ . The relative wavefunction phases (+, -) above and below the molecular plane are shown. Adapted from Pope and Swenberg (1982).

**Figure 3.15** The HOMO–LUMO gap energy calculated using a modified Gaussian basis set vs. the number of fused rings ( $n$ ) in the first five linear polyacenes (benzene to pentacene). The differences between experiment, PFE0 and LCAO theories increases with  $n$ . For the LCAO calculation,  $\beta = 2.85$  eV and  $S_{rs} = 0.25$ .

increase in separation with  $l^2$ . Using the more accurate basis of Eq. 3.42, it can be shown that the energies follow:

$$E_l = \alpha + 2\beta \cos(\theta_l), \quad (3.44)$$

which leads to “compression” of the energy levels with the largest energy gap between states  $f$  and  $g$  (corresponding to the first empty shell, or LUMO energy), similar to predictions using LCAO theory.

A comparison of the calculations by both the PFE0 and LCAO approaches along with the measured long wavelength absorption arising from equal HOMO–LUMO transitions is shown in Fig. 3.15 for linear polyacenes with an increasing number of rings,

starting with benzene ( $n = 1$ ), then naphthalene ( $n = 2$ ), anthracene ( $n = 3$ ), tetracene ( $n = 4$ ), and pentacene ( $n = 5$ ). Clearly, the approximations used lead to increasing inaccuracy with molecular size. Except in the case of benzene where both models are reasonably consistent with experiment, the PFE0 and LCAO methods lead to an underestimation of the gap energy for the somewhat arbitrary choice of  $S_{rs} = 0.25$  in Fig. 3.15 (Scherr, 1953). For  $S_{rs} = 0$ , the LCAO model significantly underestimates the energy for all of the polyacenes shown.

### 3.4 Improving accuracy: numerical models

To improve these admittedly coarse approximations that become increasingly inaccurate with molecular complexity, several of the approximations used in the LCAO method must be abandoned. A complete discussion of the more sophisticated approaches outlined here are found in the extensive literature on this subject (see *Further reading*).

There are two principal methods for improving computational accuracy. One is the *ab initio* approach based on first principles, as its name implies. These approaches all start with the Hartree–Fock equations of the individual atomic electron energies. It is then assumed that when placed in a molecule, each electron moves in a potential that is the average spherical superposition of all the other,  $n - 1$  valence electrons in the molecule. The *semi-empirical approach*, on the other hand, starts with the Hückel approximation, and then lifts assumptions that lead to the greatest

inaccuracies by employing a few empirical constants for a particular molecular system or class of structures. As already discussed, assuming  $S_{rs} = 0$  leads to significant inaccuracies. Hence, the first step is to include the overlap integrals,  $S_{rs}$  ( $|r - s| = 1$ ) between nearest neighbors. We first describe the most popular *ab initio* approach known as *density functional theory* (DFT). Next, we consider the suite of common semi-empirical methods starting with the Pariser–Parr–Pople (PPP) method, and then the complete neglect of differential overlap (CNDO), the intermediate neglect of differential overlap (INDO), and a few variations on these approaches (MINDO and ZINDO). There are many approximation methods and an equally large number of software packages that are available (many of them open source) that can be employed to calculate the orbital energetics of a wide variety of molecular systems, albeit with varying precision.

### 3.4.1 *Ab initio* approaches

*Ab initio* approaches start with the assumption that each electron in an orbital is affected by the mean potential due to the  $n - 1$  other electrons in the molecule. Thus, we decompose the  $n$ -electron problem into  $n$  one-electron problems, where the electron is in an orbital of the  $i$ th hydrogenic atom with nuclear charge  $Z_i q$ . The one-electron spin–orbital wavefunction is then  $\phi_{e,i}^0(\mathbf{r}_i, \mathbf{R}_I)$  (see Eq. 3.8), and the total wavefunction for the system is given by the product of single electron wavefunctions, Eq. 3.10. Now the energy for each electron is found using

$$H^0 \phi_{e,i}^0(\mathbf{r}_i, \mathbf{R}_I) = E^0 \phi_{e,i}^0(\mathbf{r}_i, \mathbf{R}_I) \quad (3.45)$$

and

$$H^0 = \sum_{i=1}^n h_i + \frac{1}{2} \sum_{i \neq j} \frac{q^2}{4\pi\epsilon_0 |\mathbf{r}_i - \mathbf{r}_j|}, \quad (3.46)$$

where  $h_i$  are the one-electron hydrogenic core Hamiltonians. It can be shown that Eq. 3.45 leads to  $n$  Hartree–Fock equations for the  $i$ th electron following:

$$f_i \phi_{e,i}^0(\mathbf{r}_i, \mathbf{R}_I) = \epsilon_i \phi_{e,i}^0(\mathbf{r}_i, \mathbf{R}_I) \quad (3.47)$$

with

$$f_i = h_i + \sum_{j=1}^{j \neq i} (J_j(i) - K_j(i)). \quad (3.48)$$

Here  $f_i$  is called the Fock operator, and

$$J_j = \frac{q^2}{4\pi\epsilon_0} \langle \phi_j^0 | \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} | \phi_j^0 \rangle \quad (3.49a)$$

and

$$K_j = \frac{q^2}{4\pi\epsilon_0} \langle \phi_j^0 | \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} | \phi_i^0 \rangle, \quad (3.49b)$$

where  $J_j$  is the *Coulomb integral* and is the energy due to repulsion of electrons  $i$  and  $j$ . Similarly,  $K_j$  is the *exchange integral* that gives the energy expense when the two electrons are interchanged.

This set of equations is solved for each of  $n$  electrons with a trial set of  $n$  spinorbital functions to solve for the energies,  $\epsilon_i$ . Reasonable trial basis sets are the Gaussian or Slater functions in Eqs. 3.23 and 3.24, although other functional forms are often used. This, of course, generates a new set of spinorbitals, and the process is iterated until the changes in  $\epsilon_i$  and  $\phi_{e,i}^0(\mathbf{r}_i, \mathbf{R}_I)$  between successive iterations are acceptably small. This iterative procedure continually readjusts the electron distribution such that it is consistent with the functional form of the wavefunctions, and hence is called the *self-consistent field* (SCF) *approximation*.

The most important approximation used in the SCF approach is that an electron only sees the average potential of all other electrons. Yet, as the single additional electron is added to the system, it instantaneously changes the original distribution, which changes the potential environment for the added electron. In effect, the distribution of  $n - 1$  electrons is *polarized* by the extra charge. This is known as *electron correlation*, and is treated using further approximations that account for this so-called *configuration interaction* between electrons (see Atkins and Friedman, 1997 for a review of this method).

DFT provides a second approach to the Hartree–Fock method by replacing the electron distribution with a charge distribution,  $\rho(\mathbf{r})$ , comprising the entire system of  $n$ -electrons. The energy due to this distribution is  $E(\rho)$ . The initial wavefunction with  $3n$  degrees of freedom ( $\{\mathbf{r}_i\}$ ) is reduced to a single density, with only three degrees of freedom ( $\mathbf{r}$ ) (Kohn and Hohenberg, 1964). The challenge is to determine the charge density functional that can be expressed in terms of the electronic probability density due to  $n$  single electron spatial orbitals, viz.

$$\rho(\mathbf{r}) = \sum_{i=1}^n |\phi_{e,i}(\mathbf{r}_i)|^2. \quad (3.50)$$

Thus, the energy is a function of the density, following:

$$\begin{aligned}
E(\rho) = & -\frac{\hbar^2}{2m_e} \sum_{i=1}^n \int \phi_{e,i}^*(\mathbf{r}) \nabla^2 \phi_{e,i}^*(\mathbf{r}) d^3r \\
& - \sum_{I=1}^M \int \frac{Z_I q^2}{4\pi\epsilon_0 |\mathbf{r} - \mathbf{R}_I|} \rho(\mathbf{r}) d^3r \\
& + \frac{1}{2} \sum_{i=1}^{i \neq j} \int \int \frac{\rho(\mathbf{r}_i) \rho(\mathbf{r}_j)}{4\pi\epsilon_0 |\mathbf{r}_i - \mathbf{r}_j|} d^3r_i d^3r_j \\
& + E_{XC}(\rho),
\end{aligned} \tag{3.51}$$

where  $E_{XC}(\rho)$  is the exchange-correlation energy. This energy is quantum mechanical in origin, and is comprised of both electron exchange and correlation effects on the distribution. The calculation of  $E_{XC}(\rho)$  is approximate, and can lead to the largest departures from accuracy since it is determined by placing an electron in the charge distribution using the unperturbed orbital basis set,  $\phi_{e,i}(\mathbf{r})$  in Eq. 3.50. Then the one-electron energies are minimized via the variational principle by choosing an initial  $\rho(\mathbf{r})$ . Once again we proceed with iterative solutions solved to achieve self-consistency between the orbitals and energies thus derived. Calculation of  $E_{XC}(\rho)$  is simplified by considering its value for a single electron,  $\epsilon_{XC}(\rho)$ , and then integrating over the entire distribution:

$$E_{XC} = \int \rho(\mathbf{r}) \epsilon_{XC}(\rho(\mathbf{r})) d^3r, \tag{3.52}$$

in what is known as the *local density approximation*.

Figure 3.16 shows calculated electron densities in the HOMO and LUMO of the pentacene molecule. The HOMO (Fig. 3.16a) shows four, and the LUMO (Fig. 3.16b) six nodal planes perpendicular to the long molecular axis. In addition, the HOMO has a nodal plane along the long molecular axis. The phases of the electron probability amplitudes invert across each of the nodal planes.

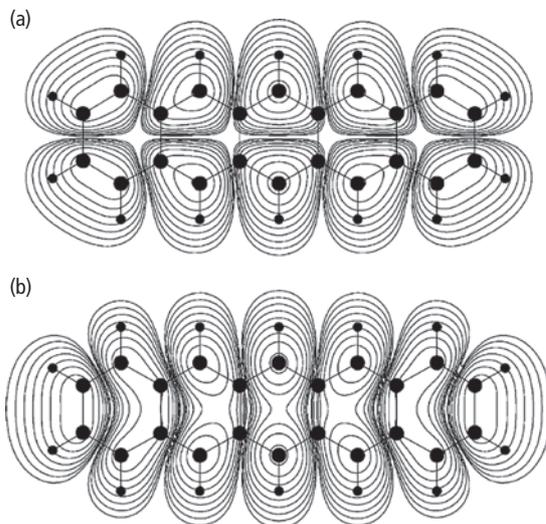

In the presence of time varying electric or magnetic fields such as encountered when light is incident on a molecule, time dependence must be included using *time dependent DFT*, or TD-DFT. The Hamiltonian now includes a time dependent external potential,  $V_{ext}(t)$ , as follows:

$$H_T(t) = T_e + V_e(t) + v_{ext}(t), \tag{3.53}$$

which is solved using the time dependent Schrödinger equation:

$$H_T(t)\Phi(t) = i\hbar \frac{\partial}{\partial t} \Phi(t), \tag{3.54}$$

where the total molecular orbital wavefunction is decomposed into its *time dependent* basis set of  $n$  single electron orbitals to give a density:

**Figure 3.16** (a) HOMO and (b) LUMO  $\pi$ -electron densities along the pentacene molecular plane. The contour lines decrease logarithmically from the carbon atom cores (large circles). Hydrogen atoms shown as small circles. Relative phases of densities are not shown (de Wijs et al., 2003). Reprinted from *Synthetic Metals*, 139, de Wijs, G. A., Mattheus, C. C., de Groot, R. A. & Palstra, T. T. M. Anisotropy of the mobility of pentacene from frustration. 109-114, Copyright (2003)

$$\rho(\mathbf{r}, t) = \sum_{i=1}^n \left| \phi_{e,i}(\mathbf{r}_i, t) \right|^2. \tag{3.55}$$

Here we have included all of the Coulomb terms (electron–electron, electron–nuclei, etc.) as well as the exchange–correlation terms in the potential,  $V_e(t)$ . Note that  $V_{ext}(t)$  is replaced with  $v_{ext}(t)$  in Eq. 3.53 to indicate that this formulation is simplified when we determine the electron distribution under small external field conditions that ensure linear response of the system.

In TD-DFT, we iterate the solution to achieve an accurate estimation of energy in both space and time. That is, the charge distribution responds to the external field as well as to a charge added to the system. This latter problem is solved using Slater determinants as in DFT, and then the time response is calculated by solving Eq. 3.54.

### 3.4.2 Semi-empirical approaches

In contrast to *ab initio* methods that utilize an atomic orbital basis founded on the Hartree–Fock equations, semi-empirical approaches take a computational short cut by making use of experimentally derived properties of molecules when it is appropriate, and when the data are available. In particular, semi-empirical approaches focus only on the  $\pi$ -electron system, greatly reducing computational intensity. This information is combined with the LCAO method to arrive at an

improved estimate (compared to using the Hückel approximation) of the molecular orbitals. Given the significant complexity of larger molecules, semi-empirical calculations can provide a sometimes orders-of-magnitude more efficient path to finding the energies and wavefunctions than purely *ab initio* techniques. However, with the continual improvement of computing power, semi-empirical approaches are losing popularity since DFT calculations are now becoming possible for even the most complex systems. Nevertheless, it is instructive to review some of the principles underlying semi-empirical calculations since they provide insight into the fundamental physics leading to observed molecular properties.

The procedure begins identically to *ab initio* approaches, with the exception that only the  $n_\pi$   $\pi$ -electrons are considered. Then we develop a Hamiltonian analogous to Eq. 3.46, but only include outer electrons thus:

$$H^\pi = \sum_{i=1}^n h_i^\pi + \frac{1}{2} \sum_{i \neq j} \frac{q^2}{4\pi\epsilon_0 |\mathbf{r}_i - \mathbf{r}_j|}, \quad (3.56)$$

where the core Hamiltonian for the  $i^{\text{th}}$   $\pi$ -electron is given by

$$h_i^\pi = -\frac{\hbar^2}{2m_e} \nabla_i^2 + V_i^\pi. \quad (3.57)$$

Here,  $V_i^\pi$  is the potential due to all the nuclei comprising the molecule, as well as all of the  $\sigma$ -bonds between the nuclei. Then the total  $\pi$ -orbital wavefunction  $\Phi^\pi(\mathbf{r})$  can be written as the product of the individual molecular orbitals:

$$\Phi^\pi(\mathbf{r}) = \prod_{i=1}^{n_\pi} \phi_{e,i}(\mathbf{r}), \quad (3.58)$$

where each molecular orbital is given by the sum over atomic orbitals ( $\varphi_k$ ) following Eq. 3.22. The individual orbitals are found via a solution to:

$$h_i^\pi \phi_{e,i}(\mathbf{r}) = \epsilon_i^\pi \phi_{e,i}(\mathbf{r}). \quad (3.59)$$

Then, the total molecular energy is simply equal to the sum of all the orbital energies as:

$$E^\pi = \sum_{i=1}^{n_\pi} n_i \epsilon_i^\pi, \quad (3.60)$$

where  $n_i$  is the total number of electrons in the  $i^{\text{th}}$   $\pi$ -orbital. Hence:

$$\epsilon_i = \frac{\sum_{k=1}^L \sum_{l=1}^L c_k^* c_l \langle \varphi_k | h_i^\pi | \varphi_l \rangle}{\sum_{k=1}^L \sum_{l=1}^L c_k^* c_l \langle \varphi_k | \varphi_l \rangle} = \frac{\sum_{k=1}^L \sum_{l=1}^L c_k^* c_l H_{i,kl}^\pi}{\sum_{k=1}^L \sum_{l=1}^L c_k^* c_l S_{i,kl}^\pi}, \quad (3.61)$$

where  $H_{i,kl}^\pi$  and  $S_{i,kl}^\pi$  are the Coulomb and overlap integrals, analogous to those used in the *ab initio* formalism, and  $L$  is the number of atomic orbitals in the basis. Equation 3.61 must be minimized using variational theory for each orbital to obtain the total energy in Eq. 3.60.

The solutions to this system of equations are found by solving the secular determinant

$$\det[\mathbf{H}^\pi - \epsilon \mathbf{S}^\pi] = 0 \quad (3.62)$$

using the usual Hückel approximations. When this semi-empirical approach was first introduced, the electron-electron repulsive interaction terms in Eq. 3.56 were ignored. This *Hückel molecular orbital theory* (HMO) was relatively easy to solve for conjugated systems, but its rather coarse approximation introduces significant errors. This has led to more robust and extended HMO methods that attempt to correct the damage done by this simplification.

The *Pariser-Parr-Pople* (PPP) method was introduced by Pariser and Parr (Pariser and Parr, 1953), and separately by Pople (Pople, 1953). The PPP method and its extensions attempt to eliminate some of the most troublesome approximations of HMO theory, particularly recovering electron-electron repulsion. The PPP method thus provides the foundation for many popular semi-empirical approaches in use today. The HMO approach assumes that the single  $\pi$ -electron takes into account the screening of all other electrons in their orbitals. Then, by adding in the repulsive term in Eq. 3.56, the interelectronic interactions will end up being over-counted (by a factor of two).

In the PPP method, we start with the  $\pi$ -system molecular orbital ( $\Phi^\pi(\mathbf{r})$ ) as the product of  $\pi$  spinorbitals ( $\psi_i^\pi(\mathbf{r})$ ) following Eq. 3.10. The atomic orbitals are given by the sum in Eq. 3.22 weighted by the coefficients,  $c_{ir}$ . Then the spinorbitals are found by minimizing the sum of secular equations:

$$\sum_{r=1}^N c_{ir} [F_{rs} - \epsilon_i S_{rs}] = 0. \quad (3.63)$$

From the previous treatment, it follows that

$$F_{rs} = H_{rs}^\pi + \sum_{t=1}^N \sum_{u=1}^N P_{tu} \left[ \langle rt | su \rangle - \frac{1}{2} \langle rt | us \rangle \right], \quad (3.64)$$

where  $H_{rs}^\pi$  includes the full core Hamiltonian in Eq. 3.46 along with the electron-electron repulsion terms. Here, we have used the shorthand notation

$$\langle rt | su \rangle = \frac{q^2}{4\pi\epsilon_0} \langle \phi_r(\mathbf{r}_1) \phi_t(\mathbf{r}_2) | \frac{1}{|\mathbf{r}_1 - \mathbf{r}_2|} | \phi_s(\mathbf{r}_1)_u(\mathbf{r}_2) \rangle \quad (3.65)$$

to denote two-electron Coulomb integrals over the atomic orbitals. Finally, we define

$$P_{tu} = 2 \sum_{w=1}^N c_{wt}^* c_{wu}, \quad (3.66)$$

which leads us to the total electronic energy (Pople, 1953):

$$E^\pi = \frac{1}{2} \sum_{r=1}^N \sum_{s=1}^N P_{rs} [H_{rs}^\pi + F_{rs}]. \quad (3.67)$$

The differences between HMO and the PPP method are contained in the two electron terms,  $\langle rt | su \rangle$ , otherwise known as the *differential overlap integrals*. As in the case of all such integrals, they decrease rapidly as the electron separation increases, thus allowing us to make some approximations. In PPP theory, we take:

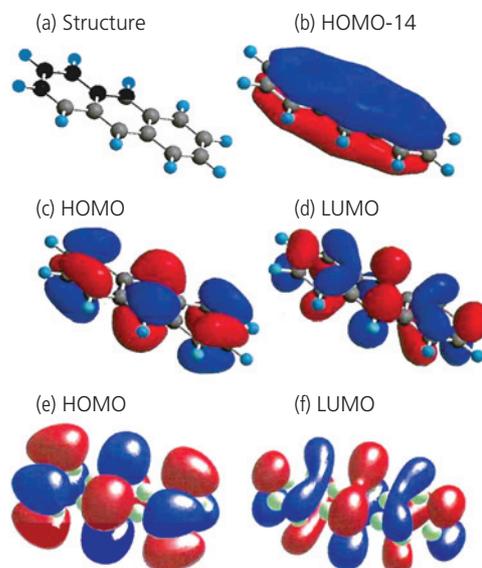

$$\langle rt | su \rangle = \delta_{rs} \delta_{tu} \langle rr | tt \rangle, \quad (3.68)$$

which corresponds to the case of zero differential overlap. This is the very simplest and approximate condition that nevertheless is a considerable improvement over HMO that neglects electron-electron interactions entirely by setting all such integrals to zero.

The approach is inherently semi-empirical since electrons in neighboring atoms that share a bond replace the off-diagonal core Hamiltonian values with an empirical parameter,  $h_{ij}^\pi = \beta_{ij}$ , whereas in *ab initio* methods this term is calculated, or perhaps even worse, it is ignored.

The CNDO method takes all electrons (not just the  $\pi$ -system) into account, and then follows an identical procedure to the PPP approach, including only integrals of the form of Eq. 3.68. The next level of precision is achieved by including the exchange integrals:  $\langle rs | rs \rangle = \langle rs | sr \rangle$ . This procedure is known as the INDO method. As the approximations are lifted one after another in an effort to achieve ever greater accuracy, their computational complexities increase accordingly. These methods go by the names of modified INDO (MINDO), Zerner's INDO (ZINDO) (Zerner, 1991) that includes more atomic species than INDO, and so on. Numerous software packages exist to calculate orbitals by these more exact means, but their further discussion is beyond the scope of this text.

A comparison of the electronic distributions in the HOMO and LUMO manifolds calculated for anthracene by both the *ab initio* LCAO Hückel method using a modified Gaussian basis set, and by the semi-empirical Austin model 1 (AM1 which is a MINDO-based method) is shown in Fig. 3.17. Close examination of these distributions indicates subtle but

**Figure 3.17** (a) Structure of anthracene ( $C_{14}H_{10}$ ). AM1 based calculation of the  $\pi$ -electron systems in anthracene for the (b) HOMO-14 level showing complete delocalization of the electrons between the  $p_z$  atomic orbitals, (c) HOMO and (d) LUMO orbitals. Similar calculations based on the LCAO model for the (e) HOMO and (f) LUMO orbitals. The red and blue regions indicate opposite phases of the spatial wavefunctions that invert across each molecular plane (cf. Fig. 3.16) (Peumans, 2004). Reprinted with permission.

nevertheless important differences that are produced using the different approaches.

## 3.5 Transitions between states

The symmetry and composition of electron wavefunctions directly impacts the spectra and conducting properties of organics. The most important ingredients for making the leap from molecular orbitals to the optoelectronic properties of a compound is by understanding the transition rates between energy levels and states, and their quantum mechanical selection rules. Those properties are the subject of this section.

### 3.5.1 Fermi's Golden Rule

Now that we are armed with expressions for the electronic and vibronic wavefunctions,  $|\phi_e\rangle$  and  $|\phi_N\rangle$ , we are prepared to calculate the allowed transitions between the ground and excited electronic states to determine the absorption and emission spectra of a molecule. The transition rate between initial state,  $i$ , and final state,  $f$ , is given by *Fermi's Golden Rule*:

$$k_{if} = \frac{2\pi}{\hbar} |\langle \psi_f | H_{int} | \psi_i \rangle|^2 \rho(E_{if}). \quad (3.69)$$

Here,  $\rho(E_{if})$  is the joint density of states of the initial and final wavefunctions,  $\psi_i$  and  $\psi_f$ , respectively, and  $H_{int}$  is the interaction Hamiltonian for the transition. The term

$$M_{if} = \langle \psi_f | H_{int} | \psi_i \rangle \quad (3.70)$$

is the transition amplitude, or *transition matrix element*, and  $M_{if}^2$  is the transition probability for  $i \rightarrow f$ . For discrete initial and final states,  $\rho(E_{if}) = \delta(E_i - E_f \mp E_{ph})$ , where  $E_{ph}$  is the photon energy. The minus sign refers to absorption, and the plus to emission. To first order, the interaction Hamiltonian is approximated by the electric dipole transition:

$$H_{int} = -\boldsymbol{\mu}_{\mathbf{r},\mathbf{R}} \cdot \mathbf{F}, \quad (3.71)$$

where  $\mathbf{F}$  is the optical electric field and  $\boldsymbol{\mu}_{\mathbf{r},\mathbf{R}}$  is the dipole moment operator that, following the Born–Oppenheimer approximation, can be separated into its nuclear and electronic components as follows:

$$\boldsymbol{\mu}_{\mathbf{r},\mathbf{R}} = \boldsymbol{\mu}_e + \boldsymbol{\mu}_N = -q \left[ \sum_k \mathbf{r}_k - \sum_K Z_K \mathbf{R}_K(Q) \right]. \quad (3.72)$$

Here the nuclear positions are given relative to their normal coordinates,  $Q$ , and the sum is over  $k$  valence electrons and  $K$  nuclei. Hence, the dipole matrix element is:

$$\mu_{if} = \langle \phi_{e,f}(\mathbf{r}, Q) \phi_{N,f}(Q) | \boldsymbol{\mu}_{\mathbf{r},\mathbf{R}} | \phi_{e,i}(\mathbf{r}, Q) \phi_{N,i}(Q) \rangle. \quad (3.73)$$

The final and initial states of the wavefunctions are orthonormal, for example,

$$\langle \phi_{N,f}(Q) | \phi_{N,i}(Q) \rangle = \int \phi_{N,f}^*(Q) \phi_{N,i}(Q) dQ = 0 \quad (3.74)$$

where  $\langle \phi_{N,i}(Q) | \phi_{N,i}(Q) \rangle = 1$ . Insertion of Eq. 3.72 into Eq. 3.73 yields the integrals:

$$\begin{aligned} \mu_{if} = & -q \left[ \sum_k \int \phi_{e,f}^*(\mathbf{r}, Q) \mathbf{r}_k \phi_{e,i}(\mathbf{r}, Q) d^3r \right. \\ & \times \left. \left( \phi_{N,f}^*(Q) \phi_{N,i}(Q) dQ \right) \right] \\ & + q \left[ \sum_K Z_K \int \phi_{e,f}^*(\mathbf{r}, Q) \phi_{e,i}(\mathbf{r}, Q) d^3r \right. \\ & \times \left. \left( \phi_{N,f}^*(Q) \mathbf{R}_K \phi_{N,i}(Q) dQ \right) \right]. \quad (3.75) \end{aligned}$$

The second integral vanishes due to orthogonality of the different electronic wavefunctions in the initial and final electronic states,  $\phi_{e,i}(\mathbf{r})$  and  $\phi_{e,f}(\mathbf{r})$ , respectively. In contrast, to first order during the transition, the nuclei are fixed (the Franck-Condon principle),

and hence only the first integral survives. Thus we arrive at:

$$\mu_{if} = -q \left[ \int \phi_{N,f}^*(Q) \phi_{N,i}(Q) dQ \sum_k \phi_{e,f}^*(\mathbf{r}, Q) \mathbf{r}_k \phi_{e,i}(\mathbf{r}, Q) d^3r \right]. \quad (3.76)$$

### 3.5.2 Quantum mechanical selection rules

From the treatment thus far, we can determine which transitions are allowed, and which are forbidden, thereby developing a set of quantum mechanical selection rules. From Eq. 3.69 and 3.70, we see that a transition is allowed if the matrix element,  $M_{if}$ , is non-zero. Since the electronic, nuclear and spin wavefunctions are separable according to the Born–Oppenheimer approximation, and since  $\mu_{if}$  operates only on the electronic wavefunction (Eq. 3.76), the matrix element leading to an allowed transition in the electric dipole approximation is given by:

$$\begin{aligned} M_{if} = & q \langle \phi_{e,f}(\mathbf{r}_f) | \mathbf{r} \cdot \mathbf{F} | \phi_{e,i}(\mathbf{r}_i) \rangle \\ & \langle \phi_{N,f}(Q_f) | \phi_{N,i}(Q_i) \rangle \langle \sigma_f(S_f) | \sigma_i(S_i) \rangle \neq 0. \quad (3.77) \end{aligned}$$

The first two terms are given by the integral in Eq. 3.76. The spatial term enforces a change in parity between  $\phi_{e,i}(\mathbf{r}_i)$  and  $\phi_{e,f}(\mathbf{r}_f)$ . That is, since the dipole operator has odd parity defined as  $\boldsymbol{\mu}_{\mathbf{r}}(\mathbf{r}) = -\boldsymbol{\mu}_{\mathbf{r}}(-\mathbf{r})$ , and since the integral is over all space, then the integral is non-zero only when  $\phi_{e,i}(\mathbf{r}_i)$  and  $\phi_{e,f}(\mathbf{r}_f)$  are of opposite parity. Generally, the ground state of a molecule with inversion symmetry has even parity (e.g. the  $A_{1g}$  state Section 3.3). Hence allowed transitions are to or from odd parity excited states (e.g.  $B_{2u}$ ). This results in the selection rule that *electric dipole transitions are allowed only between electronic states of opposite spatial symmetry*. The higher the symmetry of the molecule, the more likely it is to find transitions whereby the parity between the initial and final states is ostensibly the same, hence allowing for forbidden transitions. Finally, the spatial integral will also be very small (and hence  $M_{if} \approx 0$ ) if there is little or no overlap between the electron orbitals in  $\phi_{e,i}(\mathbf{r}_i)$  and  $\phi_{e,f}(\mathbf{r}_f)$ .

The integrals in Eq. 3.76 and 3.77 are also non-zero only if the transitions are between the same nuclear (i.e. vibronic) sub-state in the final and initial electronic states, provided that there is sufficient overlap between the vibronic wavefunctions  $\phi_{N,i}(Q_i)$  and  $\phi_{N,f}(Q_f)$ . This second selection rule implies that *transitions are only allowed between vibronics with the same quantum number,  $n_i$ , in Eq. 3.15*. This is illustrated in Fig. 3.5 by the vertical arrows that represent allowed

absorption transitions between the same vibronic levels in two different electronic states. This assumption is partially justified by the Franck–Condon principle whereby the relaxation of the electronic states follows the transition, implying that  $Q$  is constant.

In the common circumstance that the vibronic quantum number is different in  $i$  and  $f$ , that is,  $\Delta n_l \neq 0$ , then orthogonality of the wavefunctions demands that  $\mu_{if} = 0$  (cf. Eq. 3.76). However, if there is a substantial shift in the molecular coordinates between  $E_i$  and  $E_f$ , this symmetry-based selection rule is broken. This is apparent when we expand Eq. 3.76 about equilibrium (Sponer and Teller, 1941, Gribov and Orville-Thomas, 1988):

$$\begin{aligned} \mu_{if} = & -q \int \phi_{N,f}^*(Q) \phi_{N,i}(Q) dQ \sum_k \phi_{e,f}^*(r, Q) r_k \phi_{e,i}(r, Q) d^3r \\ & -q \sum_{k,l} \int \phi_{N,f}^*(Q) Q_k \phi_{N,i}(Q) dQ \int \left. \frac{\partial (\phi_{e,f}^* \phi_{e,i})}{\partial Q_k} \right|_0 r_l d^3r \\ & -\frac{q}{2} \sum_{k,l,m} \int \phi_{N,f}^*(Q) Q_k Q_m \phi_{N,i}(Q) dQ \\ & \times \int \left. \frac{\partial^2 (\phi_{e,f}^* \phi_{e,i})}{\partial Q_k \partial Q_m} \right|_0 r_l d^3r + \dots \end{aligned} \quad (3.78)$$

This is known as the *Herzberg–Teller expansion*. The first integral is the overlap between vibronics in the electronic manifolds and is known as the *Franck–Condon integral*. The intensity of the transition is thus related to the square of the integral, whose value is called the *Franck–Condon factor* ( $FC_{if}$ ) for the transition. This is conveniently written as:

$$FC_{if} = |\langle \phi_{N,f}(Q_f) | \phi_{N,i}(Q_i) \rangle|^2. \quad (3.79)$$

As noted above, if there is no change in  $Q$  from the initial to the final state, then only the first term in the expansion around the potential minimum survives, and only transitions corresponding to  $\Delta n_l = 0$  are allowed.

It is quite rare for there to be no nuclear positional adjustments between two different electronic states. This situation corresponds to a simple vertical translation of the electronic potential. Often, an electronic transition results in a significant nuclear reconfiguration of  $\Delta Q = Q_f - Q_i$ , corresponding to a horizontal as well as vertical translation of the potentials in Fig. 3.5. This causes symmetry breaking, that is, the vibronic wavefunctions in the two electronic manifolds are no longer orthogonal since they become *mixed* with the electronic states. In this case, higher order terms in the Herzberg–Teller expansion survive. Transitions between vibronic

states with  $\Delta n_l \neq 0$  are now allowed with a probability determined by time independent perturbation theory. In other words, the transition results in the *simultaneous* excitation of the vibrational as well as electronic modes. The second term in the Herzberg–Teller approximation corresponds to a transition between states when  $\Delta n_l \neq 0$ . The product of  $|\phi_{N,f}(Q_f)\rangle$  and  $|\phi_{N,i}(Q_i)\rangle$  has odd spatial symmetry which, when combined with the odd spatial coordinate,  $Q$ , results in an integrand with even symmetry. Hence, the integral is non-vanishing, whereas the first and third terms vanish.

Similarly, for the next higher order transition where two vibronics on different electronic states are excited, the third integral is non-vanishing, and so on. Each of these possible transitions is at a higher energy of

$$\Delta E_l = |E_f - E_i| + \Delta n (\hbar \omega_l) \quad (3.80)$$

in both absorption and emission. As in Eq. 3.15,  $\omega_l$  is the frequency of the  $l$ th normal vibrational mode that is excited in the transition. Thus, the transition energy differs from the energy of the electronic transition by the vibronic energies with quantum numbers that differ by  $n$ .

The final selection rule requires that the spin of the initial and final states is conserved. Since the symmetry of the  $S = 0$  and  $S = 1$  states are odd and even, respectively, the spin integral  $\langle \sigma_f(S_f) | \sigma_i(S_i) \rangle$  is *non-zero only for transitions between states of the same spin multiplicity*, that is, when  $S_i \rightarrow S_f$  or  $T_i \rightarrow T_f$ . However, an important exception to this rule occurs in the presence of spin–orbit or spin–spin coupling, a topic that is the focus of Section 3.7.

A summary of these three selection rules, and exceptions that lead to the observation of otherwise quantum mechanically forbidden transitions, is provided in Table 3.1. We note that transitions between states of opposite parity can arise from two photon transitions, that is, absorption or emission that involves more than a single photon. Also, higher order multipole transitions can also lead to violations of the parity rule.

### 3.5.3 Understanding molecular spectra

The *vibronic progression* of transitions in both absorption and emission are illustrated in Fig. 3.18. Here, the ground ( $S_0$ ) and first excited ( $S_1$ ) singlet states are shifted by a small but noticeable configuration shift,  $\Delta Q$ . Since the electron population ( $N$ ) of the vibronic states follows a Boltzmann distribution, that is,

**Table 3.1** Summary of selection rules for electronic, nuclear and spin transitions for electric dipole interactions

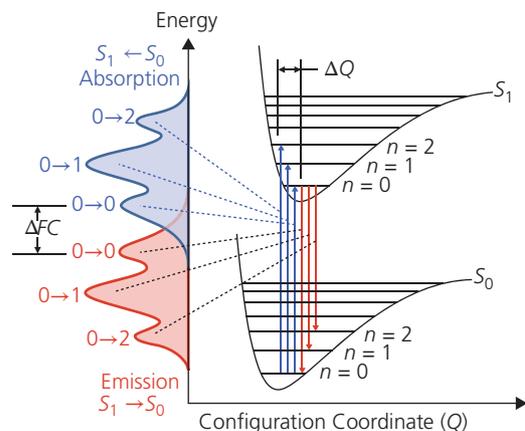

Transition	Selection rule	Matrix element	Exception
Between electronic states	Parity of $\phi_{e,f}$ and $\phi_{e,i}$ must be different (e.g. even $\rightarrow$ odd)	$\langle \phi_{e,f}(\mathbf{r})   \mathbf{r}   \phi_{e,i}(\mathbf{r}) \rangle$	Low symmetry molecules, two photon transitions, higher order multipoles
Between vibronic states in different electronic manifolds	Vibronic quantum number $n_i - n_f = 0$	$\langle \phi_{N,f}(Q)   \phi_{N,i}(Q) \rangle$	$\Delta Q_{if} \neq 0$ : nuclear reconfiguration between $\phi_{e,f}(\mathbf{r}, Q)$ and $\phi_{e,i}(\mathbf{r}, Q)$
Between spin states	$S_i \rightarrow S_f; T_i \rightarrow T_f$	$\langle \sigma_f(S_f)   \sigma_i(S_i) \rangle$	Spin-orbit coupling Spin-spin coupling

$$N(n_i) = N(0) \exp(-n_i \hbar \omega_i / k_B T), \quad (3.81)$$

then  $N$  decreases with increasing  $n_i$ , where  $N(0)$  corresponds to the electron density of the lowest vibronic ( $n = 0$ ). Equation 3.81 implies that the most intense absorption and emission spectral features are due to excitations from the lowest vibronic level in the initial electronic state,  $S_0$ . This is known as *Kasha's rule*, and it results in approximately mirror-symmetric replicas of the absorption and emission spectra, separated by an energy shift known as the *Franck-Condon shift* or *Stokes shift*,  $\Delta FC$ . The relative intensity of each transition depends on the overlap of the wavefunctions as determined by the Franck-Condon integral, Eq. 3.79. Thus, larger nuclear coordinate shifts result in a reduction in intensity in the lowest order (i.e. 0-0) transition, which is strongest for  $\Delta Q \approx 0$ . The 0-0 transition, itself is known as the zero phonon transition. The quantized vibrational levels arise from the many intramolecular phonon modes of polyatomic molecules.

Recall that the Franck-Condon principle states that molecules relax to their equilibrium configurations following an electronic transition. Hence, *absorption occurs from the ground state into the unrelaxed* (and, therefore, higher energy) *excited state*. This rapid relaxation occurs within the time it takes the nuclei to reconfigure to their new equilibrium positions, that is, on the order of a phonon lifetime of  $10^{-12}$  to  $10^{-14}$  s. In contrast, *emission occurs from the relaxed excited state* (known as the Franck-Condon state) back to the ground state. The Franck-Condon shift corresponds to this relaxation energy. The singlet exciton energy (denoted in Fig. 3.18 as  $S_1$ ) corresponds to the energy gap,  $E_G$ , reduced by the relaxation energy that is lost due to the Coulomb binding energy ( $E_B$ ), which is the difference in energy between the excited electron and the hole left in the ground state.

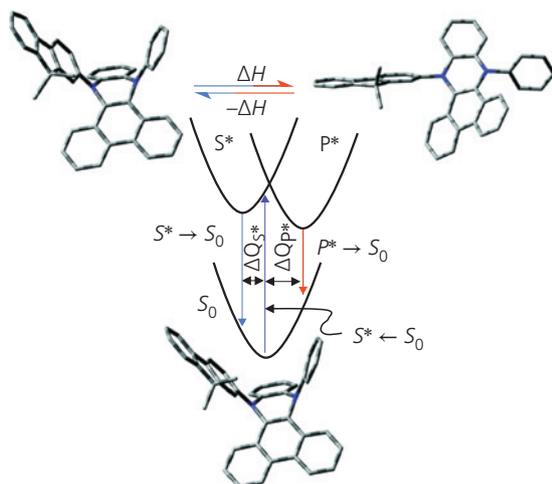

In Fig. 3.18 we use spectroscopic notation of  $S_1 \rightarrow S_0$  to denote emission, and  $S_1 \leftarrow S_0$  for absorption. In this convention, the highest energy state is

**Figure 3.18** Ground ( $S_0$ ) and first excited ( $S_1$ ) state potentials vs. the normal mode, or configuration coordinate,  $Q$ . Each vibronic level is labeled by its corresponding quantum number ( $n = 0, 1, 2, 3 \dots$ ). Emission and absorption spectra corresponding to the transitions are indicated on the left by the ascending (absorption) and descending (emission) arrows. The label for each peak indicates the vibronic quantum number of the initial and final states (i.e. in emission, 0-2 corresponds to a transition denoted as  $S_1 \rightarrow S_0$  from  $n = 0$  to 2). The Franck-Condon, or Stokes shift is labeled  $\Delta FC$ , and the configuration coordinate shift between electronic manifolds is  $\Delta Q$ .

always on the left, and the arrow points in the direction of the transition. This convention is not always rigorously followed, where the transition between the initial and final states,  $i$  and  $f$  is simply written  $i \rightarrow f$  along with an identification of the highest energy state.

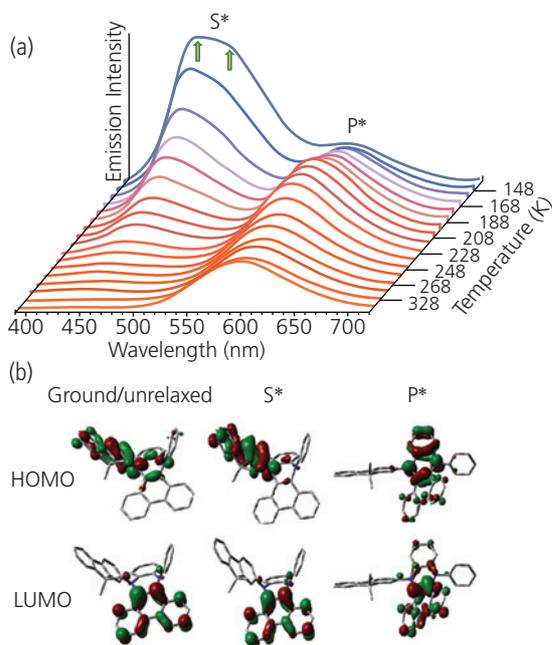

An illustration of molecular reconfiguration leading to  $|\Delta Q| > 0$  is illustrated in Fig. 3.19 for FIPAC dissolved in a solution of MeTHF. There is a dramatic configuration shift between two isomers when the temperature is changed between cryogenic and room temperature. The ground state and the high energy  $S^*$  state have a saddle like conformation. Addition of thermal energy ( $\Delta H$ ) induces an isomeric transformation into the lower energy planar  $P^*$  conformation. The conversion from  $P^*$  to  $S^*$  is reversed by cooling.

**Figure 3.19** Conversion between two structural isomers ( $S^*$  and  $P^*$ ) of FIPAC by heating ( $\Delta H$ ) or cooling ( $-\Delta H$ ). The configuration shifts ( $\Delta Q$ ) and transitions to the ground state ( $S_0$ ) are indicated. C atoms are shown in grey, N in blue. Adapted from Chen et al. (2015).

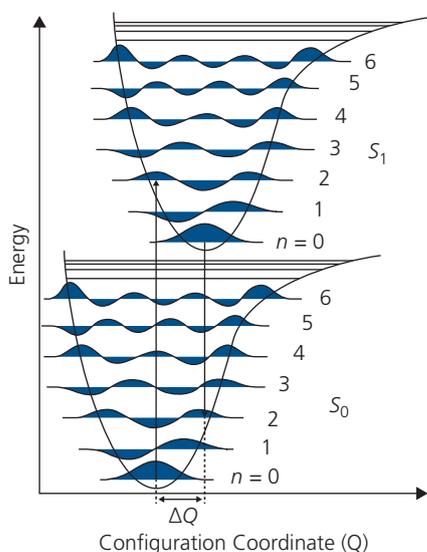

The configuration change is accompanied by a large change in nuclear coordinates that results in concomitant changes in the emission spectrum, as shown in Fig. 3.20a. The energy from the ground to the unrelaxed LUMO ( $S^* \leftarrow S_0$ ) is 3.43 eV. At room temperature, the molecule relaxes into  $S^*$ , but the small activation energy between  $S^*$  and  $P^*$  results in transfer of the excited state to  $P^*$  followed by a radiative transition at 595 nm (2.08 eV). At low temperature, the excitation is trapped in  $S^*$ , shifting the emission to 435 nm (2.85 eV). Note that the emission at  $T < 200$  K shows two clearly resolved peaks corresponding to the 0–0 and 0–1 transitions. That is, the smaller, negative configuration shift of  $S^*$  compared with the positive shift for  $P^*$  increases the overlap with the ground state, allowing for transitions to higher order ground state vibronics.

Figure 3.20b shows the electron density distributions calculated by TD-DFT using the B3LYP/6-31G\* functional. Opposite phases of the probability density are indicated by the red and green regions. Unlike nonpolar polyacenes such as PTCDA and pentacene whose HOMO and LUMO electron densities are evenly distributed across the molecular plane, the twist of FIPAC creates separate regions occupied by the frontier orbitals. The HOMO is localized on the fluorene group, apart from the LUMO on the triphenyl. Furthermore, the HOMO is largely unperturbed by transformation between the isomers. The spatial separation of the orbitals results in larger charge transfer from the HOMO to LUMO in the unrelaxed and  $S^*$  conformations compared to that in the  $P^*$  state.

**Figure 3.20** (a) Evolution of the emission spectra of FIPAC vs. temperature. Arrows show two vibronics (from left to right they correspond to 0–0 and 0–1) due to  $S^* \rightarrow S_0$  transitions. (b) DFT calculations of the HOMO and LUMO states of the unrelaxed states, as well as the  $S^*$  and  $P^*$  isomers. After Chen et al. (2015).

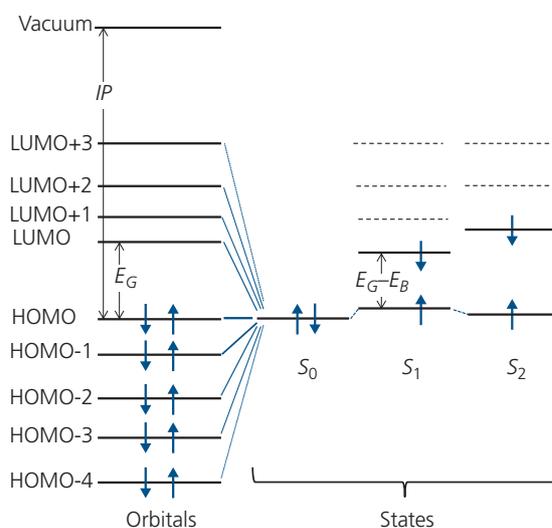

Returning to Fig. 3.18, the 0–1 transitions have the highest intensity. However, for molecules whose electronic systems are strongly coupled across a rigid molecular plane (e.g. in polyacenes such as perylene or anthracene), the 0–0 transition is often the most intense, and decreases for transitions between higher order vibronic modes. In Section 3.6.1 we will find that the strength of a transition is proportional to the magnitude of the overlap between vibronic wavefunctions in a transition between two electronic states, as expressed by  $FC_{if}$ . Figure 3.21 shows both emission and absorption transitions between  $S_1$  and  $S_2$  that are offset by a molecular reorganization of  $\Delta Q$ . Superimposed on each vibronic state is the corresponding probability amplitude of the wavefunction in the SHO approximation. The maximum overlap for the  $S_1 \leftarrow S_0$  absorption is between the  $n = 0$  vibronic in the ground state and  $n = 2$  in the first excited state. Due to the Boltzmann factor in Eq. 3.81, the ground state population is concentrated in the  $S_0, n = 0$  state; a realization of Kasha's rule. Similarly, the  $S_1, n = 0$  state also has the largest electron population after relaxation due to phonon scattering. Hence, emission in this case is most likely to the  $S_0, n = 2$  vibronic which has the largest overlap with the  $S_1, n = 0$  state (corresponding to a 0–2 transition). Both absorption

**Figure 3.21** Transitions between  $S_0$  and  $S_1$  showing the probability amplitudes of the vibronic states in each electronic manifold. Transitions are most likely where the wavefunction overlap in the  $S_0$  and  $S_1$  manifolds is highest. In this case absorption is most likely from the filled  $n = 0$  vibronic in  $S_0$  to the  $n = 2$  vibronic in  $S_1$ , and emission from  $n = 0$  in  $S_1$  to  $n = 2$  in  $S_0$ , accounting for a configuration change of  $\Delta Q$ .

and emission transitions are vertical since the photon carries very small angular momentum compared to the electron. Usually, the Frank–Condon factor decreases with increasing difference in the vibronic quantum numbers,  $n$ , between the initial and final states, resulting in a lower transition probability, and hence a concomitant decrease in spectral intensity. However, this is by no means always the case for molecules that are less rigid (and hence undergo a larger  $\Delta Q$ ), or of higher molecular weight. The intensity may be *borrowed* from one vibronic by another (Orlandi and Siebrand, 1973), creating a progression of vibronic overtones on the electronic absorption or emission spectra whose intensities are due simply to the value of the corresponding Franck–Condon integrals in Eq. 3.79.

At this point, we need to clearly distinguish between electronic orbitals as represented in Fig. 3.7, and electronic states in Fig. 3.18. Orbitals refer to energies of electrons and holes referenced to vacuum, as shown in Fig. 3.22. That is, the HOMO and LUMO energies are all negatively disposed relative to the vacuum level since these represent the energies of charges bound to a molecule. The energy needed to remove an electron from the HOMO is the *ionization potential*,  $IP$  (see Section 3.6). In contrast, *states* refer to Coulombically bound electrons in the relaxed HOMO and LUMO levels that, according to the LCAO model,

**Figure 3.22** Reconciling the differences between the electron orbital picture and that of electronic states. A state is comprised of a linear combination of orbitals, with the nearest orbital having the greatest influence. In this case, we show that the ground,  $S_0$  state is a superposition of the HOMOs, with lesser influence from the empty LUMO levels. The  $S_1$  and higher excited states are primarily determined by the LUMOs. The diagonal lines represent the relative contributions of the orbital energies to  $S_0$ , whose strengths are suggested by the boldness of the lines. While orbital energies are referenced to vacuum, states are not.  $S_1$  is comprised of one half filled HOMO orbital and one half filled LUMO.  $S_2$  is similar to  $S_1$  except the Coulombically shifted LUMO+1 is now half filled. The shifts of the state energies relative to the orbitals (dashed lines in  $S_1$  and  $S_2$ ) are indicated. Here,  $E_G$  = energy gap,  $E_B$  = binding energy between the excited electron and the hole in the ground state, and  $IP$  = ionization potential energy.

are comprised of a linear superposition of all the other relaxed orbitals in the molecule. State energies are referenced relative to each other (i.e.  $S_0$  to  $S_1$  in Fig. 3.18), and hence it does not make sense to position the state diagram relative to the vacuum level. As a consequence, states and orbitals cannot be accurately represented on the same diagram, although when referring to device energy level diagrams it is often convenient to do so, as we will see in Part II.

As above, the state, or exciton energy is given by

$$E_X = E_G - E_B. \quad (3.82)$$

In the solid, both free charges (i.e. polarons) and excitons are free to move from molecule to molecule.

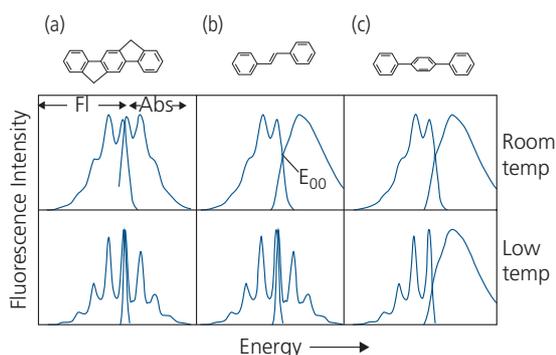

Perturbation theory implies that the influence of orbitals to a particular state decreases with the energy difference on that state. Hence, the principal contribution to the ground, or  $S_0$  state is due to the HOMO level, with diminishing contributions from states HOMO  $- i$  as  $i$  is increased from 1 to 2 to 3, etc. Similarly, the first excited state  $S_1$  consisting of one electron in the relaxed HOMO and a second in the

relaxed LUMO has a major contribution from the LUMO, with decreasing influence from LUMO +  $i$  as  $i$  increases.

A distinction between charges occupying energy levels and excitons is that while charges have spins equal to  $\frac{1}{2}$ , states are comprised of two or more spins whose combination results in the state spin multiplicity (e.g. singlets, triplets, quintets, etc.). These multiplicities are denoted by  $S$ ,  $T$ , and  $Q$ , respectively.

Figure 3.23 shows examples of the emission and absorption spectra of three molecules of varying stiffness and conjugation lengths. We notice that the absorption energy is higher than the fluorescence emission energy, with a crossing of the spectra at the *adiabatic transition energy*,  $E_{00}$ . This is often taken as equal to the energy gap,  $E_G$ , between the HOMO and LUMO energies. The absorption spectra show well-resolved vibronic progressions at low temperature that are considerably broadened at room temperature, particularly for the molecules that have multiple rotational or vibrational degrees of freedom (Fig. 3.23b and c). One reason that the vibronics in the fluorescence spectra are poorly resolved at high temperatures is that their inter-ring bonds are shortened in the excited state, resulting in a closer overlap between higher frequency vibronics and rotational modes. At low temperatures, many of these modes are “frozen out,” which results in spectral line narrowing.

The vibronic progression is often dominated by the highest energy phonon mode, which in the polyacenes and related compounds is due to the C–C stretch. An example of vibronic progressions in the mirror-symmetric absorption and fluorescence spectra at low temperature is shown for DBP in Fig. 3.24.

**Figure 3.23** Fluorescence (FI) and absorption (Abs) spectra of three molecules with different degrees of conjugation and stiffness at two different temperatures. (a) Ladder-type oligophenylene, (b) diphenylvinylene, (c) triphenylene.  $E_{00}$  is the adiabatic transition energy. From Gierschner et al. (2007).

The ability to resolve individual vibronic features in the fluorescence (or photoluminescence) and absorption spectra increases with decreasing temperature. In addition, there is a *hypsochromic* (blue) shift in  $E_{00}$  with increasing temperature, and the intensity of the 0–1 PL peak increases relative to the 0–0 (highest energy) emission peak at room temperature. The nearly featureless PL spectrum at  $T = 300$  K is due to thermal broadening of the many intramolecular vibrational, rotational and intermolecular librational features that allows for greater intensity borrowing between the substates, consistent with Eq. 3.81. Also, the room temperature PL spectral intensity is approximately 5% of that at low temperature since non-radiative exciton decay competes with radiative decay with increasing temperature. The energetic separation between vibronics,  $\Delta E = E_{0-n} - E_{0-(n+1)} \approx 0.1$  eV, corresponds to the C–C stretch mode. The absorption feature at wavelengths  $< 350$  nm is due to  $S_2 \leftarrow S_0$  transitions.

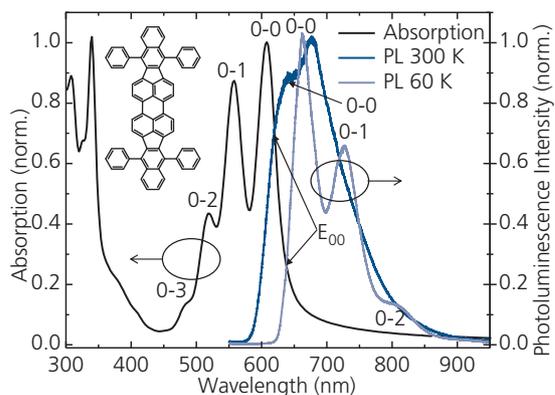

The relationship between unrelaxed excited and ground states is shown in Fig. 3.25. Here,  $\Delta E_{eq}$  is the lowest equilibrium energy within a particular manifold (corresponding to the energy of the lowest,  $n_l = 0$  vibronic) relative to the electronic energy state minimum. We have the following relations for the unrelaxed, vertical electronic transition energies:

$$E_{vert}(\text{Abs}) = E_{00} + \Delta E_{eq}(\text{Abs}) \quad (3.83a)$$

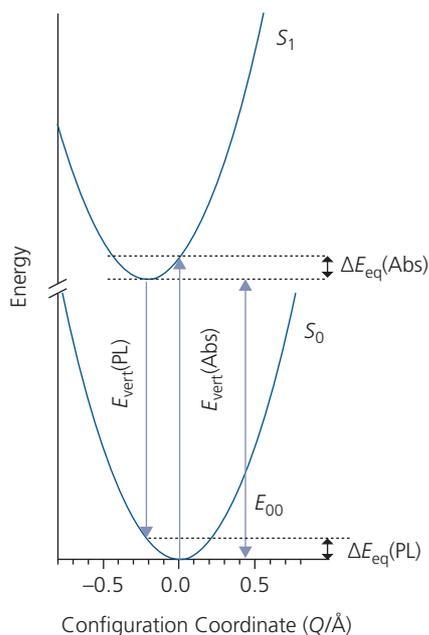

and

$$E_{vert}(\text{PL}) = E_{00} + \Delta E_{eq}(\text{PL}) \quad (3.83b)$$

with  $\Delta E(\text{PL}) \approx \Delta E(\text{Abs})$ , where PL and Abs denote emission and absorption transitions, respectively

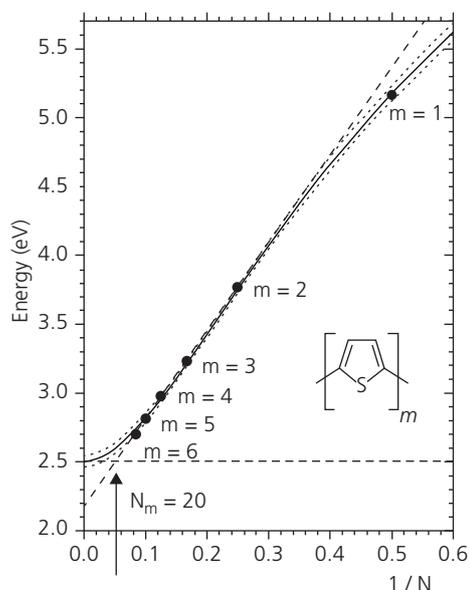

**Figure 3.24** Absorption at 300 K, and fluorescence (or photoluminescence, PL) at 60 K and 300 K spectra of DBP shown in the inset. The labeling of each peak provides the vibronic quantum numbers for a particular transition. The intensity distribution, energies and line broadening of the vibronics are strongly temperature dependent.

**Figure 3.25** Relationship between energies of the unrelaxed ground ( $S_0$ ) and excited ( $S_1$ ) molecular states (Gierschner et al., 2007).

That is, the lowest (0–0) transition is approximately equal to the energy difference between vibronics at the bottom of the  $S_0$  and  $S_1$  energy surfaces and the vertical transition energy.

While this analysis has been developed for monomeric species, with some important modifications it can also accurately provide the emission and absorption spectra of polymers consisting of a chain of individual monomers of indeterminate number. The lowest energy for a single monomer in the chain is  $E_{00}$ . However, as the chain lengthens to more than a single unit, the conjugation length also increases, resulting in accessing even lower energies of the more spatial extended states. The conjugation length corresponds to the extent of the  $\pi$ -electron system that is supported by a chain of alternating single and double C–C bonds. Thus, the long wavelength (low energy) absorption cut-off energy,  $E_0 < E_{00}$ , now corresponds to excitation of the longest continuous electronic conjugation length of the chain. This length is set by the mean spacing of defects in the chain structure that ultimately limit the spatial extent of the excited state. Defects can arise from intrinsic, thermodynamically-induced irregularities in the chain structure (e.g. due to rotation between adjacent units), or they may be of extrinsic origin (e.g. due to a kink, impurity, contact with another molecule, or other inhomogeneity along the chain).

**Figure 3.26** Lowest absorption energy of a series of thiophene oligomers as a function of the number of monomer segments,  $m$ . The extrapolated energy (diagonal dashed line) for  $m \rightarrow \infty$  is lower than the actual lowest energy shown by the horizontal dashed line that corresponds to the number of double bonds in a chain ( $N_m = 20$  corresponding to  $m = 10$ ). The solid line is a fit to a simple harmonic oscillator model (see text), with dotted lines at the 95% confidence level (Gierschner et al., 2007).

The dependence of absorption energy on the number of monomer units comprising a thiophene oligomer is shown in Fig. 3.26, which gives the equilibrium (lowest) energy as a function of the total number of double bonds ( $N$ ) in the oligomer. Each thiophene monomer unit ( $m = 1$ ) contains two double bonds, corresponding to  $N = 2$ . In this case,  $E_{00} = E_0 = 5.2$  eV. As  $m$  increases, the relationship between  $E_0$  and  $1/N$  is nearly linear, until  $m \geq 10$  ( $N \geq 20$ ), at which point the equilibrium energy reaches an asymptote of  $E_0 = 2.5$  eV (horizontal dashed line).

The dependence of  $E_0$  on  $N$  can be estimated by assuming that each monomer is a SHO consisting of double bonds that are coupled by a force constant,  $k_0$ . Then the energy of the normal modes of the  $i$ th unit in the polymer is given by  $\varepsilon = \hbar\sqrt{k_0/m_i^*}$ , where  $m_i^*$  is the reduced mass:

$$\frac{1}{m_i^*} = \frac{1}{m_c^*} + \frac{1}{m_h^*}, \quad (3.84)$$

and  $m_c^*$  ( $m_h^*$ ) is the effective mass of the electron (hole). For a chain of  $N$  double bonds, the equilibrium energy is then given by

$$E_0 = \varepsilon \sqrt{1 - 2 \frac{k_N}{k_0} \cos\left(\frac{\pi}{N+1}\right)}, \quad (3.85)$$

where  $k_N \sim 0.4k_0 > 0$  is the force constant of the total of  $N$  oscillatory modes, which can be extracted from the energy obtained from an infinitely long ( $N \gg 20$ ) chain (Kuhn, 1948). A fit of the harmonic oscillator model to the data for the thiophene oligomers in Fig. 3.26 is indicated by the solid line. The fit is reasonably predictive for shorter chain lengths, and importantly, the cosine functional behavior results in a minimum energy of 2.5 eV for a polymer of infinite length, suggesting that the limited conjugation length is indeed an intrinsic property of these molecular species.

We conclude that the maximum conjugation length in polythiophenes is limited to only 10 or fewer molecular units. This is, in general, true of most highly pure polymers: thermodynamic or structural defects limit the effective conjugation length of the molecule to only ten or so individual monomeric units. This results in a lowest energy transition that is considerably higher than the minimum  $E_{00} = 2.2$  eV for polythiophene obtained by linear extrapolation of the data in Fig. 3.26.

The electron density distribution along the polymer backbone under both ideal (i.e. completely straight and rigid) as well as more realistic chain configurations where defects, folds or torsional stresses can impact the extent of the electronic system, is illustrated for polyoligoenes in Fig. 3.27. The mean electron-hole spatial separation along the polymer backbone,  $\langle r_{eh} \rangle = |i - j|$ , calculated using DFT is plotted vs. the length of the oligoene,  $L$ , in units of the number of carbon bonds. The electron is located on polymer site  $i$  and the hole on site  $j$ . In the ideal case, the effective conjugation length (equal to  $\langle r_{eh} \rangle$ ) is  $5.1L$ , which is reached when  $L > 40$ . That is, the asymptotic conjugation length is achieved only when the ends of the chain are well removed from the excitation such that edge interactions no longer influence the electron distribution of the excited state. The size of the excited state is further reduced when the chain is twisted, as shown when the torsional deviation is less than  $\theta_{\max} = 9^\circ$  and  $21^\circ$ , resulting in  $\langle r_{eh} \rangle = 4.9L$  and  $4.4L$ , respectively.

The electron probability distributions ( $P_{i,j}$ ) in the lower insets of Fig. 3.27 show the first three excited states. The fact that the probability of finding the electron and hole confined in a narrow strip spread out only slightly along the diagonal indicates that the effective separation between them is small, even for

very long and perfect chains. This calculation also shows the nodes of the electron probability density that suggests a particle confined along a one dimensional (quantum wire) potential defined by the oligomer backbone.

From elementary quantum mechanics, the confined wavefunctions follow:

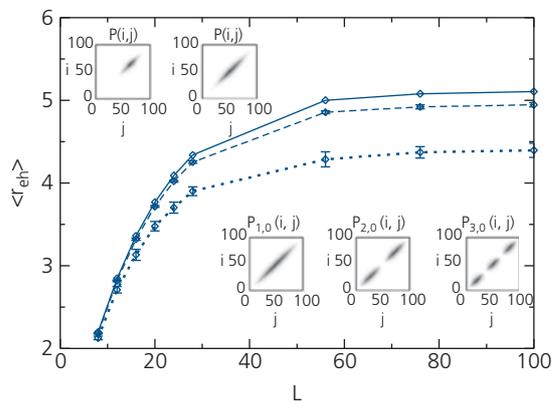

$$\phi_{e,l} = \sqrt{\frac{2}{L}} \sin\left(\frac{l\pi x}{L}\right) \quad (3.86)$$

with energies

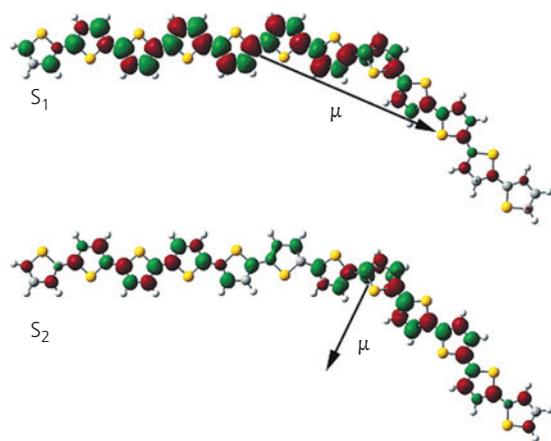

$$E_m(L) = \frac{(l\pi\hbar)^2}{2m_r^*L^2}, \quad (3.87)$$

where  $l$  is an integer. To first order, the  $1/L^2$  dependence of the energy on the number of polymer units, such as in poly-*p*-phenylenevinylene, is observed until the number of carbon bonds approaches the limit of  $L = 1$ . Then, the lowest absorption energy edge approaches the adiabatic transition energy,  $E_{00}$ , of the monomer.

The electronic density is even more spatially confined for polymers containing torsional defects, as seen in the upper insets in Fig. 3.27, with greater confinement occurring for a larger maximum torsional angle,  $\theta_{\max}$ . Confinement is shown by the electronic distributions in the first two excited states of a thiophene oligomer containing a kink in Fig. 3.28. The kink decreases the effective conjugation length with the higher excited state more confined than the lower.

**Figure 3.27** Calculated first excited state electron-hole separation,  $\langle r_{eh} \rangle$ , along a polyoligoene molecule vs. the chain length ( $L$ ) in units of C-C bonds. A defect free chain (solid line), is compared to one with a maximum torsion angle along the chain of  $\theta_{\max} = 9^\circ$  (dashed line) and  $\theta_{\max} = 21^\circ$  (dotted line). *Lower insets*: Electron probability density along  $i$  and hole density along  $j$ , for (left to right) the first, second, and third excited states of a defect-free oligomer. *Upper insets*: (left) A chain with  $\theta_{\max} = 21^\circ$ , and (right)  $\theta_{\max} = 9^\circ$  (Rissler, 2004).

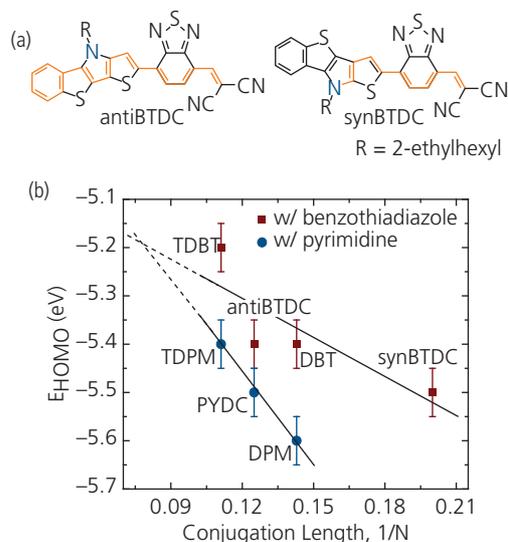

**Figure 3.28** Electron densities for the  $S_1$  and  $S_2$  states in a horizontally kinked oligomer, dodecithiophene. Also shown are the molecular transition dipole moment vectors,  $\mu$  (Beenken and Pullerits, 2004).

The kink itself does not perturb the distribution sufficiently to prevent electronic leakage beyond the position of the defect.

Similar dependences on conjugation length (i.e. the extent of the electron system) have been observed in a class of small molecules that are used in high efficiency organic photovoltaics. The design of these molecules follows a donor–acceptor–acceptor' motif, where there is a single electron donating (i.e. electron deficient) moiety (the d-group), followed by two electron accepting (i.e. electron rich) groups labeled a and a'. Two isomers of the archetype d-a-a' molecule, BTDC are shown in Fig. 3.29a, with the electron conjugation path traced in orange. The synBTDC isomer has a shorter conjugation length than antiBTDC due to *cross conjugation*. That is, the transposition of the two thiophene groups in the d-moiety in synBTDC breaks the conjugation path. The HOMO energy ( $E_{HOMO}$ ) corresponding to the ionization potential of a series of heterotetracene-based d-a-a' donors containing a benzothiadiazole or pyrimidine central electron-withdrawing block that bridges the a' unit of dicyanovinylene, and an electron-donating dithieno[3,2-b:2',3'-d]pyrrole (DTP) group is plotted vs. the inverse of the conjugation length,  $1/N$ , in Fig. 3.29b. Here,  $N=5$  to 9 is defined as the number of double bonds along the shortest path connecting the terminal carbon atoms of the backbone. Since the LUMO energies of this molecular series are all approximately equal, the energy gap scales approximately with  $E_{HOMO}$  (Gierschner et al., 2007)

The group of molecules with benzothiadiazole is shown by squares, while those with pyrimidine are

**Figure 3.29** (a) Molecular formulae of the d-a-a' type molecules antiBTDC and synBTDC. The orange line traces the electron conjugation path along the molecular backbone. (b) HOMO energy vs. the number of conjugated bonds along the d-a-a' backbone. The two sets of data correspond to molecules bridged by either a benzothiadiazole or pyrimidine group (Che et al., 2016).

shown by circles. For both molecular groups a linear relationship is observed between  $E_{HOMO}$  and  $1/N$ : the longer conjugation (smaller  $1/N$ ) leads to more extended  $\pi$ -electron delocalization, resulting in red-shifted absorption (and hence a reduced  $E_G$ ) and a shallower HOMO. With reduced aromaticity, the molecules with pyrimidine generally exhibit a larger energy gap and deeper HOMO than their benzothiadiazole counterparts with the same  $N$  (PYDC-antiBTDC; DPM-DBT; TDPM-TDBT), and their HOMO levels are more sensitive to the change of molecular conjugation as indicated by the larger fitted slope. The crossing point of the two fits at  $N = 13$  indicates an upper limit of  $E_{HOMO} = -5.2$  eV. Similar to the polymers discussed above, extended small molecules are subject to kinetically induced disruptions (e.g. twist or kinks) in the backbone, limiting the spatial extent of the orbitals in excited state. Nevertheless, further tuning of  $E_{HOMO}$  may be possible for  $N > 9$ .

From the foregoing, we see that the Born–Oppenheimer and Franck–Condon approximations are essential for interpreting electronic transitions in both small molecules and polymers. To simplify our analysis, we have intentionally neglected all but the most dominant vibronic modes corresponding to the high energy C–C bond stretch. The remaining degrees of freedom of a molecule appear as features corresponding to lower energy vibronic and

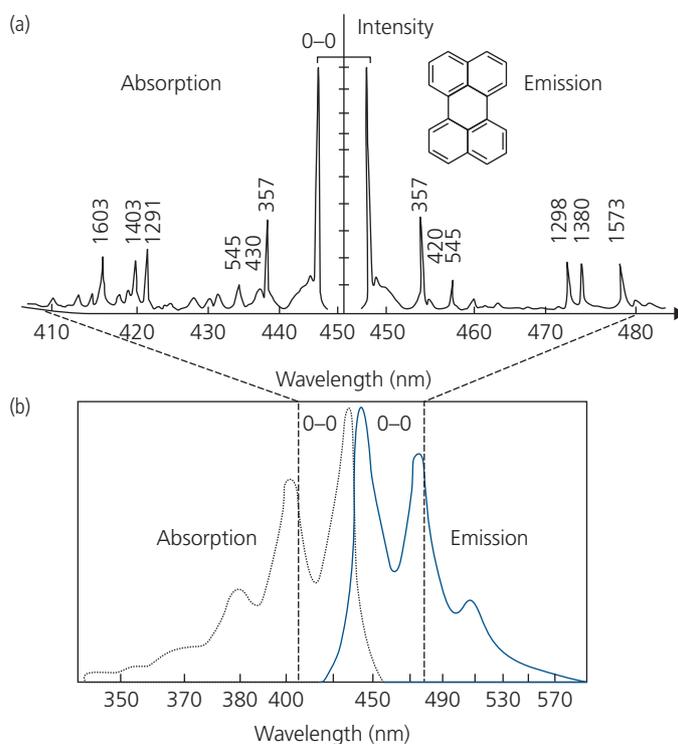

rotational intramolecular phonon modes (10–100 meV, typical), as well as by very low energy intermolecular libratory modes (1–10 meV). These finer spectral features are typically masked by *inhomogeneous thermal line broadening* that resolve into separate absorption or emission lines only at very low temperature. The low and room temperature absorption and emission spectra of perylene in Fig. 3.30a and b provide a dramatic illustration of inhomogeneous broadening. As temperature is decreased, the various modes are distinguishable as narrow, homogeneously broadened features.

Possible transitions in singly charged molecules are shown in Fig. 3.31. Charged molecules can be either *cationic* (positive) or *anionic* (negative), with transitions occurring from *singly occupied molecular orbitals* (SOMOs). To observe these transitions, the molecule must be prepared in a charged state by charge injection, or by doping with a second electron donating or accepting species. This corresponds to *oxidation* or *reduction*, respectively (cf. Section 4.4.1). That is, if a dopant is introduced whose LUMO is lower than the HOMO of the subject molecular species, an electron can transfer from its HOMO to that of the dopant,

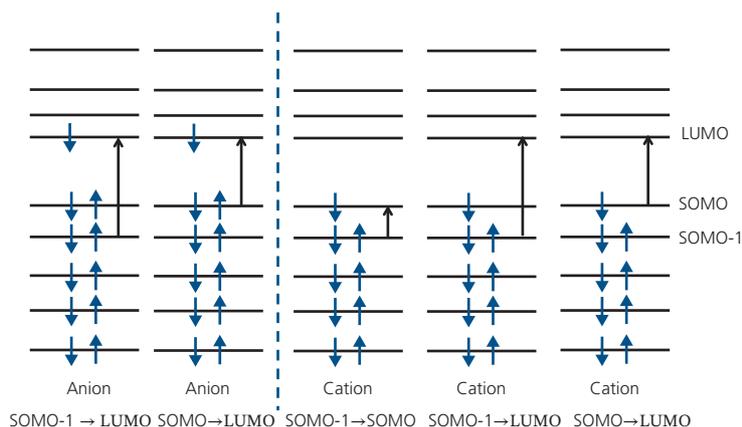

thereby oxidizing the molecule. Conversely, reduction occurs when the HOMO energy of the dopant is sufficiently high that it donates an electron to the LUMO of the host molecule. By a similar mechanism, ionic species such as the alkali metals, Na or K, serve as strong reductants, or the halogens Cl or F can serve as oxidants when doped into an organic material.

Charged PAHs have been a subject of considerable interest for understanding their optical and conducting properties (Shida and Iwata, 1973). In fact, charged PAH spectra found in interstellar space have been identified by their spectra (Halasinski et al., 2000). Low temperature (4.2 K) near infrared (NIR) spectra from both cations and anions of pentacene in solid Ne are shown in Fig. 3.32a. The radical molecular species are formed by exchanging charge with Na and K atoms that are co-deposited with pentacene in the inert gas matrixes. The cationic and anionic transitions are labeled by (+) and (–), respectively.

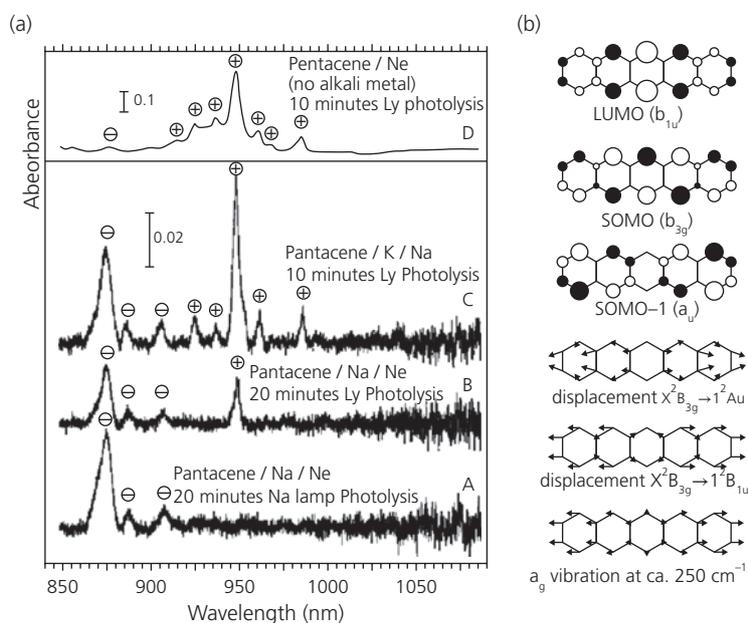

The lowest excited state neutral pentacene transitions are centered around 525 nm. Irradiating the pentacene/Na mixtures with a Na lamp ionizes the alkali metal which donates an electron to form

**Figure 3.30** (a) Mirror symmetric, low temperature ( $T = 4.2$  K) absorption and emission spectra of perylene in an *n*-hexane solution. The narrow peaks are due to discrete phonon modes. The energies (in wavenumbers) of each mode are indicated (Gribov and Orville-Thomas, 1988). Inset: Molecular structural formula of perylene. (b) The modes merge to form inhomogeneously broadened spectral features at room temperature. The dominant 0–0 transitions are indicated.

**Figure 3.31** Several example transitions from singly occupied molecular orbitals (SOMOs) from anionic and cationic molecules.

**Figure 3.32** (a) Absorption spectra of pentacene anions (–) and cations (+) in solid Ne. The pentacene radicals are formed by photolysis in the presence of ionized Na or K. Light sources used in catalysis are Na or high energy Lyman- $\alpha$  illumination. (b) TD-DFT calculations of the LUMO and SOMO levels of pentacene (top), and several high energy stretching modes (bottom three diagrams). The state symmetries are noted below each diagram (Halasinski et al., 2000).

pentacene anions (Fig. 3.32a, spectrum A). Irradiation by the 10.2 eV Lyman- $\alpha$  line from a hydrogen lamp is sufficient to directly ionize the pentacene, giving rise to a series of long wavelength features apparent in spectra B and C. The direct ionization of pentacene is confirmed by Lyman- $\alpha$  illumination of pentacene in the absence of Na or K where both cation and anion features are apparent.

Comparing the measured spectra to simulations (Halasinski et al., 2000), the feature at 979.3 nm in Fig. 3.32a is assigned to the cationic LUMO  $\leftarrow$  SOMO ( $1^2B_{1u} \leftarrow X^2B_{3g}$  in spectroscopic notation) transition,

whereas the transition at 943.9 nm is assigned to the SOMO  $\leftarrow$  SOMO-1 ( $1^2A_u \leftarrow X^2B_{3g}$ ) transition.

Simulation results are illustrated by the electron density distributions of the LUMO, SOMO, and SOMO-1 orbitals in Fig. 3.27b. The opposite phase of the probability amplitudes are indicated by the filled and open circles, and the magnitude of the wavefunction is represented by their diameters. The anionic satellite features are separated from the parent excitations by  $250 \text{ nm}^{-1}$ . These correspond to the progression of higher order  $a_g$  vibronic stretching modes, illustrated in the bottom panel of Fig. 3.32b. The

vibronics manifest themselves as symmetric stretching modes of the transitions in the SOMO-1 and SOMO states shown immediately above. Similarly, the anionic modes at 904.0 nm and 872.6 nm are identified with  $\text{SOMO} \leftarrow \text{SOMO} - 1$  and  $\text{LUMO} \leftarrow \text{SOMO}$  transitions, respectively, with the secondary peak at 883.8 nm due to the  $a_g$  vibronic.

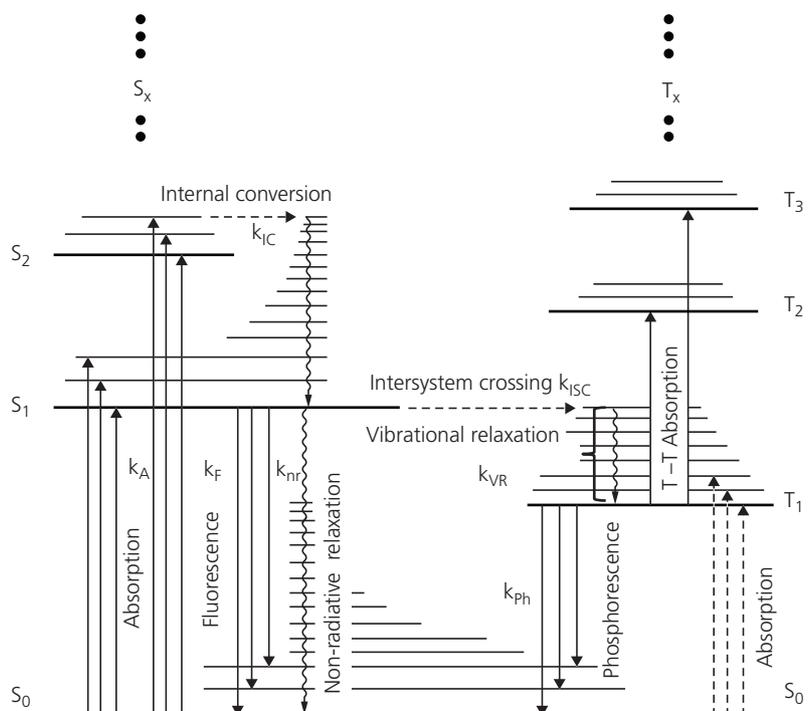

### 3.6 Excitons

Thus far, we have been concerned only with isolated molecules. However, when the molecules are condensed into solids, the excited states can diffuse from molecule to molecule. These mobile excited states are referred to as excitons, whose properties dominate the optical characteristics of organic electronic materials. An exciton is a quasiparticle that can transport energy (i.e. the molecular excited state) between molecules. Since it carries no charge, its motion is not influenced by external electric fields. Given their central role in transporting energy in organic materials, the remainder of this chapter will be concerned with excitonic properties in dielectric media, their spin characteristics, and exciton diffusion.

The relationship between excited states, spins, vibronic levels and the transition processes between

the states is illustrated by the *Jablonski diagram* (Jablonski, 1933) in Fig. 3.33. The ground state is nearly always a singlet, and hence is denoted  $S_0$ . The most common source of emission is known as *fluorescence* (subscript, F). It arises from spin-conserving transitions from the singlet manifolds to the ground state, that is, via  $S_1 \rightarrow S_0$ ,  $S_2 \rightarrow S_0$ , as well as  $T_2 \rightarrow T_1$ , for example. The process of *phosphorescence* (subscript, Ph) is spin forbidden since it originates via a transition from the spin-symmetric triplet ( $S = 1$ ) manifold, typically the  $T_1$  state, to  $S_0$ , violating the conservation of spin angular momentum (Table 3.1). In the absence of other decay processes, weak phosphorescence can be observed due to its very small transition rate,  $k_{Ph}$ .

Note that the energy of  $T_1$  is lower than  $S_1$ , as is the case of all triplet and singlet states within the same energy manifold (i.e.  $T_2 < S_2$ ,  $T_3 < S_3$ , etc.). This is understood in terms of the spinorbital wavefunctions in Eqs. 3.2 and 3.3. For triplet states, the spatial part of the wavefunction is antisymmetric. Thus, as the two electrons converge (i.e.  $\mathbf{r}_1 \rightarrow \mathbf{r}_2$ ), the spatial wavefunction gives  $\phi_a(\mathbf{r}_1)\phi_b(\mathbf{r}_2) - \phi_a(\mathbf{r}_2)\phi_b(\mathbf{r}_1) \rightarrow 0$ . On average, therefore, the electrons are located far apart, reducing Coulomb repulsion, compared to singlet states where  $\phi_a(\mathbf{r}_1)\phi_b(\mathbf{r}_2) + \phi_a(\mathbf{r}_2)\phi_b(\mathbf{r}_1) \rightarrow \text{large}$  as  $\mathbf{r}_1 \rightarrow \mathbf{r}_2$ . Due to

**Figure 3.33** Jablonski diagram for a molecular system showing the lowest energy singlet ( $S$ ) and triplet ( $T$ ) manifolds, along with vibronic levels in each manifold and the several possible transition processes. Here,  $k$  are the rates for each process, with each subscript referring to a specific transition. Adapted from McGlynn et al. (1969).

the reduced Coulomb repulsion, therefore, triplets lie at lower energies (typically between 0.5 eV and 1.0 eV) than singlets. Energies differ by the magnitude of the exchange integral (see Eq. 3.49).

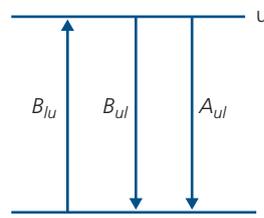

While  $T \rightarrow S$  transitions are forbidden, transitions within the triplet manifold, viz.  $T_i \rightarrow T_f$  have  $\Delta S = 0$ , and therefore are allowed. Transitions between triplet and singlet manifolds result from *intersystem crossing* (ISC), and can be exothermic, endothermic or isoenergetic. Clearly, this type of transition requires an increase or decrease in spin angular momentum, and hence is not simply mediated by a single photon. A spin conserving transition between electronic states is known as *internal conversion* (IC). *Vibronic relaxation* (VR) results in the decay of an excitation from a higher to a lower vibronic within a particular electronic state manifold. Vibronic relaxation occurs via the emission of one or more phonons (i.e. vibrational modes) within the molecule. Alternatively, absorption of a phonon can result in the promotion from a lower to higher vibronic state. Finally, *non-radiative relaxation* (NR) occurs from either the singlet or triplet state to the ground state,  $S_0$ . In the Jablonski diagram, the transitions are characterized by their respective rate constants,  $k$ , using the appropriate identifying subscript.

While the ground state is almost always a singlet, under unusual conditions it can in fact be a triplet state. If the ground state is filled but is doubly degenerate (or nearly degenerate), two electrons of the same spin can be shared between the degenerate states without violating the Pauli Exclusion Principle. The property of “near degeneracy” allows for equal populations of both states at or below room temperature. While possible, triplet ground states exist only in rare instances, and will not be considered further.

### 3.6.1 Transition probabilities, oscillator strength, and the energy gap law

The Jablonski diagram delineates the various available transition pathways. To determine the strength of a particular transition (and hence its prominence in the molecular spectrum) we must calculate its transition probability. For this, we need the *Einstein coefficients* for *spontaneous absorption*, *spontaneous emission* and *stimulated emission*, see Fig. 3.34. Now the Einstein coefficient for spontaneous absorption,  $B_{lu}$ , can be written in terms of the transition probability from the lower ( $l$ ) to the upper ( $u$ ) state (Hilborn, 1982):

$$B_{lu} = \frac{q^2 \pi}{3\epsilon_0 \hbar^2} |\langle \phi_l | \mathbf{r}_n - \mathbf{r}_m | \phi_u \rangle|^2 = \frac{\pi}{3\epsilon_0 \hbar^2} |\mu_{lu}|^2, \quad (3.88)$$

**Figure 3.34** Einstein coefficients for spontaneous absorption ( $B_{lu}$ ), spontaneous emission ( $A_{ul}$ ), and stimulated emission ( $B_{ul}$ ) for a two-level system whose upper ( $u$ ) and lower ( $l$ ) levels are indicated.

where, as in Eq. 3.76, the wavefunctions in the electric dipole approximation include both electronic and nuclear contributions. The latter are labeled  $n$  in the lower, and  $m$  in the upper electronic state. Here, we have assumed that the degeneracy,  $g$ , of final ( $u$ ) and initial states ( $l$ ) is the same. If this is not the case, Eq. 3.88 is multiplied by their ratio,  $g_u/g_l$ .

Now, Einstein showed that  $B_{lu,um}$  is related to the coefficient for absorption,  $A_{um,ln}$  via (Yariv, 1989):

$$A_{um,ln} = \frac{\hbar}{\pi^2} \left( \frac{\omega n_r}{c} \right)^3 B_{lu,um}, \quad (3.89)$$

where  $n_r$  is the refractive index of the medium. (Note that care needs to be taken when writing these coefficients in terms of angular frequency,  $\omega$ , frequency,  $\nu$ , or wavenumber,  $\tilde{\nu} = \nu/c$ . In Eq. 3.88 and 3.89,  $B_{lu,um}$  is written in terms of the angular frequency.) The total radiative lifetime ( $\tau_R$ ) is equal to the sum of  $A_{u0,ln}$  over all vibronic levels in the initial and final electronic states. We also apply Kasha’s rule by assuming all transitions occur from the lowest ( $m = 0$ ) vibronic in the excited state, while it can access a large number of final states,  $n$ . Then,

$$\tau_R^{-1} = \sum_m A_{u0,ln}. \quad (3.90)$$

Comparing Eqs. 3.89 and 3.90, we find that the radiative lifetime can also be obtained from the absorption spectrum of the molecule. For this, we integrate over the populations in the initial and final states:

$$\tau_R^{-1} = \frac{8\pi^2 n_r^3}{3\epsilon_0 \hbar c^3} \sum_m \nu_{u0,ln}^3 |\mu_{u0,ln}|^2, \quad (3.91)$$

where we have replaced  $\omega$  with frequency,  $\nu$ , for convenience in analyzing the measured spectra. To complete our treatment, we weight each contribution by a Boltzmann factor to account for the probability of finding an electron in the initial state.

The time averaged incident power on a molecule is called the *irradiance*,  $I_{inc}$ . From electromagnetic theory,

the irradiance due to an electric field of amplitude,  $F$ , is given by:

$$I_{inc} = \frac{1}{2} c \epsilon_0 F^2 = \int i(\omega) d\omega, \quad (3.92)$$

where  $i(\omega)$  is the incremental irradiance between frequencies  $\omega$  and  $\omega + d\omega$ . Since  $B_{ln,um}$  is the probability for absorbing a photon, and taking  $\rho(\omega)$  as the energy density of the incident photon field, then the incremental power per unit area absorbed within the length,  $dx$ , by  $N_l$  atoms populating the lower level is

$$dI_a = \hbar\omega B_{ln,um} N_l \rho(\omega) \gamma(\omega) d\omega dx, \quad (3.93)$$

where  $\gamma(\omega)$  is the normalized lineshape function defined by  $\int \gamma(\omega) d\omega = 1$ . Thus, within a wavelength interval,  $d\omega$ , we rewrite Eq. 3.93 in terms of  $i(\omega)$ :

$$\begin{aligned} \frac{1}{i(\omega)} \frac{di}{dx} &= -\hbar\omega n_l n_i B_{ln,um} \gamma(\omega) / c \\ &= -n_l n_i \sigma(\omega) = -a(\omega), \end{aligned} \quad (3.94)$$

where  $n_l$  is the number density of molecules in the lower level, and  $a(\omega)$  is the absorption coefficient. We thus define the normalized absorption cross section in terms of  $B_{ln,um}$  from Eq. 3.94:

$$\sigma(\omega) = \hbar\omega B_{ln,um} \gamma(\omega) / c. \quad (3.95)$$

Finally, we can express the Einstein  $B$ -coefficient using the absorption cross section:

$$B_{ln,um} = \frac{c}{\hbar n_r} \int \frac{\sigma(\omega) d\omega}{\omega}, \quad (3.96)$$

where the lineshape is now included in  $\sigma(\omega) = \sigma_0 \gamma(\omega)$ . For experimental convenience, we can replace the cross-section with the light frequency-dependent *decadic molar extinction coefficient* (in units of  $1 \text{ cm}^{-1} \text{ M}^{-1}$ ) as a function of frequency,  $\epsilon(\nu)$ , in which case we write

$$B_{in,fm} = \frac{2303}{N_A n_r} \frac{c}{h} \int \frac{\epsilon(\nu) d\nu}{\nu}, \quad (3.97)$$

where  $N_A$  is Avogadro's number. The factor, 2303, arises since the irradiance,  $I(0)$  incident on a sample with absorption coefficient,  $a(\nu)$ , will decrease to  $I(d)$  after travelling a distance,  $x$  (cf. Eq. 3.94):

$$I(d) = I(0) e^{-a(\nu)x}. \quad (3.98)$$

This is known as the *Beer–Lambert law*. Here,  $a(\nu) = \ln 10 \epsilon(\nu) C = 2.303 \epsilon(\nu) C$ , and  $C$  is the concentration of the molecule in solution (units of  $[M/l]$ ).

The radiative rate is given by the *Strickler–Berg expression* (Strickler and Berg, 1962):

$$\tau_R^{-1} = 8\pi n_r^3 \hbar \langle \tilde{\nu}^{-3} \rangle^{-1} B_{ln,um} = \frac{9212 n_r^2 c}{N_A} \langle \tilde{\nu}^{-3} \rangle^{-1} \int [\epsilon(\tilde{\nu}) \tilde{\nu}] d\tilde{\nu}, \quad (3.99)$$

where the average transition frequency,  $\langle \tilde{\nu}^{-3} \rangle$  is obtained by integration over the measured spectral intensity, via

$$\langle \tilde{\nu}^{-3} \rangle = \frac{\int \tilde{\nu}^{-3} I(\tilde{\nu}) d\tilde{\nu}}{\int I(\tilde{\nu}) d\tilde{\nu}}. \quad (3.100)$$

The *oscillator strength* is the ratio of the emission or absorption rate of the molecule to that of a classical oscillator. This is defined by

$$\begin{aligned} f_{in,fm} &= \frac{4\pi m_e c}{3\hbar} \langle \tilde{\nu}_{in,fm} \rangle |\langle \phi_{in} | \mathbf{r}_i - \mathbf{r}_f | \phi_{fm} \rangle|^2 \\ &= \frac{4\pi m_e c}{3q^2 \hbar} \langle \tilde{\nu}_{in,fm} \rangle |\boldsymbol{\mu}_{in,fm}|^2, \end{aligned} \quad (3.101)$$

where we generalize by substituting  $i$  and  $f$  for  $u$  and  $l$ . Comparing this with Eq. 3.88 and 3.96, the oscillator strength can be written in terms of the cross-section and absorption coefficients:

$$\begin{aligned} f_{in,fm} &= \frac{2m_e \epsilon_0 c}{\pi q^2 n_r} \int \sigma(\omega) d\omega = \frac{2303 m_e c^2}{N_A \pi q^2 n_r} \int \epsilon(\tilde{\nu}) d\tilde{\nu} \\ &= \frac{4.39 \times 10^{-9}}{n_r} \int \epsilon(\tilde{\nu}) d\tilde{\nu}, \end{aligned} \quad (3.102)$$

where we have removed the frequency,  $\omega$ , from the integral in Eq. 3.96 by assuming that it is approximately constant over the relatively narrow energy band subtended by the initial and final states. It is often more important to compare the relative probabilities for transitions, rather than to calculate their absolute values. For this, we normalize the oscillator strength to an easily measured quantity—the intensity of the 0–0 transition ( $f_{i0,f0}$ ). Since, the electric dipole transition probability is the same for all vibronics contained within the same electronic manifold, Eq. 3.101, then we only need to consider the ratio of Franck–Condon factors. That is, from Eq. 3.79,  $|\boldsymbol{\mu}_{in,fm}|^2 / |\boldsymbol{\mu}_{i0,f0}|^2 = |\langle \phi_{N,in} | \phi_{N,fm} \rangle|^2 = FC_{n,m}$ . This yields

$$\bar{f}_{in,fm} = \frac{\tilde{\nu}_{in,fm}}{\tilde{\nu}_{i0,f0}} FC_{n,m}, \quad (3.103)$$

where  $\bar{f}_{in,fm} = f_{in,fm} / f_{i0,f0}$ . For absorptive transitions  $f \leftarrow i$ , the initial state is  $i, 0$ , that can access the vibronic levels,  $m$ , in state  $f$ . Thus, the relative intensity of the

peaks in the vibronic progression depends on the overlap between the wavefunction of the lowest vibronic in the initial state with the vibronic wavefunctions in the final state.

We can now calculate the relative intensities of the several peaks within the vibronic progression, which are the solutions for a SHO. There are two possibilities that are generally considered to enable estimation of the relative intensities of the vibronic states. The first is the *displaced oscillator* (Fig. 3.35a), whereby the electronic potential in state  $f$  is identical to that in  $i$ , but is rigidly displaced by a change in the nuclear positions by  $\Delta Q$ . The energy separation between vibronic eigenstates remains unchanged by this displacement, which implies that the normal frequencies,  $\omega_l$  in Eq. 3.15 are also unchanged. The second is the case of a *distorted oscillator* (Fig. 3.35b), where the electronic potential shape changes from  $i$  to  $f$ . In this case, the normal modes are changed: in the figure the frequencies are increased for the distorted oscillator excited state potential (Siebrand, 1967).

To treat the general problem of the transition  $i \rightarrow f$ , we return to Fermi's Golden Rule, separating out only the nuclear part of the wavefunctions, viz.

$$k_{if} = \frac{2\pi}{\hbar} \rho(E) |\langle \phi_{f,N} | H_N | \phi_{i,N} \rangle|^2, \quad (3.104)$$

where  $H_N$  is the nuclear Hamiltonian. This can be approximated by the first term in a Taylor series expansion in the nuclear displacement,  $(Q_n - Q^0)$  (Siebrand, 1967, Engleman and Jortner, 1970):

$$H_N = \sum_{n=1}^N \frac{\partial \tilde{J}}{\partial Q_n} (Q_n - Q^0) \quad (3.105)$$

with

$$\tilde{J} = \langle \phi_{f,e} | J_N | \phi_{i,e} \rangle, \quad (3.106)$$

where the sum is over all  $N$  normal modes,  $J_N$  is the nuclear kinetic energy operator,  $\partial/\partial Q_n$ ,  $Q_n$  is the nuclear coordinate of the  $n$ th normal mode in the final state, and  $Q^0$  is the equilibrium coordinate in the initial state in which the molecule is "prepared" prior to the transition. It is assumed that there is only a single, dominant  $p$ th mode in the initial state.

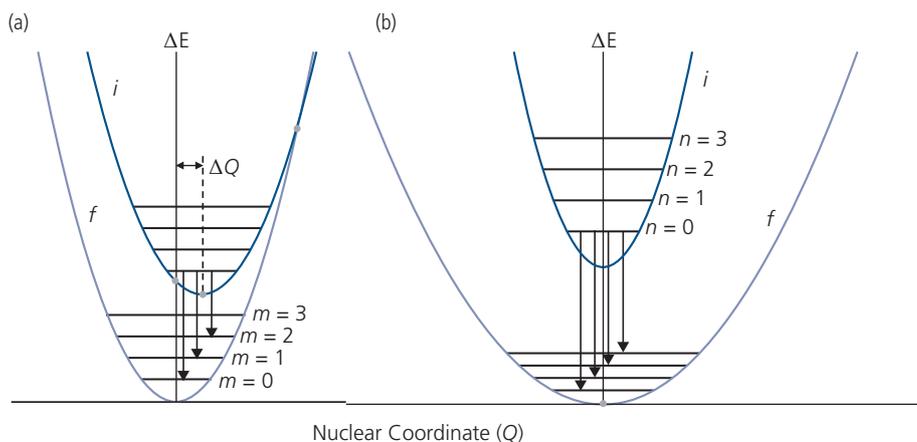

Since the vibronic modes are coupled, we need to sum over all possible final vibronic states,

$$H_N = \tilde{J} |FC_{if}(E)|^{1/2} = \tilde{J} \prod_{n \neq p=1}^N |\langle \phi_{N,n}^f(\omega_n) | \phi_{N,n}^i(\omega_p) \rangle|. \quad (3.107)$$

Equation 3.107 includes the product of Franck-Condon factors for transitions between the dominant initial, and the other  $n$  vibronics. Also, the initial and final states of the nuclear wavefunctions are denoted by superscripts for clarity. It is assumed that the system is initially in mode  $\omega_i$ , followed by a transition to one of  $n$  modes with frequencies  $\omega_p$ . Then the Franck-Condon factor for the transition is found by summing over all possible permutations,  $P$ :

$$FC_{if} = \sum_E FC_{if}(E) = \sum_P \left[ \prod_{n \neq p} |\langle \phi_{N,n}^f(\omega_n) | \phi_{N,n}^i(\omega_p) \rangle|^2 \right]. \quad (3.108)$$

The lineshape function is then obtained by multiplying the Franck-Condon factors over the modal occupancy, which is determined by a Boltzmann

**Figure 3.35** (a) Displaced oscillator and (b) distorted oscillator potential energy surfaces. The displaced oscillator undergoes a coordinate shift of  $\Delta Q$ , whereas the distorted oscillator has  $\Delta Q = 0$ . Example transitions from the  $n = 0$  initial state to various vibronics,  $m$ , in the final state are indicated.

factor, Eq. 3.81. Thus the line shape is (Engleman and Jortner, 1970)

$$F(E) = \frac{\left[ \sum_{i,f}^N FC_{ij} \exp(-E_i/k_B T) \delta(E_f - E_i - E) \right]}{\sum_i^N \exp(-E_i/k_B T)}. \quad (3.109)$$

For the displaced, but undistorted oscillator, we assume a Poisson distribution for the oscillator strength across the  $m$ -vibronic levels in the final state. Then, it can be shown (see Problem 3.7) that Eq. 3.108 yields  $FC_{n,m} = Z^m e^{-Z}/m!$ , such that (Siebrand, 1967):

$$\bar{f}_{in,fm} = \frac{\tilde{\nu}_{in,fm} Z^m}{\tilde{\nu}_{i0,f0} m!} e^{-Z}, \quad (3.110)$$

where  $Z$  is known as the *Huang–Rhys parameter*. The restoring force of the harmonic potential is  $k$ , and hence the energy due to a displacement,  $\Delta Q = |Q_i - Q_f|$ , of that state is  $\frac{1}{2}k\Delta Q^2$ . Since  $Q$  represents the configuration of all nuclear coordinates, it then follows that  $\Delta Q$  corresponds to

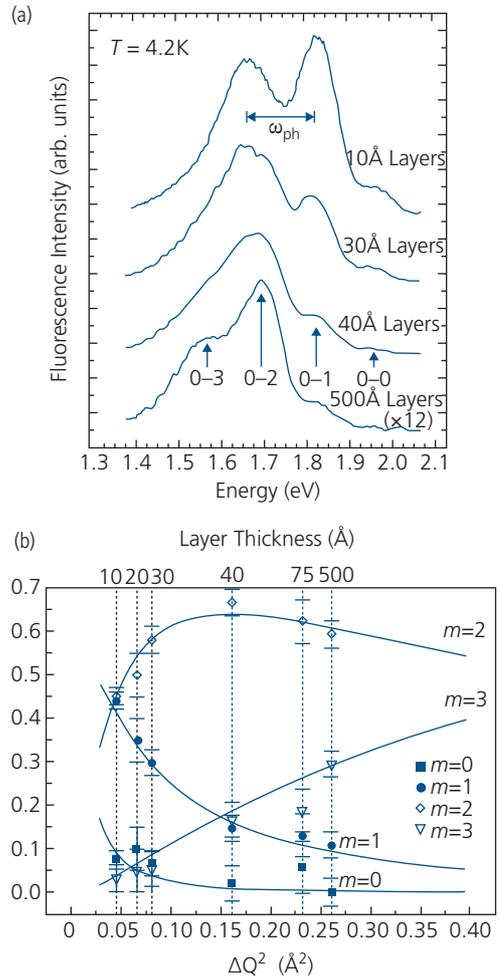

$$\Delta Q = \sqrt{\sum_{j=1}^M \Delta \mathbf{R}_j^2}, \quad (3.111)$$

where  $\Delta \mathbf{R}_j$  is the displacement of the  $j$ th nucleus in the molecule containing  $M$  atoms from its equilibrium position,  $\mathbf{R}_j$ . Thus, in Eq. 3.110 we have

$$Z = \frac{1}{2} \frac{k\Delta Q^2}{\hbar\omega_{i0,fm}} = \frac{1}{2} \frac{M\omega_{i0,fm}}{\hbar} \Delta Q^2 \quad (3.112)$$

for each final state,  $f, m$ . While this treatment assumes a Poisson distribution, this is often not the case, although its use leads to considerable simplicity and often acceptable fits to data.

Equation 3.110 is also used to describe emission. Figure 3.36a shows the low temperature fluorescence spectra of very thin films of PTCDA sandwiched between layers of the higher band gap NTCDA (Haskal et al., 1995). The layer pairs, grown by thermal evaporation in ultrahigh vacuum, are stacked such that the luminescence from one pair adds to that of another to form easily detectable PTCDA emission at  $T = 4.2$  K. No NTCDA emission is observed between 1.3 and 2.1 eV shown in the figure. Solutions to Eq. 3.110 as functions of  $\Delta Q^2$  are shown in Fig. 3.36b for the four highest energy features in the spectrum

**Figure 3.36** (a) Fluorescence spectrum at  $T = 4.2$  K of PTCDA in PTCDA/NTCDA multilayer stacks, labeling the  $S_1 \rightarrow S_0$  series of vibronic transitions. The individual layer thicknesses in the stacks are noted which are the same for both NTCDA and PTCDA. (b) Fits of the relative peak intensities in (a) for each layer thickness to the Poisson distribution in Eq. 3.110 are shown as solid lines. The values of  $n$  correspond to the vibronic level in the final state,  $S_0$  (Haskal et al., 1995).

(corresponding to the transitions from the  $S_1$ ,  $n = 0$  state, to  $S_0$  in descending order of energies from  $m = 0$  to  $m = 1, 2$  and  $m = 3$ ). Each layer thickness yields only one value of  $\Delta Q^2$  indicated by the vertical, dashed lines. The data for each layer thickness intersect the values of Eq. 3.110, from which we infer there is only a single, displaced electronic state manifold. Also note from Fig. 3.36b that  $\Delta Q^2$  increases from  $0.04 \text{ \AA}^2$  to  $0.25 \text{ \AA}^2$  as the layer thickness increases from  $10 \text{ \AA}$  to  $500 \text{ \AA}$ , which is attributed to the reduced energetic confinement of the excited states with increasing layer thickness (Haskal et al., 1995).

For distorted oscillators, the Franck–Condon factors follow (Siebrand, 1967):

$$FC_{if} = (1 - \xi^2)^{1/2} \xi^m \times \frac{1 \cdot 3 \cdot 5 \cdots (m-1)}{2 \cdot 4 \cdot 6 \cdots m}; \quad m \text{ even}, \quad (3.113a)$$

$$FC_{if} = 0; \quad m \text{ odd}. \quad (3.113b)$$

Here,  $\xi = (\omega_{i0} - \omega_{fm}) / (\omega_{i0} + \omega_{fm}) = \Delta\omega / (\omega_{i0} + \omega_{fm})$  for each final mode of frequency,  $m$ , where  $\hbar\Delta\omega$  is the equilibrium energy difference for the undistorted oscillator, and  $\hbar\omega_{fm}$  is the energy of the relaxed state. Simplified, and somewhat more intuitive expressions for the distribution of spectral intensities that takes into consideration the population of states in the distorted vs. undistorted molecular potentials is given for absorption by (Gierschner et al., 2002):

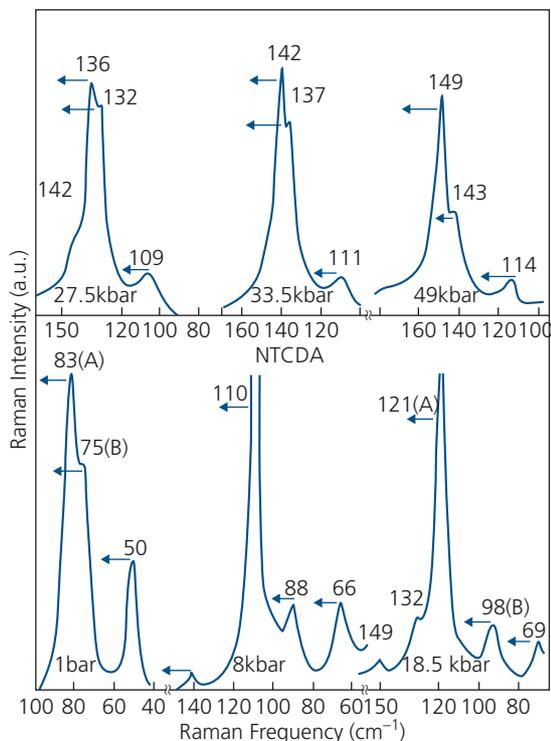

$$G(\Delta\omega) = \exp(-\hbar\Delta\omega / (D-1)k_B T) \quad (3.114)$$

and for emission:

$$G(\Delta\omega) = \exp(-\hbar\Delta\omega D / (D-1)k_B T), \quad (3.115)$$

where  $D = \omega_{i0} / \omega_{fm}$ .

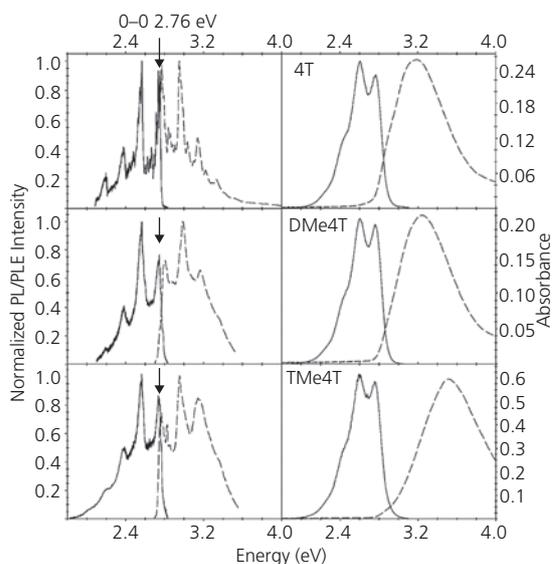

A distorted oscillator is used to describe the changes in the vibronic spectra of NTCDA under hydrostatic

**Figure 3.37** Raman spectra of NTCDA versus hydrostatic pressure. These peaks correspond to several intramolecular vibronic modes of the molecule (Jayaraman et al., 1985).

pressure (Jayaraman et al., 1985). The peaks in Fig. 3.37 are the Raman spectra of the molecular vibronic modes. They exhibit a rigid blue shift, as well as a decrease in peak spacing with increasing pressure. The *rigidochromic shift* (i.e. a peak shift without broadening) corresponds to the behavior of a displaced oscillator, while the changes in peak separation result from intramolecular distortions. For example, at atmospheric pressure (1 bar), there are peaks at 83, 75, and 50  $\text{cm}^{-1}$ , with frequency differences of 8 and 25  $\text{cm}^{-1}$ , respectively. As pressure increases, the peak energies monotonically decrease and split into doublets in some cases. Thus, at 18.5 kbar, the peaks are found at 121, 98, and 69  $\text{cm}^{-1}$ , with separations of 23 and 27  $\text{cm}^{-1}$ . Apparently, the distortion is most pronounced for the higher frequency modes with the lowest vibronic quantum numbers. Furthermore, there is a considerable increase in intensity of the highest energy mode at the expense of the lower energy modes, indicating that the vibronics are in resonance.

A further indication of potential distortion due to molecular configuration changes is the breakdown of mirror symmetry with temperature, as in Fig. 3.23b for diphenylvinylene. This distortion is due to thermally activated torsional motion of the phenyl groups, which can also result in an increase in the Stokes shift between absorption and emission. An even more extreme example of potential distortion is found for a series of methyl-substituted quaterthiophenes (4T) in Fig. 3.38.

**Figure 3.38** Normalized photoluminescence (PL) and PL excitation (PLE)/absorption spectra of quaterthiophene (4T), 3,3''-dimethyl 4T (Dme4T) and 3'',4',5,5''-tetramethyl 4T (TMe4T). Note the breakdown of mirror symmetry between the data at 4 K (left) and 300 K (right) (Macchi et al., 2009).

The intensities provided by this analysis are only approximate, avoiding common departures from idealized situations, such as anharmonicity of the equilibrium potential, non-Boltzmann excited state distribution statistics, coupling between states, and the presence of multiple overlapping (i.e. degenerate) vibronics. It is nevertheless instructive since it demonstrates the relationship between transition probabilities, Franck–Condon factors, and the oscillator strengths.

Non-radiative transitions between vibronic states (in this case from the  $p^{\text{th}}$  mode in the initial state to one of the  $N$  normal modes in the final state) also have an exponential dependence of the transition rates on the energy gap,  $E_G = E_i - E_f$ . Assuming once again that there is a single, dominant mode of frequency,  $\omega_p$ , the non-radiative rate follows (Engleman and Jortner, 1970):

$$k_{if} = \frac{C^2 \sqrt{2\pi}}{\hbar \sqrt{\hbar \omega_p E_G}} \exp(-\gamma E_G / \hbar \omega_p) = A \exp(-\gamma E_G / \hbar \omega_p), \quad (3.116)$$

where  $C \sim \sum_k^N J_k \langle \phi_{N,ik} | \frac{\partial}{\partial Q_n} | \phi_{N,fk} \rangle$  is the kinetic energy of the nuclei. This expression is valid in the weak coupling limit, that is, when the relative displacement of the states,  $\Delta Q$ , is small, which is the primary assumption in using the expansion in Eq. 3.105. Also,

$$\gamma = \log \left( \frac{E_G}{\Omega E_p} \right) - 1, \quad (3.117)$$

where  $\Omega$  is the number of modes contributing the maximum energy,  $E_p = \frac{1}{2} \hbar \omega_p \Delta_p^2$ , which is half the Stokes shift. It is assumed that there are  $\Omega$  equivalent modes of energy  $\hbar \omega_p$  in the final state. Here,  $\Delta_p = \sqrt{M \omega_p / \hbar} (Q_p - Q^0)$  is the reduced (unitless) displacement between the excited and equilibrium modes with coordinates  $Q_p$  and  $Q^0$ , respectively, and  $M$  is the molecular mass. We note that Eq. 3.116 is dependent on  $E_G$  (i.e. as  $E_G$  increases,  $k_{if}$  exponentially decreases). Also,  $\gamma$  is a function of energy gap. Its weak logarithmic dependence does not strongly influence  $k_{if}$ .

Equation 3.116 is known as the *energy gap law*, which states that the larger the energy gap, the lower the probability for non-radiative recombination. That is, as the energy gap of a molecular species decreases, competition between radiative vs. non-radiative decay of the excited state increases.

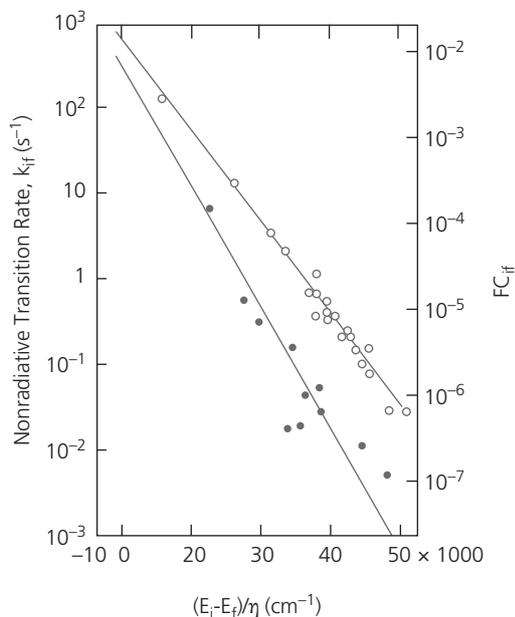

As we will find in Chapter 6, organics are far more likely to have a high radiative efficiency as their energy gap increases, that is, while it is common to observe very high red, green and blue emission efficiencies, it is less common to observe emission from molecules with energy gaps at near and mid-infrared wavelengths. The energy gap law is followed in both polymers and small molecules, and is widely observed for singlet, triplet, and charge transfer transitions (Siebrand and Williams, 1967, Caspar et al., 1982, Bixon et al., 1994, Chynwat and Frank, 1995, Wilson et al., 2001). An example of the energy gap law is shown in Fig. 3.39 for triplet transitions in a series of aromatic hydrocarbons, and their deuterated isotopes. (Siebrand and Williams, 1967). The dominant vibrational energy is  $E_p = 4000 \text{ cm}^{-1}$  due to the C–H bond stretch. In the deuterated isotopes, the stiffer C–D bond has a higher  $E_p = 5500 \text{ cm}^{-1}$ , also leading to a higher slope vs. energy for  $k_{if}$  according to Eq. 3.116.

The difference in behavior for the two different isotopes of the aromatic hydrocarbons can be used to determine the energy of the dominant vibronics. That is, by replacing a H with a D atom within the molecule, the force constant  $k = M\omega^2$  undergoes a corresponding change. To identify the dominant excitation, we take the derivative of  $FC_{if}$  in Eq. 3.108 (Siebrand and Williams, 1967):

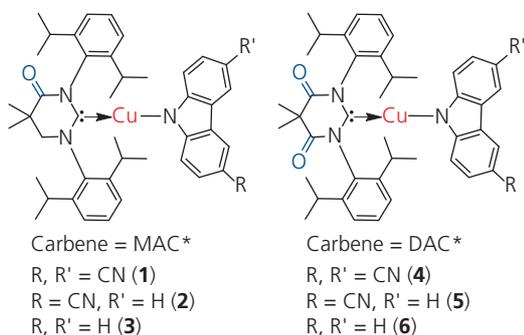

$$\left. \frac{\partial \log FC_{if,H}(E)}{\partial E} \right|_{E'} = \left( \sqrt{\frac{M_H}{M_L}} \right) \left. \frac{\partial \log FC_{if,L}(E)}{\partial E} \right|_{E'}. \quad (3.118)$$

Here,  $FC_{if,H}$  refers to the Stokes shift of the heavier isotope with mass  $M_H$ , compared to the lighter with  $M_L$ . The ratio of the masses of the heavier to the lighter isotopes determines the slope of the line in Fig. 3.39. This dependence of the shift in oscillator strength with isotopic mass is known as the *isotope rule*.

The non-radiative rates in Fig. 3.39 are for  $S_1 \rightarrow S_0$  transitions. The generality of the energy gap law is demonstrated by triplet transitions,  $T_1 \rightarrow S_0$  of a homologous series of *thermally assisted delayed fluorescent* (TADF) metal–organic Cu complexes whose molecular structural formulae are shown in **Scheme 1**. Varying the ligand composition tunes the energy gap of the complexes from the red with a HOMO–LUMO gap energy of 2.04 eV (compound 6), to the blue, with  $E_G = 3.54 \text{ eV}$ . Correspondingly, emission from the  $T_1$  state ranges from 704 nm to 432 nm when the phosphor is dispersed at very low concentration (1%) in a wide energy gap polystyrene matrix.

**Figure 3.39** Non-radiative triplet transition rates measured for a series of aromatic hydrocarbons (open circles) and their deuterated isotopes (filled circles). The slopes of the solid lines fit to the energy gap law are in the ratio of  $4000/5500 = 0.73$  which is compared to the predicted value of 0.55 for these isotopes. Here,  $FC_{if}$  is the Frank–Condon factor, and  $\eta$  is the relative number of H or D atoms in the molecule (Siebrand and Williams, 1967).

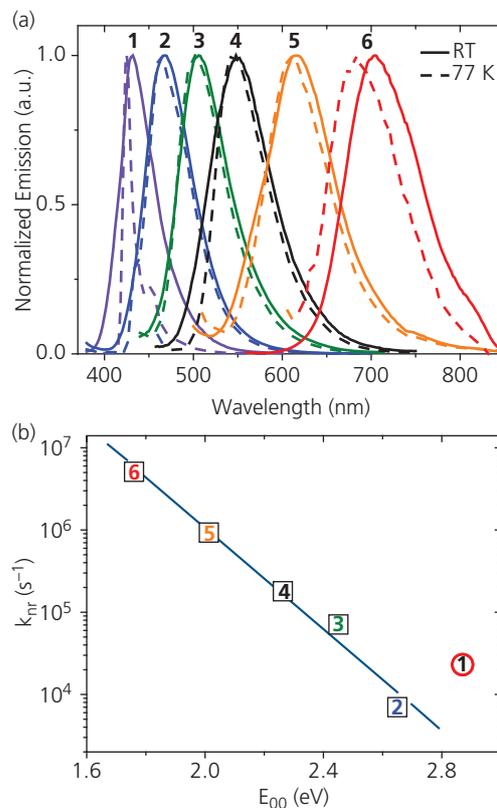

**Scheme 1** Cu-based TADF compounds.

The non-radiative transition rate is related to the photoluminescence quantum yield,  $\Phi_{PL}$ , via:

$$\Phi_{PL} = \frac{k_r}{k_r + k_{nr}}, \quad (3.119)$$

where  $k_r$  is the radiative rate. Hence, the non-radiative rate is measured from the values of  $\Phi_{PL}$ , taking  $k_{nr} \rightarrow 0$  at low temperatures, where  $k_r$  is measured from the luminescent decay transient. Using this analysis,  $k_{nr}$  is plotted vs.  $E_{00}$  in Fig. 3.40b. Consistent with the energy gap law, the non-radiative rate decreases with increasing  $E_{00}$ , except for compound 1 which falls considerably off of the trend. This is

**Figure 3.40** (a) The emission spectra of complexes 1–6 (Scheme 1) in polystyrene at room temperature and 77 K. (b) Non-radiative recombination rate vs.  $E_{00}$  (Shi et al., 2019).

attributed to a different composition for the orbitals on 1 vs. the other compounds, which is also reflected in its comparatively lower  $\Phi_{PL}$  (Shi et al., 2019).

### 3.6.2 Dimers

Understanding exciton transport in solids begins by consideration of the interaction of an isolated pair of identical molecules, known as a *dimer*, which is the smallest possible molecular aggregate. If the pair forms a bond, the system is known as a *chemical dimer*, whereas if they interact by van der Waals or other electrostatic attraction, the pair forms a *physical dimer*. In the following, we consider only physical dimers. Aggregation of molecules into dimers results in energy level splitting and the development of band structure for the excited states. Level splitting red shifts the broadened electronic states, resulting in differences between the spectra of individual molecules and the solid.

The wavefunction of one molecule at  $\mathbf{r}_1$  of a dimer pair is  $\psi_1(\mathbf{r}_1)$ , and the other at  $\mathbf{r}_2$  is  $\psi_2(\mathbf{r}_2)$ . If their coupling is small, then the *Heitler–London formalism* for the ground state dimer wavefunction gives:  $\psi_0(\mathbf{r}_1, \mathbf{r}_2) = \psi_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2)$ , each with ground state energies  $E_1 = E_2 = E_0$ . The total ground state energy must also include the intermolecular interaction energy,  $E_I$ . In the simple case of van der Waals bonding, then  $H_{int} = -\frac{A_{disp}}{r_{12}^6}$ , where  $A_{disp}$  is the dispersion coefficient and  $r_{12} = |\mathbf{r}_1 - \mathbf{r}_2|$  (c.f. Eq. 2.66). Then:

$$E_I = \langle \psi_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) | H_{int} | \psi_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) \rangle, \quad (3.120)$$

leading to a ground state energy of  $E_G = 2E_0 + E_I$ . Since  $E_I < 0$ , the bound ground state energies of the two individual molecules is less than that of the dimer that is, therefore, the more stable species. If the molecules have fixed dipole moments,  $H_{int}$  is modified according to the analysis in Section 2.4.3.

If one molecule is excited, time dependent perturbation theory predicts that the excited state oscillates between the molecules forming the dimer. Hence, the system is described by a linear superposition of the two possible excited states, or two orthogonal normal modes of the system:

$$\psi'_\pm(\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{\sqrt{2}}(\psi'_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) \pm \psi_1(\mathbf{r}_1)\psi'_2(\mathbf{r}_2)), \quad (3.121)$$

where  $\psi'(\mathbf{r})$  denotes an excited state. These modes are similar to two SHOs coupled by a spring: one (+) corresponds to both oscillators moving coherently in phase, while the other (–) is for the oscillators moving  $180^\circ$  out of phase.

The total energy is the sum of the energies of the excited state of one molecule,  $E'_1 = E'_2 = E'$ , the ground state of the other molecule,  $E_0$ , and interaction terms from the wavefunctions in Eq. 3.121. This yields the Coulomb energy:

$$E'_I = \langle \psi'_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) | H_{int} | \psi'_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) \rangle \quad (3.122)$$

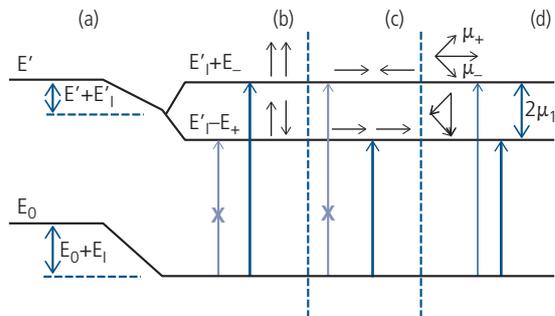

plus the resonance energy:

$$E_\pm = \pm \langle \psi'_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) | H_{int} | \psi_1(\mathbf{r}_1)\psi'_2(\mathbf{r}_2) \rangle \quad (3.123)$$

giving the total energy:

$$E'_T = E_0 + E' + E'_I + E_\pm. \quad (3.124)$$

Recall that  $E'_I < 0$  since  $H_{int}$  itself is negative, resulting in the dimer energy diagram in Fig. 3.41. Letting  $E_+ = \beta = E_-$ , then the total energy splitting is  $\Delta E = 2E_\pm = 2\beta$ .

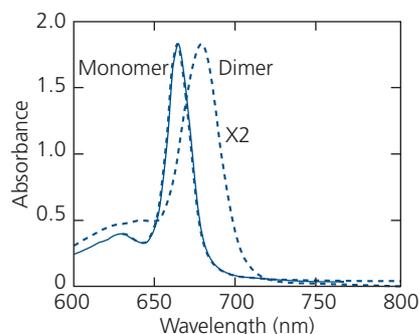

**Figure 3.41** Energy level splitting for a physical dimer. Energy of the (a) ground ( $E_0$ ) and first excited ( $E'$ ) state of the isolated monomers, (b) ground and first excited state of the dimer showing the dominant absorption transition into the upper and (c) lower doublet levels. (d) Transition energies for dimer dipoles that are neither parallel nor antiparallel (arrows). The doublet splitting energy is  $2\mu_1 = 2\mu_2$ .

The transition dipole moment is obtained using the Hamiltonian in Eq. 3.71 along with the dipole operator Eq. 3.72. Thus

$$\begin{aligned} \mu_\pm &= -\frac{q}{\sqrt{2}} \langle \psi'_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) \pm \psi_1(\mathbf{r}_1)\psi'_2(\mathbf{r}_2) | \mathbf{r} | \psi_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) \rangle \\ &= \frac{1}{\sqrt{2}} (\mu_1 \pm \mu_2), \end{aligned} \quad (3.125)$$

where  $\mu_1$  and  $\mu_2$  are the individual transition moments of the respective monomers between their ground and excited states (e.g.  $\mu_1 = -q \langle \psi'_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) | \mathbf{r} | \psi_1(\mathbf{r}_1)\psi_2(\mathbf{r}_2) \rangle$ ). Since  $\mu_1 = \mu_2$  for identical molecules, transitions into the antisymmetric state  $\psi_-$  have a vanishing transition dipole,  $\mu_- = \mu_1 - \mu_2 = 0$ , see the lower level, Fig. 3.41b. Figures 3.41b and c show situations where the dipoles are translationally invariant. Figure 3.41b shows the molecular dipoles aligned in a side-by-side arrangement. The lowest energy is achieved when the dipoles are antiparallel, that is  $\mu_- = 0$ . Then only transitions to the upper antisymmetric state at  $E' + E'_+ + E_+$  are allowed. When the dipoles are arranged end-on-end (Fig. 3.41c), the vector sum of the transition dipole is zero in the upper level, allowing only transitions to the lower state. Figure 3.41d shows a situation where neither of the parallel arrangements exist (such as in a herringbone crystal structure). Thus, transitions are possible into both the upper and lower levels. The energy separation of the levels is equal to  $2\mu_1 = 2\mu_2$ .

An example of the red shift in the dimer absorption spectrum compared with that of a monomer is shown in Fig. 3.42 for the molecule 4-*n*-propyl-5-ethyl farne-syl bacteriochlorophyll-c in dichloromethane (Olson

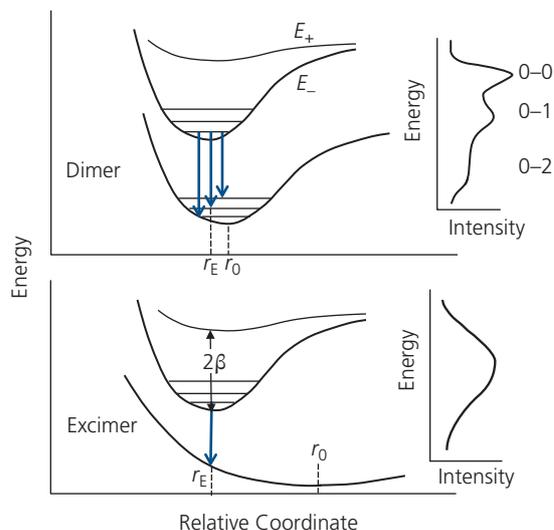

**Figure 3.42** Monomer and dimer absorption spectra for bacteriochlorophyll in dichloromethane (Olson and Cox, 1991).

and Cox, 1991). The peak shows a rigidochromic shift from a wavelength of  $\lambda = 665$  nm to 679 nm as the solution is concentrated, thereby increasing the probability for molecular aggregation into dimers, trimers, etc. In the concentrated solution, the dimers coexist with the monomers, and hence the dimer peak was extracted by subtracting the monomer contribution obtained in a dilute solution. Two dimer peaks, one at 670 nm and the second at  $\sim 690$  nm are superposed to result in the peak at 679 nm, although the contribution from the lower energy peak is significantly less than the shorter wavelength peak since it corresponds to transitions into a forbidden dipole state. Since both peaks are present, this corresponds to the situation in Fig. 3.41d.

### 3.6.3 Excimers and exciplexes

Physical dimers support an excitation that resonantly oscillates between two electrostatically bound molecules. When the spacing of the molecules is close, the pair may not necessarily be bound in the ground state. When one of the pair is excited, the resonance interaction,  $\beta$ , becomes large, thus stabilizing the pair in a closely spaced, bound configuration. A dimer that has no bound ground state but is bound in the excited state is called an *excimer*, which is a contraction of the words “excited dimer.” If the pair of excited molecules are of different composition, the state is an *exciplex*.

The difference between dimers and excimers is illustrated in Fig. 3.43, which shows the dimer splitting into  $E_+$  and  $E_-$ , along with possible transitions to the ground ( $S_0$ ) state. In the dimer,  $S_0$  is a bound state, and hence the vibronic progression is observable in the luminescence spectrum shown at the right. In this diagram, the excited state has a smaller displacement than the ground state (i.e. the molecules move toward each other when one of the pair is excited). This is not

**Figure 3.43** Configurational energy diagrams distinguishing a dimer and an excimer. To the right are characteristic luminescence spectra due to excited-to-ground state transitions. A dimer shows a clear vibronic progression, whereas excimer luminescence is broad and featureless. Luminescent transitions are indicated by the vertical arrows,  $r_E$  and  $r_0$  are the equilibrium excited and ground state molecular coordinates. Note the lack of a bound ground state for the excimer.

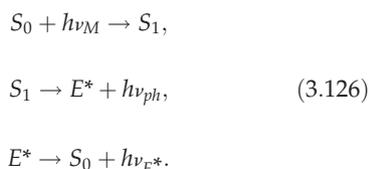

the case for all dimers since the displacement depends on the relative contributions from the Coulomb and resonance integrals. For the excimer, the coordinate change is considerably larger and always negative, that is, the individual molecules transition from an unbound to a stable and more closely spaced bound pair after excitation. The lack of a ground state replaces the resolved vibronic features of the monomer with a broad and featureless spectrum. The calculation of excimer energies is identical to that used for dimers, although the relative magnitudes of  $\beta$  and  $E_i'$  are different.

Excimers are typically observed in solution: as an excited molecule collides with a ground state molecule, they form a bound pair that shares the excitation. This pair exists until a photon is emitted, or until a random event results in non-radiative return to the ground state, at which point the molecules once more disassociate. Evidence for excimers is the dependence of a broad luminescence feature on molecular concentration in solution. As the solution is increasingly diluted, the probability for excimer formation decreases proportionately.

In the solid state, random molecular encounters are absent. However, in some crystals, molecules can closely stack in a facial arrangement, forming physical dimers. When one of the molecules is excited, the lattice can distort to decrease the stacking distance,

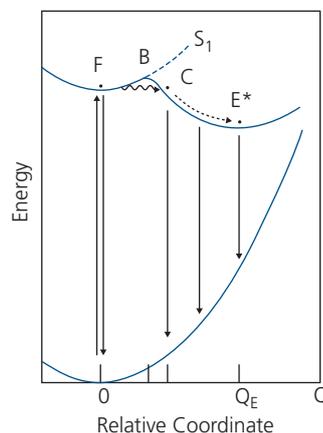

forming a lower energy excimer state. By polarizing the surrounding lattice, the free exciton becomes *self-trapped* on the excimer, where it remains until it recombines in the ground state (Song and Williams, 1993). Thus, the unexcited crystal is said to be in a *pre-excimeric* configuration. In solid amorphous blends of a high concentration of luminescent molecules in a high energy gap (i.e. transparent) matrix, the chromophores may find themselves in closely spaced pre-excimeric states. Then, both excimer and monomer luminescence are simultaneously observed due to the coexistence of aggregates and isolated molecules. As the chromophore concentration increases, the excimer and monomer luminescence proportionately increase and decrease, respectively.

An additional difference between monomer and excimer emission is that the broad excimer spectrum does not narrow nor vary significantly at very low temperatures (Birks and Kazzaz, 1968). To excite the molecular pair, the monomer transition energy (corresponding to  $S_1 \leftarrow S_0$ ) must overcome the excimer binding energy at point B, by either thermionic emission or tunneling to point C in Fig. 3.44. Excimers lower the system energy by reducing both the Coulomb and resonance energies, ultimately resulting in emission from the excimer,  $E^*$ . The multistep dynamical process leading to excimer emission is described by

Here, the energies  $h\nu_M$ ,  $h\nu_{ph}$ , and  $h\nu_{E^*}$  correspond to the monomer excitation energy, the phonon energy leading to internal conversion to  $E^*$ , and the excimer emission energy, respectively. As the exciton moves from a free to a self-trapped state, additional thermal (phonon) energy is required to surmount the barrier, B. As temperature is decreased, the probability of excimer vs. monomer emission is also decreased.

Planar molecules are particularly susceptible to excimer generation since they tend to form tight, facial  $\pi$ - $\pi$  stacks that result in the sharing of excitations between molecular neighbors. An archetype excimeric PAH is pyrene, whose structure is shown in Fig. 3.45a. In the ground state, the equilibrium intermolecular spacing is  $r_0 = 3.53 \text{ \AA}$  (Robertson and White, 1947), decreasing to  $r_E = 3.34 \text{ \AA}$  for the self-trapped excimer (Birks, 1975). The changes in dimension as well as the energies of the transitions are indicated in the energy scheme in Fig. 3.45b. Excimer

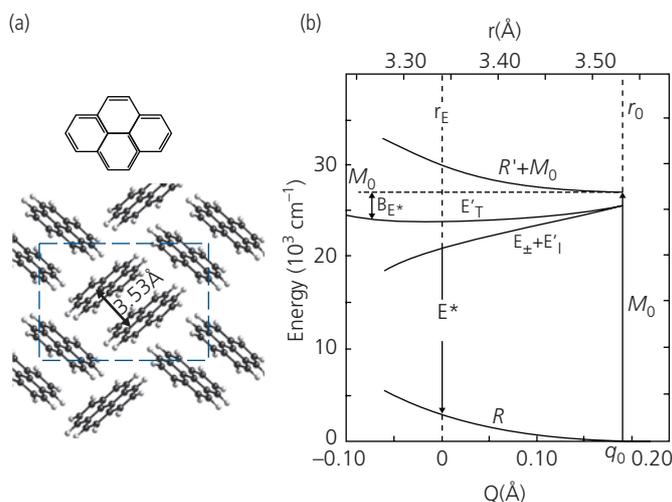

**Figure 3.44** Energy transfer from a free exciton (F) to a self-trapped, or excimer state ( $E^*$ ). Possible transitions of the free, excimer and intermediate states are shown as the energy surface is traversed between initial and final states. Excimers are formed by overcoming of the barrier B by either thermionic emission, or tunneling to C. After Nasu (1987).

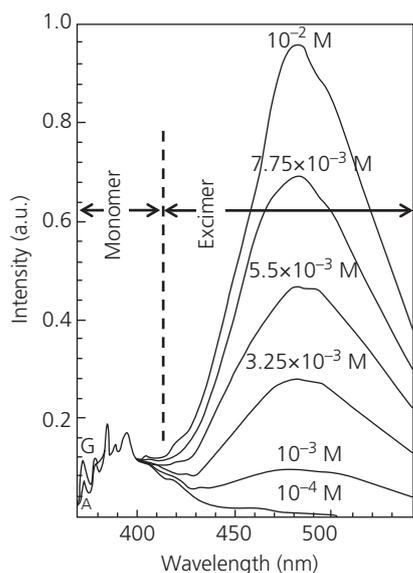

emission from a dilute solution of pyrene in is shown in Fig. 3.46 (Birks and Christophorou, 1963). In the most dilute solutions ( $10^{-4}$ – $10^{-3}$  M), the monomer spectrum coexists with the broad excimer feature, illustrating the differences between these two excited states. The monomer spectrum has noticeable structure, whereas the excimer spectrum is broad and featureless. Note the very strong dependence of the ratio of excimer-to-monomer fluorescence intensity with increasing pyrene concentration.

An example of excimer phosphorescence in a solid mixture is shown in Fig. 3.47 for the triplet emitting platinum complex, FPt1, diluted in CBP (D’Andrade et al., 2002). The energy gap of CBP is 3.1 eV and that of FPt1 is 2.6 eV. The data are collected by using short wavelength illumination to selectively excite only the  $S_1 \leftarrow S_0$  transition in CBP, which then transfers its excited state by a Förster process to the FPt1 triplet state (see Section 3.8.1). The triplet then emits in the 450–550 nm wavelength range, following  $T_1 \rightarrow S_0$ . At very low concentrations, the planar FPt1 molecules are isolated in the solid CBP matrix, and primarily light blue monomer emission is observed, as characterized by the vibronic progression in the spectrum from Film 2. The long wavelength emission tail at  $> 550$  nm is due to excimer emission from FPt1 aggregates present even at low concentrations. At the higher phosphor concentration (7 wt%) of Film 3, excimer emission is dominant.

An exciplex is analogous to an excimer except that the pair of molecules are of different composition. Exciplex, therefore, refers to an “excited molecular

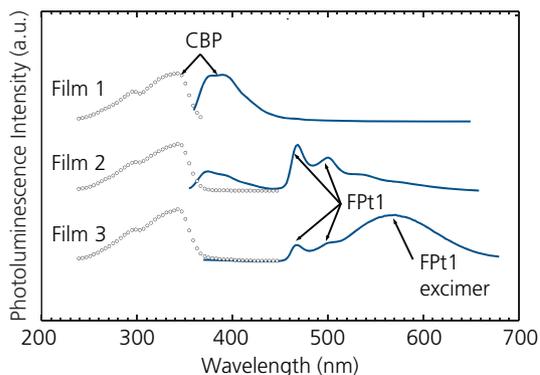

**Figure 3.45** (a) Molecular structural formula of pyrene ( $C_{15}H_{10}$ ) and its equilibrium crystal structure, showing four molecules per unit cell and an equilibrium interplanar spacing of 3.53 Å. A projection of the  $a$ - $b$  plane of the unit cell along the  $c$ -axis is shown by the dashed line. (b) Energy level diagram of the excimer ( $E_T^*$ ) and monomer ( $M_0$ ) energies, along with the attractive interaction term ( $E_{\pm} + E_1^*$ ), and the repulsive monomer energy in the excited ( $R'$ ) and ground ( $R$ ) states.  $B_{E^*}$  is the excimer binding energy. Both the absolute ( $r$ ) and relative coordinates ( $Q$ ) are shown (Birks, 1975).

complex." Due to the obvious asymmetry of the system, the charge density is not shared equally between molecules; in effect there is a limited degree of charge transfer from one to the other. Thus, one molecule serves as an anionic electron acceptor (A), and the other as the cationic donor (D), depending on the relative positions of the HOMO and LUMO levels of the pair (see Fig. 3.48). Only partial charge transfer

**Figure 3.47** Photoluminescence (solid lines) and excitation spectra (circles) of a neat CBP (Film 1), <1% (by weight) FPt1 in CBP (Film 2) and 7% FPt1 in CBP (Film 3) (D'Andrade et al., 2002).

**Figure 3.48** Energetics of an exciplex. Individual electron spins are shown, with transfer of charge from the donor (D) to the acceptor (A) molecule forming the exciplex (dashed ellipse).

occurs that comprises a fractional charge ( $\delta^\pm$ ) redistribution of  $\delta^+ = \delta^- < q$  across the exciplex. We can express the charge transfer reaction as follows:

where  $D^*$  is the excited donor,  $A^0$  is the ground state acceptor, and the term in parentheses represents the bound exciplex state.

Charge transfer can occur in both the ground and excited states, again depending on their energy level offsets. When there is ground state charge exchange, the molecular pair is called a *charge transfer complex*, discussed in Section 3.6.6.

The exciplex wavefunction is described as a linear combination of individual molecular wavefunctions. This differs from the treatment of a dimer (and excimer) in Eq. 3.121 since the two wavefunctions are now associated with *different* molecules. The ground and excited state wavefunctions are thus:

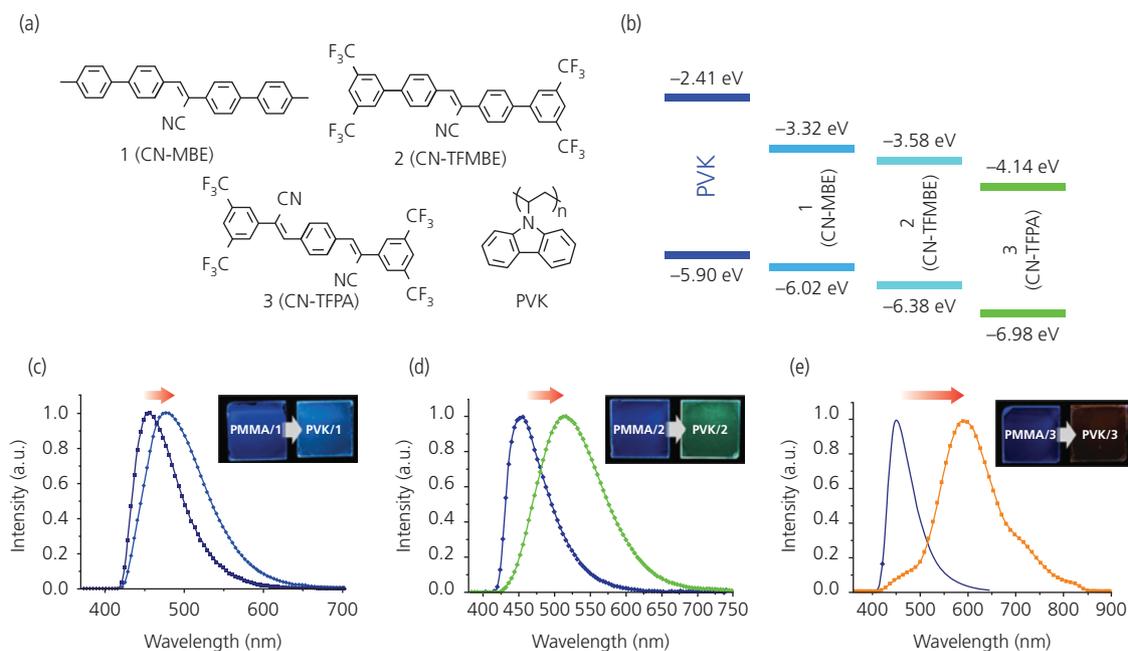

$$\psi_D^0 = \alpha^0 \psi_1 \psi_2 + \gamma^0 \psi_1^+ \psi_2^- + \delta^0 \psi_1^- \psi_2^+, \quad (3.128)$$

$$\psi_T = \alpha \psi_1 \psi_2 + \beta \psi_1 \psi_2^+ + \gamma \psi_1^+ \psi_2^- + \delta \psi_1^- \psi_2^+, \quad (3.129)$$

where the coefficients,  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ , etc., can be either positive or negative, and their magnitudes give the

strengths of their contributions to the total exciplex wavefunction. The subscripts refer to molecules 1, 2 forming the complex, superscript 0 indicates the ground state,  $\psi_{1,2}^0$  is the wavefunction for the corresponding individual molecular excited state, and  $\psi^\pm$  indicates the net charge on the molecule. Note that the charge can transfer in either direction, depending how large an energy step exists between frontier energy levels in the two molecules.

There are many examples of exciplexes in mixtures of aromatic hydrocarbons such as derivatives of benzene, naphthalene, anthracene, etc. due to their planar (and hence close packing) structures (Birks, 1970). An example of exciplex fluorescence for a series of acceptors in a PVK donor matrix is shown in Fig. 3.49. All acceptors have closely matched HOMO-LUMO energy gaps of 2.70 eV for CN-MBE, to 2.84 eV for CN-TFPA. However, their HOMO energies, measured by ultraviolet photoelectron spectroscopy, (Appendix C) are offset due to a differing amount of electron withdrawing character afforded by the cyano ( $-\text{CN}$ ) and trifluoromethyl ( $-\text{CF}_3$ ) groups comprising each molecule. The molecules are also mixed into the very wide energy gap PMMA matrix that does not interact with the various acceptors. These mixtures luminesce only from the acceptor molecules themselves without

**Figure 3.49** (a) Molecular structural formulae for a series of three acceptor molecules and the electron donor, PVK. (b) Frontier orbitals of the compounds in (a) indicating their HOMO (lower) and LUMO (upper) energies. The LUMO energy is estimated by subtracting the low energy cut-off of the optical absorption tail of the compound (i.e. the *optical energy gap*) from its ionization energy. (c)–(e) The spectra of compounds **1**, **2**, and **3** in PMMA (purple line) and PVK (blue, green and orange lines). The red shift for the mixtures in PVK is due to exciplex emission, whereas the unshifted spectra for the PMMA-based mixtures are due to the individual acceptor molecules themselves (Kim et al., 2014).

charge or energy transfer. Thus, the red shift in the spectra is presumed due only to luminescence from exciplexes formed at the PVK/acceptor interface.

To understand the red shifts in the exciplex spectra in Fig. 3.49, the transition energy ( $D^+A^-$ )  $\rightarrow S_0$  is (Giebink et al., 2010):

$$\Delta E = |E_{A,LUMO} - E_{D,HOMO}| - \frac{q^2}{4\pi\epsilon_0\epsilon_r a_0}, \quad (3.130)$$

where  $E_{A,LUMO}$  is the LUMO energy of the acceptor,  $E_{D,HOMO}$  is the HOMO energy of the donor,  $\epsilon_r$  is the relative dielectric constant of the medium, and  $a_0$  is the radius of the charge transfer state. The last term expresses the Coulomb binding energy ( $E_B$ ) of the exciplex. For convenience, we assume that a full unit charge is transferred from D to A. If we assume that  $a_0 \sim 1$  nm, or approximately the size of a molecule in the pair, and  $\epsilon_r \sim 3$  typical of organic materials, then  $E_B \sim 0.2$  eV. Hence, for the blends in Fig. 3.49, we expect the red shift and the peak energies to follow the trends implied by the energy offsets in Fig. 3.49b. The PVK/1 mixture should have the highest energy transition of approximately  $E_G = E_{A,LUMO} - E_{D,HOMO} = 5.90 - 3.32 - 0.2$  eV = 2.38 eV, with the greatest red shift corresponding to PVK/3, with  $E_G = 1.56$  eV.

While the energy trends qualitatively match expectations, the magnitude of the shift diverges as the LUMO energy is decreased from PVK/1 to PVK/3, as summarized in Table 3.2. Given the approximate means for determining  $E_{A,LUMO}$  by adding the optical energy gap (corresponding to  $S_1$ , not the conduction level) to  $E_{D,LUMO}$ , it is not surprising that the divergence is large. Furthermore, it is incorrect to assume that  $E_B$  is independent of the details of molecular structure and morphology. Nevertheless, given the consistency of the trends with variations in frontier orbital energies, we conclude that emission from this system of D–A pairs is due to exciplex formation.

**Table 3.2** Calculated and measured energies for exciplex systems in Fig. 3.49 (Kim et al., 2014)

Blend	$E_{D,LUMO}$	$E_{A,HOMO}$	$E_{AD}$	$\Delta E$ (meas.)
PVK/1	-5.90	-3.32	2.58	2.59
PVK/2	-5.90	-3.58	2.32	2.40
PVK/3	-5.90	-4.14	1.76	2.10

All energies in eV.

### 3.6.4 Excited states in crystals

Davydov extended considerations of identical molecules to a crystal unit cell consisting of an arbitrary

number of translationally *inequivalent* molecules. It was found that the spectrum splits into branches whose number is equal to the number of inequivalent molecules. Generally a crystal consisting of  $N$  unit cells, with a basis of  $m \geq 1$  has the following Hamiltonian (Sibley et al., 1965):

$$H = \sum_i^N \sum_\mu^m H_{i\mu} + \sum_{i\mu < k\nu}^{N,m} V_{i\mu,k\nu}, \quad (3.131)$$

where  $H_{i\mu}$  is the Hamiltonian for the individual molecule in  $i$ th unit cell at site  $\mu$ , and  $V_{i\mu,k\nu}$  is the interaction between molecules at  $i, \mu$  and  $k, \nu$ . The ground state wavefunction is

$$\psi_{i\mu}^0 = A \prod_{i\mu}^{N,m} \phi_{i\mu}, \quad (3.132)$$

where  $A$  is an operator that antisymmetrizes the wavefunction under electron exchange between individual ground state molecular wavefunctions,  $\phi_{i\mu}$ . When a single molecule at site  $k, \nu$  is excited, the “one-site” exciton wavefunction becomes

$$\psi'_{k\nu} = A \phi'_{k\nu} \prod_{i\mu \neq k\nu}^{N,m} \phi_{i\mu}. \quad (3.133)$$

Since the excited state (i.e. exciton) can move between all molecules in the crystal, we use Bloch’s theorem to describe the delocalized wavefunction to yield

$$\Psi_\mu = \frac{1}{\sqrt{N}} \sum_i^N \psi'_{i\mu} \exp(i\mathbf{k} \cdot \mathbf{R}_{i\mu}). \quad (3.134)$$

That is, we assume that the exciton can be described by a periodic plane wave with wavevector  $\mathbf{k}$ , that can propagate among equivalent positions in the lattice,  $\mathbf{R}_{i\mu}$ .

Continuing to follow the procedure used to determine the energy of a dimer, we write the excited state energy for the crystal as

$$E(\mathbf{k}) = E_0 + E' + E'_I + E_\pm(\mathbf{k}), \quad (3.135)$$

where  $E'_I$  and  $E_\pm(\mathbf{k})$  are the molecular interaction energies analogous to their definitions in Eqs. 3.122 and 3.123. Thus,  $E(\mathbf{k})$  defines the dispersion relationship between energy and exciton momentum,  $\mathbf{k}$ . Using Eq. 3.132 to 3.134 with the Hamiltonian, Eq. 3.131, we have:

$$E'_I = \sum_{k\nu} \left( \langle \psi'_{i\mu} \psi'_{i\mu} | V_{i\mu,k\nu} | \psi_{k\nu}^0 \psi_{k\nu}^0 \rangle - \langle \psi'_{i\mu} \psi'_{i\mu} | V_{i\mu,k\nu} | \psi_{k\nu}^0 \psi_{k\nu}^0 \rangle \right), \quad (3.136)$$

where the second term eliminates contributions from molecular pairs in the ground state. This is known as

the *self-polarization energy* of the molecule in the crystal, see Section 3.6.7. The interaction energy,  $V_{i\mu,k\nu} < 0$ , and thus shifts the center of the band of exciton states from its initial value of  $E'$  as in Fig. 3.50a. Similarly:

$$\begin{aligned} E_{\pm}(\mathbf{k}) &= \sum_{i,k} \sum_{\mu} \langle \phi'_{i\mu} \phi_{k\mu} | V_{i\mu,k\mu} | \phi_{i\mu} \phi'_{k\mu} \rangle \exp(i\mathbf{k} \cdot \Delta\mathbf{R}_{i\mu,k\mu}) \\ &\quad \pm \sum_{i,k} \sum_{\nu \neq \mu} \langle \phi'_{i\mu} \phi_{k\nu} | V_{i\mu,k\nu} | \phi_{i\mu} \phi'_{k\nu} \rangle \exp(i\mathbf{k} \cdot \Delta\mathbf{R}_{i\mu,k\nu}) \\ &= E_{\mu\mu} \pm E_{\mu\nu} \end{aligned} \quad (3.137)$$

where the first term corresponds to sites that are translationally equivalent within the unit cells (i.e. the expression is found by diagonalizing the matrices in Eqs. 3.132 and 3.133), and the second to translationally inequivalent sites. Then,  $\Delta\mathbf{R}_{i\mu,k\nu} = \mathbf{R}_{i\mu} - \mathbf{R}_{k\nu}$  is the lattice translation vector.

This situation is considerably simplified when only nearest neighbor interactions are considered, which is consistent with the short range of van der Waals

bonds in molecular crystals. Then the wavefunctions in Eq. 3.134 are

$$\Psi_{\mu} = \frac{1}{\sqrt{N}} \sum_i \phi'_{i\mu} \exp(i\mathbf{k} \cdot \Delta\mathbf{R}_{i\mu}), \quad (3.138)$$

where  $\Delta\mathbf{R}_{i\mu}$  is now restricted to distances between nearest neighbors. For a one-dimensional (1D) crystal of length  $N$  unit cells (which serves as a reasonable approximation to transport along a molecular stacking axis), or for a cubic lattice of lattice constant  $a$ , then  $\exp(i\mathbf{k} \cdot \Delta\mathbf{R}_{i\mu}) = \exp(ika)$ , with  $N$  values for  $k$ , viz.  $k = 0, \pm \frac{2\pi}{Na}, \dots, \pm \frac{\pi}{a}$ . Then it is straightforward to show that

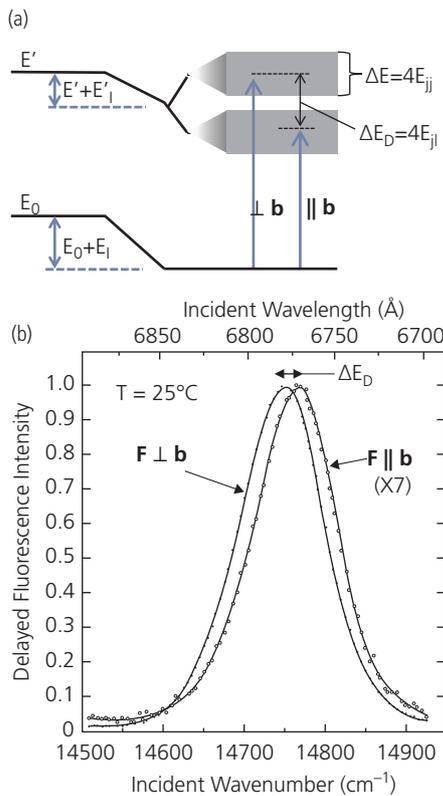

$$E(\mathbf{k}) = E_0 + E' + E'_I + 2E_{\mu\mu} \cos(\mathbf{k} \cdot \Delta\mathbf{R}). \quad (3.139)$$

The energies of the two dimer states are now split into  $2N$  different, but nearly degenerate states whose wavefunctions are given in Eq. 3.133. These states form the *Davydov band* whose bandwidth is  $\Delta E = 4E_{\mu\mu}$ . The exciton states that occupy this band are known as *Frenkel excitons*.

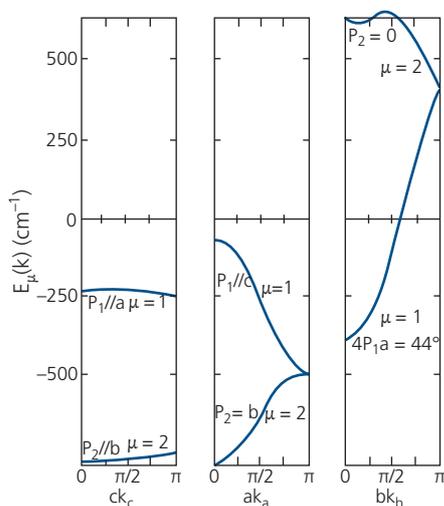

Note that Eq. 3.137 is analogous to the solution obtained for a dimer, Eq. 3.123. However, the energy splitting between the bands in the crystal is (from Eq. 3.139) equal to  $\Delta E = 4E_{\mu\mu}$ , which is twice that for the dimer. The difference arises since a molecule in the 1D crystal stack has inversion symmetry, and hence each molecule has two nearest neighbors—one above and another below each site.

When more than one translationally inequivalent molecule forms the crystal basis, the approximation of Eq. 3.139 is no longer valid since  $E_{\mu\nu} \neq E_{\mu\mu}$  for  $\mu \neq \nu$ . Referring to Eq. 3.136, there is an additional splitting of the exciton energy. For example, anthracene consists of a basis of two, translationally inequivalent molecules (see Fig. 2.8c), thereby splitting the spectrum into two absorption bands sensitive to light polarized parallel and perpendicular to the  $\mathbf{b}$  crystal symmetry axis. This polarization-dependent spectral shift is known as *Davydov splitting* with energy  $\Delta E_D$  (Davydov, 1962). Band splitting and example spectra showing the Davydov energy for the anthracene triplet state are shown in Fig. 3.50b. In the three-dimensional crystal, each molecule has four nearest neighbors that share the excitation, such that  $\Delta E_D \approx 8E_{\mu\nu}$ .

From a solution to the eigenvalue equation using the Hamiltonian in Eq. 3.131 along with the excited state wavefunctions in Eq. 3.133, one arrives at the Frenkel exciton band energy dispersion,  $E(\mathbf{k})$ , first calculated for anthracene by Davydov and Sheka (1965). Figure 3.51 shows the lowest two Frenkel

**Figure 3.50** (a) Energy splitting in a crystal, resulting in bandwidth,  $\Delta E$ , and a Davydov splitting energy,  $\Delta E_D$ . The transitions for anthracene with the incident field ( $\mathbf{F}$ )  $\perp \mathbf{b}$  and  $\parallel \mathbf{b}$  crystal axes are shown. (b) Spectra due to delayed fluorescence originating from the triplet state of anthracene (Avakian et al., 1968).

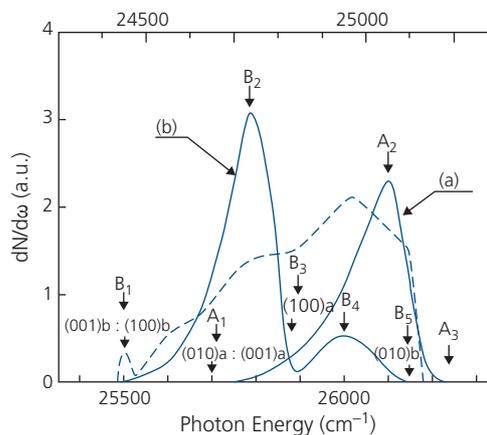

**Figure 3.51** Dispersion relationships,  $E_{\mu}(\mathbf{k})$ , of the lowest two exciton bands in anthracene in the first Brillouin zone along the (a) **c**, (b) **a**, and (c) **b** crystal axes. The light polarization directions  $P_{\mu}$  for the different bands ( $\mu$ ) are indicated (Davydov and Sheka, 1965).

bands in the first Brillouin zone along the three symmetry directions (the **a**, **b** and **c** axes), using the folded zone representation. The  $S_1 \leftarrow S_0$  transition energy is  $\tilde{\nu} = 27,570 \text{ cm}^{-1} = 3.42 \text{ eV}$ , corresponding to a wavelength of 275.8 nm.

Optical transitions occur near to the  $\mathbf{k} = 0$  point since the photon carries only a small momentum compared with the crystal (i.e. the transition is restricted to momentum changes of  $\Delta\mathbf{k} \approx 0$ ). The electron effective mass tensor is due to the band curvature, and is defined by

$$\frac{1}{m_{i,j}^*} = \left[ \frac{1}{\hbar^2} \frac{\partial^2 E(\mathbf{k})}{\partial k^2} \right]_{i,j} = \frac{1}{\hbar^2} \frac{\partial^2 E(\mathbf{k})}{\partial k_i \partial k_j}. \quad (3.140)$$

The bandwidths in molecular solids (i.e. the energy difference between the bottom of a band, typically at  $k = 0$  for direct bandgap systems, and the top of the band often found at the edge of the Brillouin zone) are small ( $\leq 300 \text{ cm}^{-1}$ ) compared to inorganic semiconductors with bandwidths  $\sim 1 \text{ eV}$  (equivalent to  $\sim 8065 \text{ cm}^{-1}$ ). The largest bandwidth in anthracene is along the **b**-axis which, among the three symmetry axes, has the smallest intermolecular spacing of 6.04 Å (Robertson, 1958). The bandwidth along this axis is approximately 0.09 eV ( $725 \text{ cm}^{-1}$ ), which is consistent with measurements of the singlet exciton band density of states using thermoabsorption spectroscopy, with results shown in Fig. 3.52 (Matsui et al., 1973). The Davydov splitting between the peaks,  $A_2 - B_2$ , is  $210 \text{ cm}^{-1}$ , which is consistent with calculated values. Note that this is greater than  $10 \text{ cm}^{-1}$  for the triplet

**Figure 3.52** Thermoabsorption spectra give the density of states ( $dN/d\omega$ ) of the first exciton bands of anthracene along the (a) **a** and (b) **b** directions. The low energy, peak and high energy edges along these directions are denoted by the letters with subscripts 1, 2, 3, respectively. Features  $B_4$  and  $B_5$  along **b** are also noted. The top abscissa gives the measured energy, and the lower axis is the calculated energy. The scales are offset by  $1050 \text{ cm}^{-1}$  to align the calculation to the measured fundamental 0–0 transition. The dashed curve is the calculated density of states (Matsui et al., 1973).

state in Fig. 3.50 due to the considerably larger oscillator strength of the singlet transition.

The anthracene bandwidths are smaller than bandwidths typical of inorganic semiconductors, the latter therefore having correspondingly smaller effective masses. Very tightly packed organic molecular solids can have broader bandwidths than that of anthracene. For example, PTCDA (with  $\Delta E \sim 0.1 \text{ eV}$ , see Fig. 3.53) and rubrene support excited states that bridge more than just nearest neighbors, and hence share characteristics common to both organic and inorganic materials. These intermediate systems and their excitonic properties are discussed further in the following section.

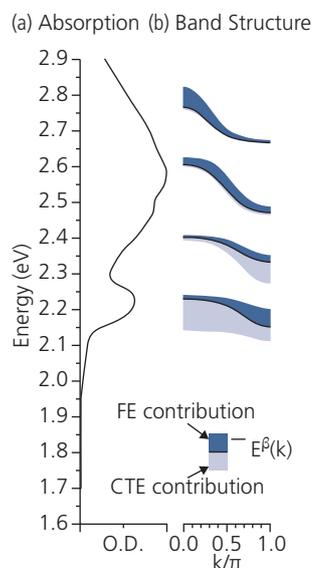

This chapter has taken us from the consideration of the energetics of individual molecules, to physical dimers, and finally to a crystal with a basis consisting of more than one translationally inequivalent molecule. The crystal exhibits a band structure for Frenkel excitons following the usual Bloch formalism used for describing electronic states in infinite crystal lattices. The transition from an isolated molecule to an infinite solid provides a picture that is useful in understanding molecular materials that apparently share many features of both the solid and isolated molecules of which it is comprised. This is in striking contrast to covalent or ionic materials whose spectroscopic properties seem to bear no resemblance to that of the individual atoms that make up the lattice. The differences in these systems, of course, is a result of the very

weak electrostatic bonds of van der Waals solids that only slightly perturb the electronic systems of their molecular constituents, whereas strong chemical bonds result in the sharing of, and strongly influence the valence electrons in inorganic semiconductors. Analogously, the covalent bonding within the

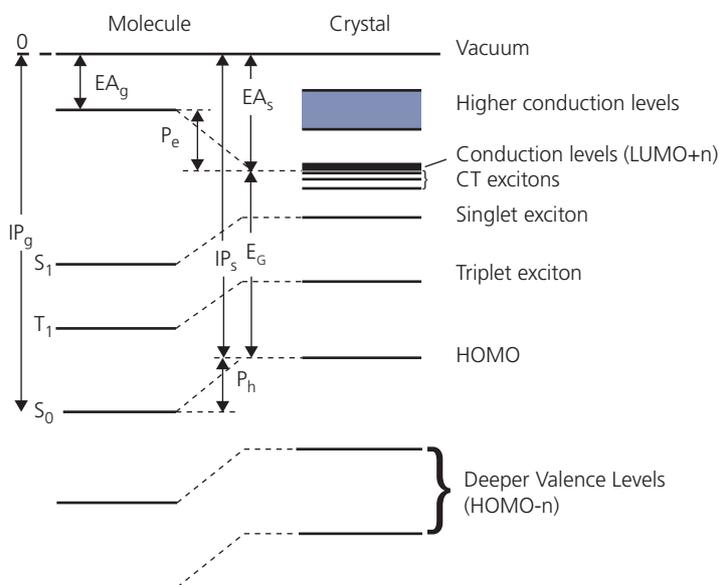

molecule itself results in energetics that bear only a faint resemblance to the constituent atoms.

The transition from molecule to solid is shown graphically in Fig. 3.54. This picture is a modified version of the *Lyons model* (Silinsh, 1980), which provides a bridge between the Jablonski diagram (Fig. 3.33) for individual molecules and the properties of the solid. Figure 3.54 shows the various transition energies observed for the molecule and the crystal referenced to the vacuum level. The *electron affinity* ( $EA$ ) is the energy required to remove an electron from the lowest conduction state in the solid to the vacuum level. The *ionization energy* (often stated as the *ionization potential*,  $IP$ ) is the energy difference between the ground state of the molecule, or HOMO, to the vacuum. The *polarization energy* of the solid for both electrons and holes ( $P_e$ ,  $P_h$ , respectively) lowers their *frontier orbital* (i.e. HOMO and LUMO) energies from values in the isolated molecules, as discussed in Sections 3.6.6 and 3.6.7.

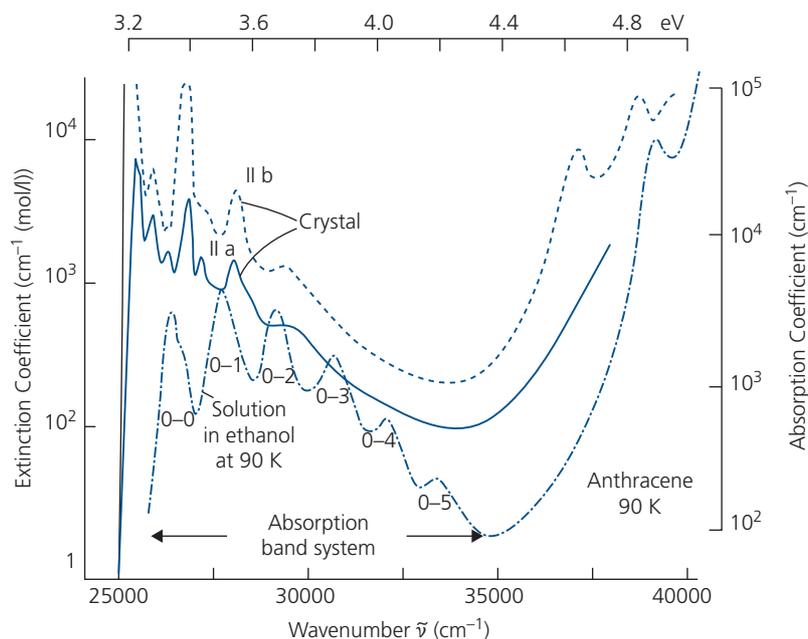

The changes in frontier orbital energies and their segregation into bands are accessed by different polarizations of the incident radiation. Their comparative spectra are shown in Fig. 3.55 for isolated anthracene molecules in a dilute ethanol solution. The solid state spectra are red-shifted and broadened relative to the solution spectra due to interactions between molecules (cf. Eq. 3.139). Similar phenomenological features for PTCDA are discussed below.

**Figure 3.53** (a) The absorption spectrum and (b) calculated exciton band structure for PTCDA. Here, FE is the Frenkel and CTE is the charge transfer exciton contributions to the band structure. See also Section 3.6.6 (Hoffmann et al., 2000).

**Figure 3.54** The correspondence between the energetics of isolated molecules and their crystals. The vacuum level energy is  $E = 0$ . Other energies shown are:  $EA$  = electron affinity,  $IP$  = ionization energy (subscript  $s$  = solid,  $g$  = gas),  $P_e$  ( $P_h$ ) = polarization energy of the electron (hole), and  $E_G$  = energy gap.

**Figure 3.55** Solution and solid state spectra of anthracene in ethanol. The solid state spectra are taken along two crystal axes, **a** and **b**. Note the red shift and broadening of the crystal spectra indicate the formation of energy bands. The vibronic progression is clearly visible in the solution spectrum; each transition is identified (Wolf, 1959).

### 3.6.5 Classification of excitons

If we approximate the exciton as a hydrogenic state, that is, the hole and electron are Coulombically bound, then from the Bohr model we obtain a binding energy of

$$E_B = -\frac{q^2}{8\pi a_0(\epsilon_r \epsilon_0)} \frac{1}{n^2} \quad (3.141)$$

with Bohr radius

$$a_0 = \frac{4\pi(\epsilon_0 \epsilon_r) \hbar^2}{m_r^* q^2} \quad (3.142)$$

Here,  $n$  is the principal quantum number of the excited state and  $m_r^*$  is the reduced effective mass of the exciton (Eq. 3.84). From this simplified treatment, we see that  $E_B \propto 1/\epsilon_r^2$  and  $a_0 \propto \epsilon_r$ . The exciton binding energies and radii for different semiconductors are listed in Table 3.3.

There are several differences between inorganic and organic semiconductors. The most notable is that the dielectric constants for the organic materials are significantly smaller, and the effective masses are larger than for inorganic semiconductors. As noted previously, these differences stem from the purely electrostatic bonds of organics that give rise to a smaller dielectric constant, and thus a concomitant increase in exciton

**Table 3.3** Comparison of exciton radii and binding energies for a variety of organic and inorganic semiconductors

Medium	$\epsilon_r$	$m_r^*/m_e$	$a_0$ (Å)	$E_B$ (eV)
Vacuum (H atom)	1	1	0.5	13.6
Anthracene <sup>a</sup>	2.4–4.1	1	1.2–2.1	0.8–2.4
PTCDA <sup>b</sup>	2.0–4.4	0.14–1	2.2–7.1	0.5–0.7
ZnS <sup>c</sup>	5.2	0.4	5.2	0.2
Si <sup>c</sup>	11.9	0.14	43	0.014
GaAs <sup>c</sup>	13.1	0.07	94	0.006

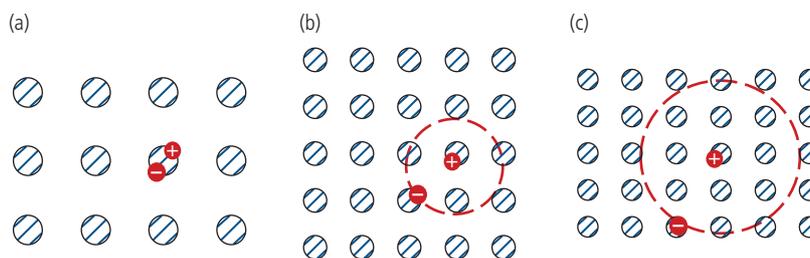

<sup>a</sup> From Cummins and Dunmur (1974).

<sup>b</sup> From Forrest (1997) and van der Meer (2014).

<sup>c</sup> From Sze (1981).

binding energy and decrease in radius compared to chemically bonded inorganic materials. Figure 3.56 classifies the three types of excited states that characterize these different materials.

- (i) *Frenkel excitons*: Molecular excitons are typically confined to a single molecule in the solid (Fig. 3.56a). These are known as Frenkel excitons. The exciton energy is influenced by polarization of the surrounding medium. Further, the Frenkel state can readily diffuse within the material by hopping from a molecule to its neighbors. Their very high binding energies ( $\sim 0.5$ – $1$  eV) make

**Figure 3.56** Three types of excitons illustrated by a positive and negative charge separated by an effective Bohr radius (dashed lines) in a lattice consisting of atoms or molecules (shaded circles): (a) Frenkel; (b) charge transfer; and (c) Wannier–Mott excitons.

these states stable at room temperature and above. Hence, Frenkel excitons dominate the optical properties of organics.

- (ii) *Charge transfer excitons*: During transport, the electron and hole may briefly reside on adjacent molecules. These molecules can be similar, or two dissimilar materials can form a *heterojunction* that is spanned by the Coulombically bound electron and hole. As inferred from the data in Fig. 3.36, the excited state may extend across several nearby molecules when their stacking distance is particularly small. For example, the intermolecular spacing along the (102) axis of PTCDA is only 3.21 Å (Forrest, 1997). PTCDA forms extended stacks that support a charge transfer (CT) state. These intermediate species are illustrated in Fig. 3.56b. Organic materials with prominent charge transfer characteristics can simultaneously exhibit Frenkel-like features in their optical properties. Such materials primarily behave as conventional excitonic materials, yet they share some important characteristics with chemically bonded inorganic semiconductors.
- (iii) *Wannier–Mott excitons*: Chemically bonded inorganic materials have high dielectric constants, leading to very low exciton binding energies (~5–50 meV) that are unstable at room temperature. These excited states, with concomitantly large radii that span many tens of lattice constants, are known as Wannier–Mott (W-M) excitons. Given their instability and low oscillator strengths, materials that support W-M excitons have optical and transport properties that are almost entirely independent of the exciton. Rather, inorganic materials exhibit optical and electronic properties that are dominated by band-to-band absorption and emission, and band transport phenomena. Engineered inorganic materials such as quantum wells, wires and dots comprising a very thin, low band gap

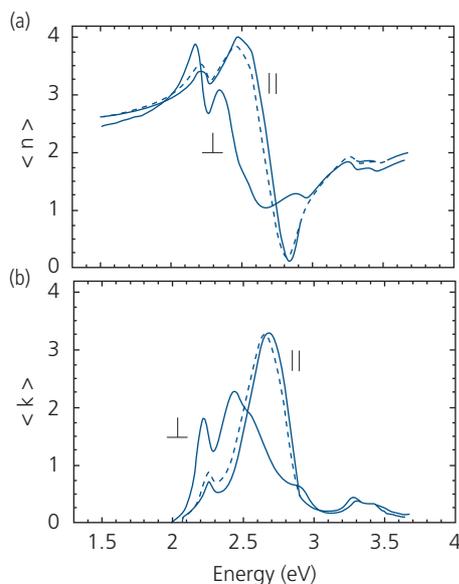

semiconductor sandwiched between two larger energy gap semiconductors can artificially reduce the size (and dimensionality) of the exciton while increasing its binding energy. In this way, engineered inorganic materials can be made to approximate Frenkel-like behavior.

We notice from Table 3.3 that organic materials exhibit pronounced anisotropies in their electronic properties: typically the coupling between molecules along the  $\pi$ -stacking direction is far stronger than in the other directions where there is comparatively little orbital overlap. This is in contrast to inorganic semiconductors that tend to have a higher level of lattice symmetry (e.g. cubic or hexagonal), leading to more isotropic properties.

The absorption spectra along different crystal axes reflect the large anisotropies in dielectric properties. Indeed, for PTCDA, the difference in the real part of the refractive index (known as the *birefringence*) is particularly large. Thus,  $\Delta n_r = 0.75\text{--}1.0$  (depending on wavelength), with the larger index in the plane of the molecule and the smaller along the stacking direction. In contrast, nearly isotropic dielectric properties are observed in the molecular plane due to the herringbone structure along this direction (see Fig. 2.18a). Figure 3.57 illustrates the directional dependence of the birefringence in both the real ( $n$ ) and imaginary ( $k$ ) parts of the refractive index for a single crystal of PTCDA both parallel and perpendicular to the (102) stacking direction (Zang et al., 1991, Alonso et al., 2002).

Anisotropy is also found in the molecular conductivities, as will be discussed in Chapter 4. Both Si and GaAs, for example, are found in lattices with cubic symmetry, whose properties are the same properties along the three orthogonal lattice directions.

Note that ZnS is the most ionic semiconductor in Table 3.3. It has a particularly large binding energy and small exciton radius for an inorganic material.

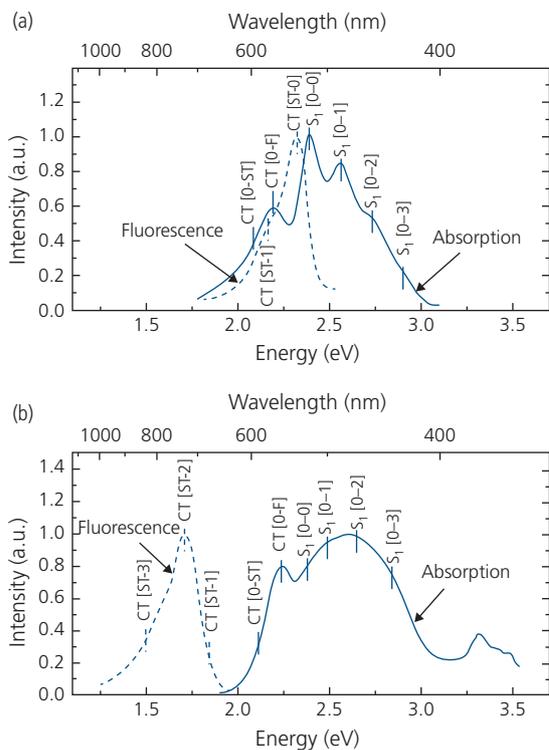

**Figure 3.57** Real ( $n$ ) and imaginary ( $k$ ) parts of the refractive index of a single crystal of PTCDA. Here,  $\parallel$  refers to light incident parallel to the crystal  $\mathbf{b}$ -axis (i.e. the in-plane direction) and  $\perp$  is along the stacking axis (perpendicular to the  $\mathbf{b}$ -axis). Slight differences in the  $\parallel$  spectra are observed for measurements at  $180^\circ$  relative to each other. From Alonso et al. (2002).

Ionic materials can exhibit stable, charge transfer-like properties due to their electron distributions localized among neighboring atomic cores in the lattice.

### 3.6.6 Charge transfer states

Typically, the CT state features are strongest at the low energy limb of the Frenkel exciton absorption and emission spectra in tightly stacked molecular solids. Furthermore, the large dielectric anisotropies characteristic of organics can result in the *mixing* of both Frenkel and CT properties across the entire spectral feature. That is, the CT state can extend along the  $\pi$ -stacking direction where the molecular orbitals significantly overlap, whereas perpendicular to the stacking direction the overlap is small, leading to nearly pure Frenkel-like behavior. The coexistence of these distinct excitonic states is particularly pronounced in the solution and thin film solid-state absorption and emission spectra of PTCDA shown in Fig. 3.58. In these spectra,  $S_1$  is the lowest Frenkel state. Hence, in spectroscopic notation, the several transitions correspond to  $S_1 \leftrightarrow S_0$  and  $CT \leftrightarrow S_0$ . Notice that there is a significant shift ( $\sim 0.6$  eV) of the fluorescence spectrum in the solid state compared to

**Figure 3.58** (a) Solution and (b) 100 nm thick film absorption and emission (fluorescence) spectra of PTCDA. The dilute solution consists of  $2 \mu\text{M}$  PTCDA dissolved in DMSO (Bulovic et al., 1996).

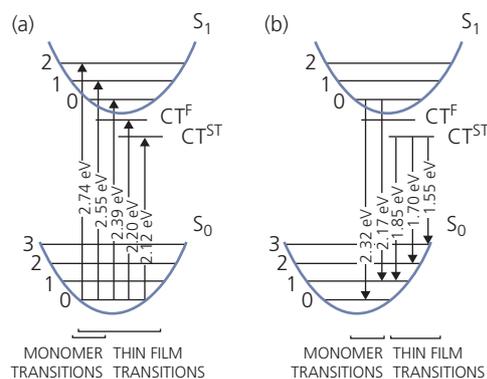

that in solution. This is attributed to emission from the relaxed CT state that lies below the Frenkel exciton, but is absent in solutions where the density of aggregates (and hence the CT state that depends on the cooperative excitation of several neighboring molecules) is low (see Section 3.6.2).

These spectral features are understood from the energy diagram in Fig. 3.59. Two CT states are identified:  $CT^F$  is a free charge transfer state, whereas  $CT^{ST}$  corresponds to a self-trapped state due to local lattice polarization by the extended CT state (Song and Williams, 1993). No direct  $S_1 \leftrightarrow S_0$  emission is observed since internal conversion transitions of  $S_1 \rightarrow CT^F$  and  $S_1 \rightarrow CT^{ST}$  are extremely rapid ( $\sim 10$  ns vs. 10 fs, the latter corresponding to the intramolecular phonon lifetime). In solids, energy stabilization in the vicinity of a lattice defect, impurity or free surface gives rise to self-trapping where the dielectric environment is locally distorted to immobilize the excited state (Craig et al., 1977). This is the proposed origin of the self-trapped CT exciton in PTCDA, whose energy is red-shifted by  $\sim 0.15$  eV from that of the free, or mobile  $CT^F$  exciton.

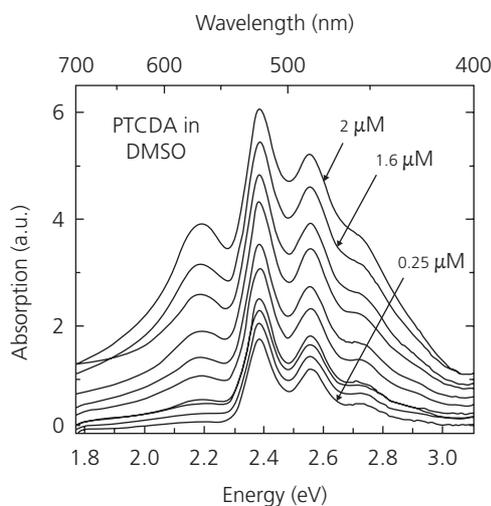

The solution spectrum shows clear evidence for a Frenkel-like vibronic progression, which is obscured

in the thin film spectrum due to line broadening from interactions with the intermolecular vibronic modes. While the solution is very dilute, there is, nevertheless, a sufficient concentration of aggregates to allow for easily detectable absorption at energies below the Frenkel manifold, that is, between 1.7 eV and 2.2 eV. However, the strength of CT vs. Frenkel absorption is less than in the solid state.

The CT states can be unambiguously identified by their absorption strength as a function of molecular concentration in the solvent. That is, since the CT states result from aggregation, we expect the absorption intensity to decrease superlinearly with dilution, compared to the linear concentration dependence of monomer states. In Fig. 3.60 we show the PTCDA absorption spectra as a function of concentration in a DMSO solution. The 2.25 eV peak intensity (i.e. its oscillator strength,  $f$ , relative to the  $S_1(0-0)$  peak at a

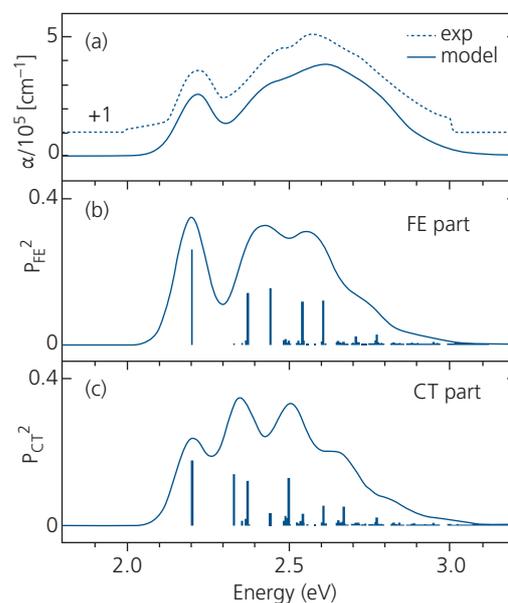

**Figure 3.59** Frenkel (monomer) and thin film CT transitions identified from the PTCDA spectra in Fig. 3.58 (Bulovic et al., 1996).

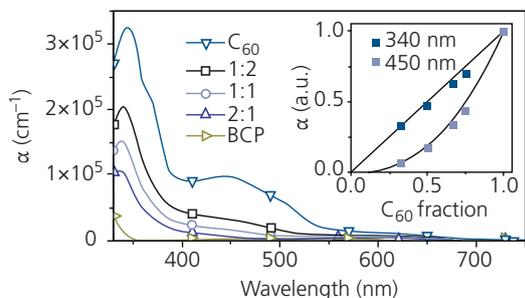

**Figure 3.60** Spectrum of a dilute solution of PTCDA in DMSO as a function of concentration (Bulovic et al., 1996).

concentration of  $[C_{\text{PTCDA}}] = 2 \mu\text{M}$ ) falls off superlinearly with concentration, and indeed completely vanishes at  $[C_{\text{PTCDA}}] < 0.2 \mu\text{M}$ , whereas the decrease in the higher energy Frenkel peak intensities between 2.3 and 2.8 eV are apparent at even the lowest molarity. Since the absorption intensity depends on the aggregate density, it must decrease with dilution until the solution becomes unsaturated, at which point neither aggregation nor their associated CT states exist. On the other hand, the monomer intensity should scale approximately linearly with  $[C_{\text{PTCDA}}]$ . However, the spectra in Fig. 3.60 show that the monomer concentration follows  $[C_M] \sim [C_{\text{PTCDA}}]^{0.64}$  whereas at lower energies there is an aggregate concentration dependence of  $[C_A] \sim [C_{\text{PTCDA}}]^{1.75}$ . The sublinear dependence of the monomer intensity suggests that residual aggregates are present in even the most dilute solutions, and that  $S_1$  and CT are mixed across the entire PTCDA absorption spectrum.

Charge transfer and Frenkel exciton mixing has been theoretically predicted for PTCDA, as shown in Figs. 3.53 and 3.61 (Hoffmann and Soos, 2002). The model considers all observed excited states, that are represented by the vertical bars in Fig. 3.61b and c. It accurately reproduces the positions of the measured absorption peaks in the spectrum in Fig. 3.61a that

**Figure 3.61** (a) Calculated and measured solid-state spectra of PTCDA. (b) Transition spectral weights due to Frenkel (FE) and (c) charge transfer (CT) excitons in the absorption spectrum.  $P_{\text{FE}}^2$  and  $P_{\text{CT}}^2$  are the corresponding transition moments. Vertical bars in (b) and (c) correspond to the eigenstate positions and oscillator strengths contributing to the spectra before including line broadening. From Hoffmann and Soos (2002).

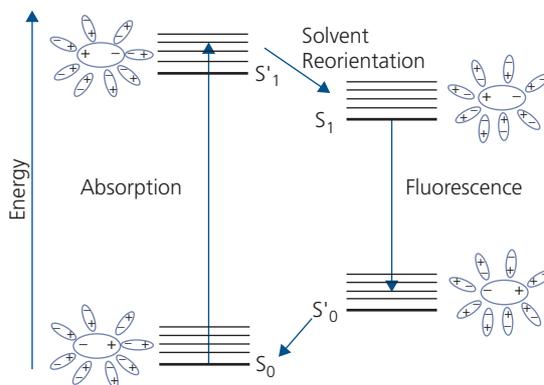

**Figure 3.62** Absorption spectra of  $C_{60}$  mixed at varying dilutions in a wide energy gap bathocuproine (BCP) host. The ratios shown are X:Y (by volume) of BCP: $C_{60}$ . Inset: Normalized absorption peak intensities at the two wavelengths indicated, with the peak at 450 nm due to CT state absorption, and at 340 nm to Frenkel exciton absorption (Bartynski et al., 2013).

includes line broadening due to vibronic coupling, excited state lifetime, and other extrinsic sources. The closely coupled molecular orbitals within the PTCDA stacks result in an admixture of both CT and Frenkel states across the observed spectra.

A second example of a strong spectral contribution from CT states is  $C_{60}$ , whose spherical symmetry allows for a tightly spaced hexagonal close-packed lattice. The low energy tail of the  $C_{60}$  absorption spectrum is dominated by a CT state centered at a wavelength of  $\lambda \sim 450$  nm (Kazaoui et al., 1998). In Fig. 3.62, we show the absorption spectra of films of  $C_{60}$  diluted in a wide energy gap matrix of bathocuproine (BCP) (Bartynski et al., 2013). As in the case of the solution spectra of PTCDA, the CT peak intensity falls off rapidly with decreasing  $C_{60}$  concentration (as  $[C_{60}]^{2.7}$ ), whereas the monomer peak at  $\lambda = 340$  nm follows a linear dependence on  $[C_{60}]$ , as expected from Beer's law. DFT calculations show that the CT and Frenkel excitons are not entirely independent, which is similar to the situation with PTCDA. Indeed, the entire  $C_{60}$  spectrum contains contributions from both localized and extended molecular states (Kazaoui et al., 1998).

### 3.6.7 Solvatochromism and dielectric effects

We have seen that the dielectric environment can play a significant role on the excited state energies. This is especially true for molecules whose excited states and extended  $\pi$ -electron systems interact with neighboring molecules. The spectral shifts that result are the origin of the phenomenon broadly referred to as *solvatochromism*, which is most pronounced for dipolar molecules in dipolar solvents where intermolecular interactions are strongest (Reichardt, 2003). The

**Figure 3.63** The origin and spectral consequences of solvatochromism. Shown adjacent to each state is a dipolar fluorescent molecule (large ovals) surrounded by solvent molecules (small ovals) whose dipoles orient to respond to that of the solute in both the ground and excited states. The lines above the lowest state energies represent the vibronic states (Reichardt, 2003).

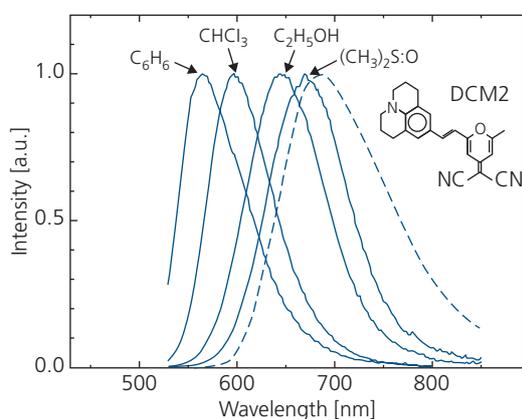

solvent can be in either the liquid or solid phase. While the treatment of solvatochromism has been widely studied in liquid solution, we are ultimately concerned with energy shifts due to self-polarization (or self-trapping as discussed in Section 3.6.6) from solvation in the solid state due to its relevance to electronic devices.

Addition of a dipole into a dielectric polarizes the surrounding medium that either lowers the energy of the molecule, thereby causing a red shift in its emission that is added to the Franck–Condon energy, or less frequently it raises the dipole energy inducing a blue shift. In Fig. 3.63 we show the dipolar orientation of solvent molecules surrounding a polar solute in both the ground and first excited states. This reorientation lowers the total system energy, thereby stabilizing the molecular states. The red shifted emission is called *positive solvatochromism*, and the shift to lower energy is known as a *bathochromic shift*. A blue, or *hypsochromic shift*, is known as *negative solvatochromism*.

Three different situations can occur in solution (and analogously, in solids). (i) Both the solvent and the solute are nonpolar, in which case the solvatochromatic energy stabilization is due to weak van der Waals or London forces. Their very short range ( $\sim 1/r^6$ ) only contributes minor shifts in the absorption and emission spectra of the solute molecule. (ii) One of the species (solvent or solute) has a fixed ground state dipole moment. Then the forces between solvent and solute are due to longer range fixed dipole-induced dipole forces ( $\sim 1/r^3$ ). And finally, (iii) a dipolar solute is in a polar solvent. This is the situation in Fig. 3.63 where the solvent molecules form a “cage” around the

solute that screens the electric field, stabilizing both solvent and solute. If the solute dipole moment in the excited state increases relative to the ground state, the excited state is more highly stabilized in the solvent resulting in a bathochromic shift of the absorption spectrum. Alternatively, if the excited dipole moment is reduced, a hypsochromic shift ensues.

The more polar the solvent, the larger the spectral shift, as shown in Fig. 3.64 for the dipolar, red fluorophore DCM2 in different solvents. A fluorescence emission shift of  $\sim 0.5$  eV is observed between dilution in the nonpolar benzene to self-solvation in its highly polar thin film (with a dipole moment of  $\mu = 11.3$  D). From these data, it is apparent that solvent shifts can occur both in liquids and solids, and have a common

**Figure 3.64** Fluorescence spectrum of DCM2 (shown in inset) dissolved in increasingly polar solvents, from the nonpolar benzene ( $C_6H_6$  with a dipole moment of  $\mu = 0$  D) to 1.15 D for  $CHCl_3$  (chloroform), 1.69 D for  $C_2H_5OH$  (ethanol), to 3.9 D for  $(CH_3)_2S:O$  (DMSO). Fluorescence from a neat thin film of DCM2 is also shown (dashed line,  $\mu = 11.3$  D) (Bulovic et al., 1998).

R., Bright, saturated red-to-yellow organic light-emitting devices based on polarization-induced spectral shifts copyright 1998 with permission from Elsevier.

origin—stabilization of the excited or ground state molecules within the dielectric environment. Of course, the solvent dipoles can fully reorient in liquids, whereas only induced dipoles can reorient in the solid state.

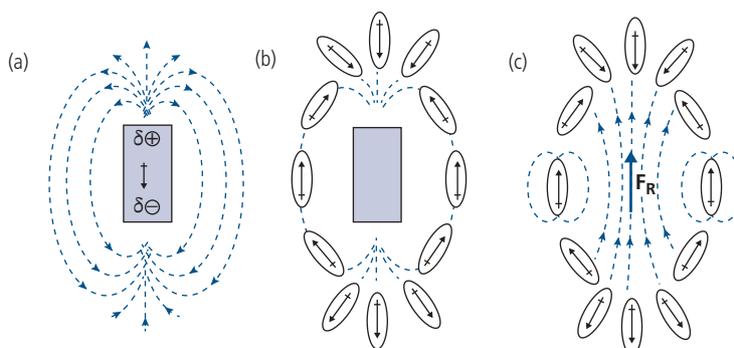

Molecular reorientation due to lattice polarization occurs slowly compared to the time scale required for absorption, and hence the Franck–Condon principle can be applied to analyze solvent effects. On the other hand, the time between absorption and emission is generally sufficiently long to allow for dielectric relaxation due to electron-phonon interactions within the molecule itself. Phonon lifetimes result in spectral shifts on times scales ranging from  $10^{-13}$  to  $10^{-11}$  s.

We model solvation effects by considering the *reaction field* created by the dipoles of the solvent responding to that of the solute, forming the solvent cage in Fig. 3.65a and b. If the solute molecule is removed from the center of the cage, we are left with a reaction field,  $F_R$  resulting from the solvent molecular alignment (Fig. 3.65c). This field opposes the solute dipole field, consequently enhancing both the permanent and induced dipoles, leading to a spectral energy shift. To determine the magnitude of the shifts, we must calculate  $F_R$ .

Onsager calculated the reaction field using the *continuum approximation*, whereby the dipole is placed in a homogeneous nonpolar dielectric medium (Onsager, 1936). The total electric dipole moment in an electric field,  $F_0$ , is the sum of the permanent and induced dipole moments ( $\alpha F$ ):

$$\mathbf{p}_T = p_M \hat{\mathbf{r}} + \alpha \mathbf{F}_0, \quad (3.143)$$

where  $\mathbf{p}_T$  is the dipole moment of the solute,  $p_M$  is that of the solute in vacuum,  $\alpha$  is the polarizability of the medium, and  $\hat{\mathbf{r}}$  is a unit vector along the direction of

**Figure 3.65** Origin of solvatochromism. (a) Dipole field of the isolated solute molecule. The dipole direction is indicated by the arrow. (b) Orientation of the solvent molecules in response to the dipolar solute. (c) Reaction field from the solvent molecules due to orientation to, but in the absence of the solute molecule itself (Klessinger and Michl, 1995).

the dipole moment. From Debye's expression for the dielectric constant ( $\epsilon_r$ ), the reaction field is

$$\mathbf{F}_R = -\frac{2(\epsilon_r - 1)\mathbf{p}_T}{2\epsilon_r + 1} \frac{1}{a^3}, \quad (3.144)$$

where the molecule is assumed to be spherical, with radius  $a$ . For an induced dipole (see Section 2.4.3), the energy is  $E = -\frac{1}{2}\mathbf{p} \cdot \mathbf{F}$ , giving a solvatochromatic energy shift of

$$\Delta E_{\text{SOL}} = -\frac{12(\epsilon_r - 1)p_T^2}{2} \frac{1}{2\epsilon_r + 1} \frac{1}{a^3}. \quad (3.145)$$

This treatment ignores changes in  $\mathbf{p}$  from the ground to the excited states, and it assumes that the dipole in solution is free to align with  $\mathbf{F}_R$ .

For polar solvents, we must also add to the energy contributions due to reorientation of the dipoles in both the solvent and solute. When these are included we obtain (Karelson and Zerner, 1992)

$$\Delta E_{\text{SOL}} = -\frac{1}{2a} \left[ \frac{2(\epsilon_r - 1)}{2\epsilon_r + 1} (\mathbf{p}_G - \mathbf{p}_E) \cdot \mathbf{p}_G + \frac{2(n_r^2 - 1)}{2n_r^2 + 1} (\mathbf{p}_G - \mathbf{p}_E) \cdot \mathbf{p}_E \right], \quad (3.146)$$

where  $\mathbf{p}_G$  ( $\mathbf{p}_E$ ) is the ground (excited) state dipole moment of the solute molecule. Also,  $n_r$  is the index of refraction of the solvent ( $\epsilon_r = n_r^2$  at optical frequencies,  $\omega \rightarrow \infty$ ). This expression is reasonably accurate for predicting bathochromic and hypsochromic spectral shifts, depending on whether  $p_G$  is larger or less than  $p_E$ , respectively.

Solvatochromism in liquids using the continuum approximation has been rigorously analyzed by Liptay based on the Helmholtz free energy of the system,  $A_S$ , with results that can also be applied with some modification to the solid state (Liptay, 1974). The free energy is

$$A_S = A_{\text{sol}}^0 + VN \sum_k w_{k\lambda} \{W_k^0 + W_{lk\lambda} + W_{Ck} + W_{Dk} + W_{Pk} - \mathbf{p}_k \cdot \mathbf{F}_{Rk} - \frac{1}{2} \alpha_k F_{Rk}^2\}. \quad (3.147)$$

Here,  $k$  refers to the vibrational and  $\lambda$  to the librational states of the solute molecule,  $V$  is the volume, and  $N$  is the number density. Librations are relative motions between molecules, excited by intermolecular phonons that are at a considerably lower energy (by more than 10 times) than the most energetic intramolecular phonon modes. This expression is instructive, since it decomposes the total energy of the solvent-solute system into each of its contributions. Thus,  $w_{kl}$  is the

probability for the solute molecule to be in state  $(k, \lambda)$ ,  $A_{\text{sol}}^0$  and  $W_k^0$  are the energies of the solvent and isolated solute molecules, respectively,  $W_{lk\lambda}$  is the change of molecular librational energy due to solvent-solute interactions,  $W_{Ck}$  is the work required to form the cage in Fig. 3.65b,  $W_{Dk}$  is the dispersion interaction energy between solute and solvent, and  $W_{Pk}$  is the polarization energy due to the dipole in solution. The last two terms are the work required to place the dipole,  $\mathbf{p}_k$ , in solution, and the energy arising from the polarization of the surrounding solvent due to that dipole (see Eq. 3.143). The equilibrium energies of the solvent and solute do not contribute to the spectral shift, leaving

$$\Delta E_{\text{SOL}} = A_S - A_{\text{sol}}^0 - VN \sum_k w_{k\lambda} \{W_k^0 + W_{lk\lambda}\}. \quad (3.148)$$

Each of the terms in Eq. 3.147 is model-dependent, and hence we will not explore their derivation further here. The reader is referred to the extensive literature for more details (see, for example, Liptay, 1974, Reichardt, 2003).

Given the extended and directional nature of CT states that involves at least two neighboring molecules, we need to consider the limits of the continuum approximation. That is, at what point does a system transition from one consisting of discrete molecules in a perhaps highly anisotropic crystal, to that of a homogeneous dielectric medium? This situation has been generally treated in anthracene (Bounds and Siebrand, 1980, Bounds et al., 1981), and subsequently for the archetype molecular solids of PTCDA and NTCDA (Shen and Forrest, 1997). While NTCDA is approximately isotropic, PTCDA is a highly anisotropic molecular crystal, hence providing an interesting contrast between these structures.

The dipole moment of the electron and hole comprising an exciton results in a polarization energy shift,  $p_E(\mathbf{r})$ , that is particularly pronounced for highly interacting electronic systems such as in closely stacked PTCDA. To calculate  $p_E(\mathbf{r})$ , consider a molecule at position,  $\mathbf{r}(i, \mu)$ , in a lattice with a basis whose unit cell volume is  $v$ . Here,  $i = \{i_a, i_b, i_c\}$  is the lattice index, and  $\mu = \{1, 2, 3, \dots\}$  is the index of a particular basis molecule within the unit cell. In the presence of an external electric field,  $\mathbf{F}_o$ , the total field at site  $(i, \mu)$  is

$$\mathbf{F}_{\text{tot}}(i, \mu) = \mathbf{F}_o(i, \mu) + F_{\text{ind}}(i, \mu), \quad (3.149)$$

where  $F_{\text{ind}}(i, \mu)$  is the sum of the fields due to the dipole at the same site (i.e. the self-field,  $\mathbf{F}_{\text{self}}(i, \mu)$ ), and that due to the surrounding dipoles. Thus, we have

$$\mathbf{F}_{ind}(i, \mu) = \mathbf{F}_{self}(i, \mu) + \sum_{\substack{N,m \\ k,v \neq i,\mu}} \vec{t}(i, \mu; k, v) \mathbf{p}_{ind}(k, v), \quad (3.150)$$

where, as in Section 3.6.4,  $N$  is the number of unit cells and  $m$  is the number of molecules in the basis. Also,  $\vec{t}$  is the dipole tensor (Jackson, 1998):

$$\vec{t}(i, \mu; k, v) = \lim_{r \rightarrow r(k,v)} \nabla^2 \left| \frac{1}{|\mathbf{r}(i, \mu) - \mathbf{r}|} \right|. \quad (3.151)$$

This is the equivalent of the reaction field in solution. Assuming a spherical dipole for homogenous and isotropic media (which is different from the case of anisotropic molecular crystals), we can approximate  $\mathbf{F}_{self}(i, \mu) = -\mathbf{p}_{ind}(i, \mu)/3v\epsilon_0$  (Jackson, 1998). Then the induced dipole moment in the solid is (cf. Eq. 3.143)

$$\mathbf{p}_{ind}(i, \mu) = \vec{\alpha}(i, \mu) \mathbf{F}(i, \mu), \quad (3.152)$$

where  $\vec{\alpha}(i, \mu)$  is the effective polarizability tensor of the molecule at  $\mu$ , and  $\mathbf{F}_{loc}(i, \mu)$  is the local (average) field at site  $(i, \mu)$  excluding the induced field due to the molecule itself. Hence,

$$\mathbf{F}_{loc}(i, \mu) = \mathbf{F}_{tot}(i, \mu) - \mathbf{F}_{self}(i, \mu). \quad (3.153)$$

Finally, we arrive at the induced dipole moment at  $(i, \mu)$  due to a reaction from dipoles at  $(k, v)$  in an external field:

$$\mathbf{p}_{ind}(i, \mu) = \vec{\alpha}(i, \mu) \left[ \mathbf{F}_0(i, \mu) + \sum_{\substack{N,m \\ k,v \neq i,\mu}} \vec{t}(i, \mu; k, v) \mathbf{p}_{ind}(k, v) \right] \quad (3.154)$$

The total crystal polarization energy is found by summing over all individual dipoles to obtain (Shen and Forrest, 1997)

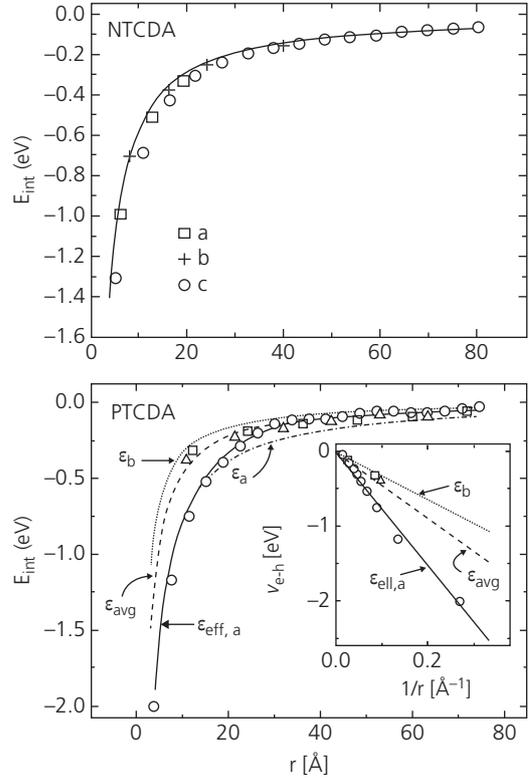

$$p_E(k, v) = -\frac{1}{2} \sum_{i,\mu}^{N,m} \mathbf{p}_{ind}(i, \mu) \cdot \mathbf{F}_0(i, \mu). \quad (3.155)$$

Thus, the total electron–hole interaction energy for the exciton is the sum of the unscreened Coulomb attraction and the crystal polarization energy resulting from the local lattice response from the charge pair, via

$$E_{int} = -\frac{q^2}{4\pi\epsilon_0 |\mathbf{r}(i, \mu) - \mathbf{r}(k, v)|} + p_E(k, v). \quad (3.156)$$

The relative dielectric constant of the medium arises from the crystal polarization given by the second term in Eq. 3.156.

The energy,  $E_{int}$ , is calculated for NTCDA and PTCDA using known dielectric tensor elements, with the results shown in Fig. 3.66 (Shen and Forrest,

**Figure 3.66** Calculated interaction energies for two molecular crystals. NTCDA is a herringbone structure with nearly isotropic dielectric properties, evidenced by the similarities in interaction energies of the CT state ( $E_{int}$ ) along the **a**, **b**, and **c** lattice directions. The solid line corresponds to an isotropic crystal with a single average dielectric constant,  $\epsilon_{avg}$ . PTCDA is a planar stacking crystal with large dielectric anisotropies. The dashed line corresponds to the spatial average, and the lower solid line shows a phenomenological fit to an “effective” isotropic dielectric constant,  $\epsilon_{eff,a}$ . Inset: Data replotted vs.  $1/r$  (Shen and Forrest, 1997).

1997). These results are compared with the “screened” Coulomb potential,

$$E_{int} = -\frac{q^2}{4\pi\epsilon_0 \vec{\epsilon} r} \quad (3.157)$$

where  $\vec{\epsilon}$  is the *macroscopic* dielectric tensor for the crystal. Since diagonal elements of the NTCDA dielectric tensor are approximately equal (characteristic of a nearly isotropic herringbone structure, see Fig. 2.18b), the electron–hole interaction energy is comparable to that obtained with a single, spatially averaged dielectric constant,  $\epsilon_{avg}$ , as shown by the solid line in Fig. 3.66 (top), along with the calculation using the actual dielectric constants from Eq. 3.157 along the **a**, **b**, and **c** crystal directions. The separate points correspond to interaction energies due to CT states where the electron is located on discrete molecular lattice sites at different distances from the hole to which it is Coulombically

bound. Clearly,  $E_{int} = -\frac{q^2}{4\pi\epsilon_0\epsilon_{avg}r}$ , characteristic of a nearly spherical Wannier–Mott-like state provides a good fit to the calculated values along all crystalline directions, and even for excitons that sample only nearest neighbors (i.e. for  $r \sim 4$  Å). Indeed, we can consider the interaction energy to follow the Bohr progression of  $E_B \sim 1/n^2$  (Eq. 3.141) where  $n \geq 1$  is the principal quantum number of a nearly spherical CT state whose electron and hole are separated by increasing, but discrete distances since each is located on a distinct molecule at site  $i$  (Bounds and Siebrand, 1980).

For anisotropic PTCDA, however,  $E_{int}$  depends sensitively on the crystal direction for  $r < 20$  Å. The

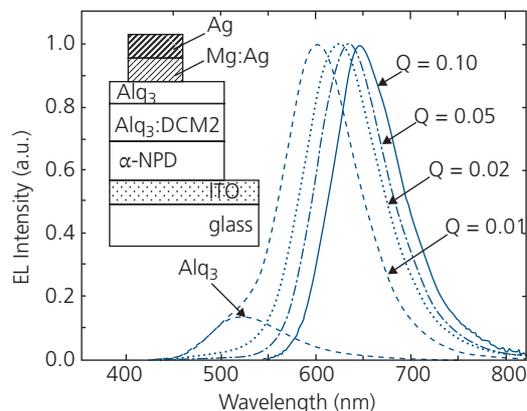

dashed curve in Fig. 3.66 is a plot of  $E_{int} = -\frac{q^2}{4\pi\epsilon_0\epsilon_{avg}r}$

where the dielectric constants along the three axes are averaged following  $\epsilon_{avg} = 3/(1/\epsilon_{\perp} + 2/\epsilon_{\parallel}) = 3.2$  (Shen and Forrest, 1997). Here,  $\epsilon_{\perp}$  is the dielectric constant along the (102)  $\pi$ -stacking axis, and  $\epsilon_{\parallel}$  is along the more loosely packed, in-plane directions. The “isotropic approximation” results in reasonable fits to  $E_{int}$  only for large  $r$  ( $>25$  Å), suggesting that the potential becomes spatially averaged at electron–hole separations of several molecular lattice constants ( $\geq 5$ ) from the origin. However, for small  $r$  ( $<15$  Å),  $E_{int}$  noticeably deviates from the spatial average. This deviation is more apparent in the inset of Fig. 3.66, where  $E_{int}$  is plotted vs.  $1/r$  to accentuate variances with the isotropic approximation as  $r \rightarrow 0$ . For small  $r$ , the mean dielectric constant can be approximated using

$E_{int} = -\frac{q^2}{4\pi\epsilon_0\epsilon_i r}$ , where  $i$  refers to the three crystal lattice directions.

The foregoing results are, in some respects, similar to the case of conventional semiconductors where the crystal lattice is regarded as a macroscopic polarizable medium with spatially averaged dielectric constants, as long as the electron–hole distance is large compared to the lattice constant. Fundamentally, an electron in the LUMO as well as a hole in the HOMO in molecular crystals are accompanied by significant electronic polarization of the surrounding medium. This suggests that CT excitons with radii of only a very few lattice constants sample a sufficiently large volume to respond as if the medium were macroscopic, even though at that scale individual molecules exist in an environment that is considerably more discrete than found in inorganic materials.

An example of solvatochromism in organic light emitting diodes (OLEDs) whose emissive region comprises solid binary mixtures (called the *solid state solvation effect*, SSSE) of the fluorophores DCM2 and Alq<sub>3</sub>

**Figure 3.67** Solid state solvation effect observed in the electroluminescence spectrum of an OLED with different concentrations ( $Q$ ) of the red emitting fluorophore, DCM2, in Alq<sub>3</sub>. Here, ITO is indium tin oxide, and the hole transport layer is  $\alpha$ -NPD. As the DCM2 concentration increases from 0.01 to 0.10, the mixture becomes increasingly dipolar, resulting in a pronounced red shift of the emission peak from 575 nm to 650 nm. The neat Alq<sub>3</sub> spectrum is shown for reference. (Bulovic et al., 1998)

is shown in Fig. 3.67. A rigid bathochromic shift of the emission peak from  $\lambda = 575$  nm to 650 nm (corresponding to an energy shift of 0.26 eV) is observed as the concentration is increased from 1% to 10% DCM2. The DCM2 molecule has a dipole moment of 11 D, compared with its host, Alq<sub>3</sub>, at 5.5 D. Hence, the average dipole moment of the solid solution increases with DCM2 concentration, resulting in the shift in the OLED emission spectrum. Bathochromic shifts are often attributed to excimer formation (Tang et al., 1989). However, the shift is not accompanied by spectral broadening. Furthermore, similar spectral changes are observed for DCM2 in dipolar solutions in Fig. 3.64. This is evidence that the shifts are due to solvation effects in the solid, binary mixture (Bulovic et al., 1998). We will show in Section 6.3.2 that the SSSE is an effective means for controlling the color emission from OLEDs.

The above analysis suggests that the solvatochromatic energy shift linearly increases with the dipole field (cf. Eqs. 3.155 and 3.156). This, in turn, should increase with the dipole density. The change in relative dielectric constant,  $\Delta\epsilon_r$ , is expected to depend on the change in dipole (i.e. fluorophore) density,  $\Delta N$ , due to the applied pressure,  $P$ . This approach eliminates red shifts due to aggregation or other extrinsic effects that may accompany increasing concentrations of the dipolar fluorophore in a host matrix.

Relating the density to the uniaxial pressure, it can be shown that (Chang et al., 2015)

$$\frac{\Delta\epsilon_r}{\epsilon_r - 1} = \frac{\Delta N}{N_0} \approx \frac{1 - 2\nu}{Y} P = aP, \quad (3.158)$$

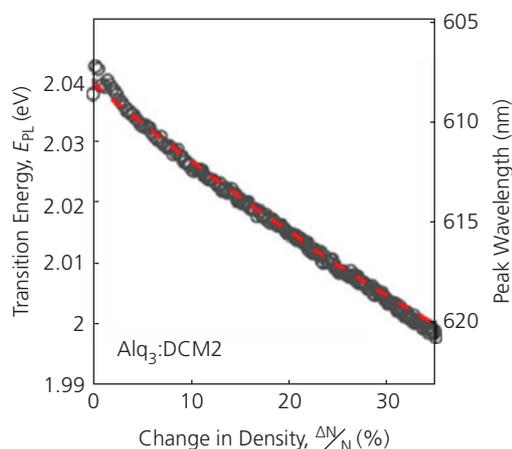

where  $N_0$  is the equilibrium dipole density,  $\nu$  is Poisson's ratio (Chapter 2), and  $a$  is a constant. Also,  $Y$  is *Young's modulus*, which is the ratio of the stress to the strain, that is, it relates the elongation or compression of a solid to the amount of pressure applied. Thus,

$$Y = \frac{\mathcal{F}a_0}{A\Delta a}, \quad (3.159)$$

where  $\mathcal{F}$  is the force applied,  $\Delta a$  is the strain (i.e. its change from its equilibrium lattice constant,  $a_0$ ), and  $A$  is the sample area.

The pressure dependence of solvatochromism in DCM2 doped at 2 vol.% in Alq<sub>3</sub> was investigated using a micrometer head that was advanced to apply pressure to the doped film while measuring the peak emission wavelength, spectral width and radiative lifetime of DCM2. As shown in Fig. 3.68, the peak red shifts with the change in pressure from 0 to 0.4 GPa (and hence the DCM2 density). Recall from our discussion of dimers in Section 3.6.2 that aggregation results in a broadened and featureless emission spectrum, and it can reduce the PL quantum yield due to strong coupling to intermolecular vibrational modes. Since neither the peak width nor its radiative lifetime show significant changes with pressure, we conclude that molecular aggregation effects are absent, and the spectral shifts are due entirely to increased dipole coupling over the range of pressures investigated.

The dashed line in Fig. 3.68 is a fit to the data following Eq. 3.158, with a pressure coefficient of  $\alpha = 1.1 \text{ GPa}^{-1}$ . This is at least a factor of 2–4 higher

**Figure 3.68** DCM2 peak energy vs. the change in molecular density,  $\Delta N/N$ , which is linearly proportional to the pressure applied. Data points are overlaid with a phenomenological model (dashed line) described in the text (Chang et al., 2015).

than predicted using measured values of  $\nu$  and  $Y$ . The discrepancy is attributed to simplifications leading to Eq. 3.158, as well as to errors in estimating the pressure in the experiments (Chang et al., 2015). Nevertheless, the pressure-dependent peak shifts illustrate the importance of dipole density, and hence the local dipole-induced electric field in influencing the energetics of organic semiconductors.

### 3.7 Spin

In Section 3.1 we noted that excitonic states can have either an odd or even symmetry under spin exchange. This results in either a singlet (with spin total quantum number  $S = 0$ ) or a triplet ( $S = 1$ ) quantum state. The triplet and singlet wavefunctions are provided in Eqs. 3.2 and 3.3, respectively. As discussed, the Pauli Exclusion Principle requires that the total spinorbital wavefunction,  $\Phi^{\sigma}(\mathbf{r})$ , must be asymmetric under electron exchange. Since the singlet state is antisymmetric, its spatial (orbital) wavefunction is symmetric (Eq. 3.2), and for the symmetric triplet states, the spatial wavefunction is antisymmetric (Eq. 3.3). Now, the dominant optical transition between states is due to electric dipole interactions whose Hamiltonian contains the dipole operator  $\hat{\mu}_e = -q\mathbf{r}$ . Hence, the expectation value of electronic transitions is determined by the integral:

$$\langle \psi_f(\mathbf{r}_1, \mathbf{r}_2; S, m_S) | H_{int} | \psi_i(\mathbf{r}_1, \mathbf{r}_2; S, m_S) \rangle \sim \langle \psi_f(\mathbf{r}_1, \mathbf{r}_2; S, m_S) | \mathbf{r} | \psi_i(\mathbf{r}_1, \mathbf{r}_2; S, m_S) \rangle. \quad (3.160)$$

Since the operator symmetry is odd, allowed transitions can only occur between states whose spatial symmetry is different (this is known as the *Laporte selection rule*, Table 3.1). That is, there must be a change in parity between the initial and final states. However, since the dipole operator carries no spin-related terms (it operates only on the spatial wavefunction), the initial spin states are conserved in dipole transitions. Since the ground state is typically a singlet ( $S_0$ ), this implies that the dominant transition from the ground state is to a singlet excited state (e.g.  $S_1 \leftarrow S_0$ ). Transitions between triplet states (e.g.  $T_3 \leftarrow T_1$ ) are also dipole allowed.

Other factors can lead to otherwise spin-forbidden transitions. Most important are the disallowed triplet-singlet transitions that lead to phosphorescence in organic heavy metal complexes. According to Fig. 3.33,  $T \leftrightarrow S$  transitions can arise from ISC between spin states of different symmetry. Once such a transition occurs in the excited state, rapid and radiative fluorescent de-excitation to the ground state

is observed. The opposite transition, if it occurs on a time scale shorter than the fluorescence lifetime ( $\sim 1\text{--}10$  ns), can result in phosphorescent emission.

### 3.7.1 Spin-orbit coupling

Violation of the spin selection rule can occur when the triplet and singlet states are mixed. An effective source of mixing is *spin-orbit coupling*, whereby the spin of the electron is perturbed by interacting with its orbital angular momentum. Spin-orbit coupling can be understood by calculating the field generated by a charge moving in an orbital. The *Biot-Savart law* gives the magnetic field in the reference frame of a charge of velocity,  $\mathbf{v}$ , in an electric field,  $\mathbf{F}$ , as follows:

$$\mathbf{B} = -\frac{\mathbf{v} \times \mathbf{F}}{c^2}. \quad (3.161)$$

Since the field of a point charge is isotropic, we can write  $\mathbf{F}$  in terms of the radial potential,  $V$ :

$$\mathbf{F}(\mathbf{r}) = -\hat{\mathbf{r}} \frac{dV(r)}{dr}, \quad (3.162)$$

from which we obtain:

$$\mathbf{B} = \mathbf{v} \times \frac{\hat{\mathbf{r}}}{c^2} \frac{dV(r)}{dr}. \quad (3.163)$$

Now, the angular momentum of the charge of mass,  $m_e$ , is

$$\mathbf{l} = \mathbf{r} \times m_e \mathbf{v}, \quad (3.164)$$

which leads to

$$\mathbf{B} = \frac{1}{m_e r c^2} \frac{dV(r)}{dr} \mathbf{l}. \quad (3.165)$$

Hence, an electron in an orbital of radius,  $r$ , produces a magnetic field whose strength is proportional to the gradient of the electrostatic potential. This field perturbs the spin whose magnetic moment is given by

$$\mathbf{m}_s = -g_s \mu_B \frac{\mathbf{s}}{\hbar} = -g_s \frac{q}{2m_e} \mathbf{s}, \quad (3.166)$$

where  $\mu_B = q\hbar/2m_e = 9.27 \times 10^{-24}$  J/T is the *Bohr magneton* and  $g_s \approx 2$  is the electron spin *g-factor*. Also, it is helpful to define the *gyromagnetic ratio*,  $\gamma_e = -\mu_B/\hbar = 1.76 \times 10^{11}$  s $^{-1}$  T $^{-1}$  (also known as the *magnetogyric ratio*). The interaction energy of a magnetic field and a magnetic dipole is

$$E_{int} = -\mathbf{m} \cdot \mathbf{B}. \quad (3.167)$$

Combining Eqs. 3.163–3.165, we obtain the Hamiltonian for the spin-orbit interaction in the reference frame of the electron:

$$H_{SO} = -g_s \frac{q}{2m_e^2 c^2} \frac{1}{r} \frac{dV(r)}{dr} \mathbf{l} \cdot \mathbf{s}. \quad (3.168)$$

Thus far, we have considered the field in the rest frame of the electron. However, Llewellyn Thomas recognized that in the rest frame of the stationary nucleus, relativistic effects need to be included. That is, the rate of precession of the spin in the trajectory of the electron of velocity,  $v$ , around the nucleus needs to be corrected by the Lorentz factor,  $\gamma = (1 - v^2/c^2)^{-1/2}$  giving the *Thomas precession frequency*:

$$\Omega_T = \omega(\gamma - 1), \quad (3.169)$$

where  $\omega = v/r$ . To first order, the Lorentz factor results in  $\Omega_T \rightarrow \omega \left( \frac{1}{2} \frac{v^2}{c^2} \right)$ , from which it can be shown that the magnetic field in Eq. 3.161 is reduced by a factor of  $1/2$ . That is, in the rest frame of the nucleus (Kroemer, 2004):

$$\mathbf{B} \rightarrow -\frac{\mathbf{v} \times \mathbf{F}}{2c^2}. \quad (3.170)$$

This introduces the well-known Thomas relativistic correction to the spin-orbit coupling leading to the following SO Hamiltonian:

$$H_{SO} = -\frac{q}{2m_e^2 c^2} \frac{1}{r} \frac{dV(r)}{dr} \mathbf{l} \cdot \mathbf{s} = \xi(r) \mathbf{l} \cdot \mathbf{s}, \quad (3.171)$$

where we have used  $g_s = 2$ .

Our final task is to evaluate the spin-orbit coupling factor,  $\xi(r)$ . For a hydrogenic atom with atomic number  $Z$ ,  $V(r) = -Zq/4\pi\epsilon_0 r$ , in which case Eq. 3.171 gives

$$\xi(r) = -\frac{Zq^2}{8\pi\epsilon_0 m_e^2 c^2} \frac{1}{r^3}. \quad (3.172)$$

The spin-orbit interaction energy is found by calculating the expectation value of  $H_{SO}$  (given by  $\langle H_{SO} \rangle$ ) for the hydrogenic wavefunction:  $|nlm_l\rangle = R_{nl}(r)Y_{lm_l}(\theta, \phi)$ , where  $R_{nl}(r)$  is the radial part of the wavefunction, and  $Y_{lm_l}(\theta, \phi)$  is the angular part given by the spherical harmonic functions for angular momentum quantum numbers  $l, m_l$ . Since  $H_{SO}$  is only a function of  $r$ , we simply need to calculate the expectation value  $\langle 1/r^3 \rangle$  via

$$\left\langle \frac{1}{r^3} \right\rangle = \langle nl | \frac{1}{r^3} | nl \rangle = \int_0^\infty \frac{1}{r} R_{nl}^2 dr = \frac{(Z/a_0)^3}{n^3 l(l + \frac{1}{2})(l + 1)}, \quad (3.173)$$

where  $a_0$  is the Bohr radius (Eq. 3.142). Hence, the spin-orbit interaction energy is:

$$E_{SO} = \langle H_{SO} \rangle = \frac{Z^4 q^2}{8\pi\epsilon_0 a_0^3 m_e^2 c^2} \frac{1}{n^3 l(l + \frac{1}{2})(l + 1)} \langle \mathbf{l} \cdot \mathbf{s} \rangle, \quad (3.174)$$

which in more compact form is expressed as

$$E_{SO} = \frac{2\pi\alpha^2 R_\infty Z^4 c}{n^3 l(l + \frac{1}{2})(l + 1)\hbar} \langle \mathbf{l} \cdot \mathbf{s} \rangle, \quad (3.175)$$

where  $\alpha = q^2/4\pi\epsilon_0\hbar c \approx 1/137$  is the *fine structure constant* and the *Rydberg constant* is  $R_\infty = m_e q^4 / 64\pi^3 \epsilon_0^3 \hbar^3 c \approx 1.097 \times 10^7 \text{ m}^{-1}$ .

The interaction scales as  $Z^4$ , hence we expect that spin-orbit interactions are far stronger in molecules containing an atom with a high atomic number. Thus, emission from Ir ( $Z = 77$ ) and Pt ( $Z = 78$ ) and other heavy metal-based organic complexes is entirely from their triplet states, even though the singlet state might initially be excited. That is, spin-orbit coupling in heavy-metal containing molecules promotes rapid non-radiative ISC from the first singlet to the triplet excited state, followed by triplet emission as the excited state relaxes back into the singlet ground state. This process leads to 100% internal quantum efficiency in phosphorescent OLEDs (Baldo et al., 1998, Adachi et al., 2001).

Finally, we must evaluate  $\langle \mathbf{l} \cdot \mathbf{s} \rangle$  to obtain the spin-orbit interaction energy. Since the total angular momentum operator of a composite system with contributions from both orbital and spin momenta is

$$\mathbf{j} = \mathbf{l} + \mathbf{s}, \quad (3.176)$$

it follows that

$$j^2 = |\mathbf{l} + \mathbf{s}|^2 = l^2 + s^2 + 2\mathbf{l} \cdot \mathbf{s}. \quad (3.177)$$

Now, the orbital angular momentum operator gives the relationships  $l^2 |nlm\rangle = \hbar^2 l(l+1) |nlm\rangle$ , with analogous expressions for  $j^2$  and  $s^2$ , from which we get

$$E_{SO} = \frac{\alpha^2 R_\infty Z^4 \hbar c [j(j+1) - l(l+1) - s(s+1)]}{2n^3 l(l + \frac{1}{2})(l + 1)}. \quad (3.178)$$

As the principal quantum number ( $n$ ) increases, spin-orbit coupling decreases, whereas it increases with  $l$ , as expected. That is, an  $s$ -state has  $l = 0$  and  $j = s$ , from which it follows that  $E_{SO} = 0$ .

While Eqs. 3.175 and 3.178 provide the energy of the spin-orbit interaction, they do not explain how the multiplicity of the spin state changes due to this interaction. That is, we have yet to show that  $S \leftrightarrow T$  transitions are allowed due to symmetry breaking via singlet-triplet mixing.

The  $S \rightarrow T$  transition is non-radiative, implying that it is an isoenergetic transition from the relaxed singlet (i.e. from the  $\nu = 0$  vibronic) to the triplet manifold where  $\nu > 0$ . Then, ISC is followed by rapid internal conversion to the  $\nu = 0$  triplet state. To quantitatively treat ISC, we follow the analysis of McClure based on group theory (McClure, 1949). Using the Hamiltonian Eq. 3.171 for a system of  $N > 1$  electrons in a central field:

$$H_{SO} = \sum_i^N \xi_i(r) \mathbf{l}_i \cdot \mathbf{s}_i. \quad (3.179)$$

Under exchange of two electrons,  $i$  and  $j$  ( $i \neq j$ ), Eq. 3.179 becomes

$$H_{SO} = \sum_i^N \sum_j^N \left[ \xi_i(r) \mathbf{l}_i \cdot \mathbf{s}_i + \xi_j(r) \mathbf{l}_j \cdot \mathbf{s}_j \right]. \quad (3.180)$$

This can be expanded to

$$H_{SO} = \frac{1}{2N} \sum_i^N \sum_j^N \left[ \left( \xi_i(r) \mathbf{l}_i + \xi_j(r) \mathbf{l}_j \right) \cdot (\mathbf{s}_i + \mathbf{s}_j) + \left( \xi_i(r) \mathbf{l}_i - \xi_j(r) \mathbf{l}_j \right) \cdot (\mathbf{s}_i - \mathbf{s}_j) \right]. \quad (3.181)$$

The terms to the left correspond to states of even symmetry under exchange, and on the right to odd symmetry. The even symmetry term preserves the symmetry of the state on which it operates: if either its orbital or spin wavefunction is symmetric or anti-symmetric under exchange, its symmetry will remain unchanged when operated on by this term. However, the second (odd) term results in a symmetry change: if the initial wavefunction has even spin symmetry (a triplet state), it will be transformed into an odd symmetry singlet. Furthermore, the orbital angular momentum undergoes a symmetry change due to the second term. While the first term preserves the symmetry of the initial and final states, it leads to multiplet splitting. That is, it lifts the degeneracy of the three  $m_s = 0, \pm 1$  substates of the  $S = 1$  manifold. This separation of the spin state energies in the absence of an external magnetic field is known as the zero-field splitting energy. In contrast, the second term leads directly to S-T mixing without a significant change in energy. The strength of mixing determines the rate of ISC,  $k_{ISC}$  (Fig. 3.33). In fact, it can be shown that the  $z$ -axis operators of Eq. 3.181 mix singlet and triplet states with  $m_s = 0$ , and the  $x$  and  $y$  operators mix S and T states with a change in quantum numbers of  $\Delta m_s = \pm 1$  (McGlynn et al., 1969).

Now that we have shown that  $H_{SO}$  mixes the S and T states via simple symmetry arguments, we can calculate the radiative phosphorescence emission rate

from the triplet state,  $k_{ph}$ , using perturbation theory. From the Jablonski diagram (Fig. 3.33) we find several levels in both the singlet and triplet manifolds. For example, the triplet state is comprised of  $T_1, T_2, \dots, T_N$ , and similarly for singlets. Not shown are higher order spin states such as the  $S = 2$  quintet manifold, where each quintet consists of five degenerate spin states corresponding to  $m_S = 0, \pm 1, \pm 2$ , and so on. Since we are only interested in the fundamental  $S_0 \leftrightarrow T_1$  transition, the effects of quintets are ignored. Now, the triplet spinorbital perturbed by an admixture of singlet content is, to first order:

$$|T_1^{m_s}\rangle = |T_1^{m_s}\rangle + \sum_i^N |S_i\rangle \frac{\langle S_i | H_{SO} | T_1^{m_s} \rangle}{E(T_1) - E(S_i)} + \sum_i^N \sum_{k=-1}^1 |T_i^k\rangle \frac{\langle T_i^k | H_{SO} | T_1^{m_s} \rangle}{E(T_1) - E(T_i)}. \quad (3.182)$$

Here,  $|T_1^{m_s}\rangle$  is the perturbed spinorbital for the first triplet state ( $T_1$ ) whose spin quantum number projection along the z-axis is denoted by  $m_s$ . We also note that all the triplets within a particular manifold are degenerate (i.e. the energies of the  $m_S = 0, \pm 1$  states are equal). It follows that there are three  $|T_1^{m_s}\rangle$  that comprise the first triplet state manifold; these three substates are reflected by their contributions in the second summation over  $k = -1, 0, 1$  in Eq. 3.182. Thus, the sums are over all  $N$  singlet and triplet states, although since the energy denominator increases for higher order excited states, in practice only the states nearest in energy are required.

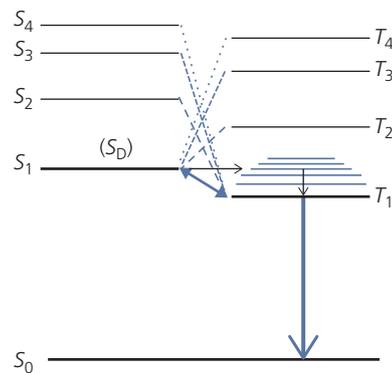

Similarly, the perturbed S-state has only a single expression corresponding to  $m_S = 0$ :

$$|S'_0\rangle = |S_0\rangle + \sum_i^N \sum_{k=-1}^1 |T_i^k\rangle \frac{\langle T_i^k | H_{SO} | S_0 \rangle}{E(S_0) - E(T_i)}. \quad (3.183)$$

Since the energy gap between  $S_0$  and all the triplet states is large, we can approximate Eq. 3.183 by:  $|S'_0\rangle \approx |S_0\rangle$ . Furthermore, it is often assumed that only one S-state contributes significantly to the  $S_0 \leftrightarrow T_1$  transitions. State mixing leading to ISC is illustrated in Fig. 3.69. Denoting the dominant perturbing singlet as  $S_D$ , the second term on the right in Eq. 3.183 can be removed from the summation. Similarly, contributions to  $|T_1^{m_s}\rangle$  from other separate triplet states are small. Thus:

$$|T_1^{m_s}\rangle \approx |T_1^{m_s}\rangle + |S_D\rangle \frac{\langle S_D | H_{SO} | T_1^{m_s} \rangle}{E(T_1) - E(S_D)}. \quad (3.184)$$

Generally,  $S_D$  can be replaced by  $S_1$  since this approximation leads to the smallest energy denominator due to the larger separation between  $E(T_1)$  and  $E(S_i)$ ,  $i \neq 1$ .

**Figure 3.69** Representation of the admixtures of  $S_1$  and  $T_1$  leading to ISC and phosphorescence. The stronger interactions are shown as bolder dashed lines. Also, the dominant mixed state,  $S_D = S_1$ , and ISC from  $S_1$  to  $T_1$  followed by internal conversion is shown.

From perturbation theory, the energy,  $E^{m_s}$ , of  $|T_1^{m_s}\rangle$  is stabilized by spin-orbit coupling from its unperturbed value,  $E(T_1)$  as follows:

$$E^{m_s} = E(T_1) + \sum_i^N \frac{|\langle S_i | H_{SO} | T_1^{m_s} \rangle|^2}{E(T_1) - E(S_i)} + \sum_i^N \sum_{k=-1}^1 \frac{|\langle T_i^k | H_{SO} | T_1^{m_s} \rangle|^2}{E(T_1) - E(T_i)}, \quad (3.185)$$

where we assume that the energy splitting between  $m_s$  substates is negligible in the absence of spin-orbit coupling. Since the denominator is negative (see Fig. 3.69), the energy of the perturbed state is lower (hence stabilized) compared to the original state,  $T_1$ . As in Eq. 3.184, we note that generally only a single state exists that minimizes the denominator in this expression, leading to the simplified expression:

$$E^{m_s} = E(T_1) + \frac{|\langle S_D | H_{SO} | T_1^{m_s} \rangle|^2}{E(T_1) - E(S_D)} \quad (3.186)$$

To calculate  $k_{ph}$  we turn to Fermi's Golden Rule, Eq. 3.69. For electric dipole transitions from  $T_1$  to  $S_0$  (denoted  $T_1 \leftarrow S_0$ ), we obtain a triplet decay rate between spin-orbit mixed states of:

$$k_{ph} = \frac{8\pi\omega^3}{3hc^3} \sum_{k=-1}^1 |\langle S_0 | q\mathbf{r} | T_1^k \rangle|^2 \quad (3.187)$$

In this expression, we have used the photon density of states for incident illumination at frequency,  $\omega$ :

$$\rho(E_{fi}) = \frac{2\omega^3}{3\pi c^3}. \quad (3.188)$$

Substituting Eq. 3.184 into Eq. 3.187:

$$k_{ph} = \frac{8\pi\omega^3}{3hc^3} \sum_{k=-1}^1 \left| \frac{\langle S_D | H_{SO} | T_1^k \rangle}{E(T_1) - E(S_D)} \right|^2 |\langle S_0 | q\mathbf{r} | S_D \rangle|^2. \quad (3.189)$$

The same spin–orbit coupling process that leads to phosphorescent emission (e.g.  $T_1 \rightarrow S_0$ ) also leads to ISC ( $S_1 \leftarrow T_1$ ). We note that a calculation of  $k_{ISC}$  introduces additional complications since the transfer between manifolds must take non-radiative as well as radiative contributions into consideration. Still, application of Fermi’s Golden Rule that accounts for these additional terms remains valid for both small molecules and polymers (Henry and Siebrand, 1971, Beljonne et al., 2001, Tatchen et al., 2007).

Including non-radiative contributions to  $k_{ISC}$  requires the full Born–Oppenheimer wavefunction that comprises both electronic as well as nuclear (i.e. vibronic) coordinates (see Eq. 3.8). Then the initial and final wavefunctions are:  $|S_1(\mathbf{r}_i, \mathbf{R}_i)\rangle = \phi_e(\mathbf{r}_i, \mathbf{R}_i)\phi_N(\mathbf{R}_i)$  and  $|T_f(\{\mathbf{r}_f\}, \{\mathbf{R}_f\})\rangle = \phi_e(\{\mathbf{r}_f\}, \{\mathbf{R}_f\})\phi_N(\mathbf{R}_f)$ , respectively, from which it follows:

$$k_{ISC} = \frac{2\pi}{\hbar} \sum_{\{f\}} \left| \langle S_1(\mathbf{r}_i, \mathbf{R}_i) | H_{SO} | T_f(\{\mathbf{r}_f\}, \{\mathbf{R}_f\}) \rangle \right|^2 \times \delta(E_{S_1}^0 - E_{T_f}^0), \quad (3.190)$$

where the unperturbed singlet and triplet energies are provided in the Kronecker delta-function and  $\{f\}$  is the set of all final states. We can reduce the nuclear coordinate terms to wavefunctions labeled by their vibronic quantum numbers, viz.  $|v_k\rangle$ , such that  $\langle S_1(\mathbf{r}_i, \mathbf{R}_i) | H_{SO} | T_f(\{\mathbf{r}_f\}, \{\mathbf{R}_f\}) \rangle = \langle S_1(v_i) | H_{SO} | T_f\{v_f\} \rangle$ . We now expand each term in Eq. 3.190 about the equilibrium nuclear coordinate,  $Q_0 = 0$ , to obtain (Tatchen et al., 2007)

$$\langle S_1(v_i) | H_{SO} | T_f(v_f) \rangle = \langle S_1(\mathbf{r}_i) | H_{SO} | T_f(\mathbf{r}_f) \rangle |_{Q_0} \langle v_i | v_f \rangle + \sum_k \left( \frac{\partial}{\partial Q_k} \langle S_1(\mathbf{r}_i) | H_{SO} | T_f(\mathbf{r}_f) \rangle \right)_{Q_0} \times \langle v_i | Q_k | v_f \rangle + O(|Q^2|). \quad (3.191)$$

This is the Herzberg–Teller expansion of Eq. 3.78. Note that  $FC_{if} = \langle v_i | v_f \rangle$  is the Franck–Condon factor of Eq. 3.79. The second term in the expansion is known as the *vibronic spin–orbit coupling factor*. Inserting the sum over all final vibronic and electronic states,  $|T_f(\{\mathbf{r}_f\}, \{\mathbf{R}_f\})\rangle$  in Eq. 3.190 thus leads to the rate for ISC. This is clearly a much more involved calculation than that used to obtain  $k_{ph}$  due to the vibronic couplings, although we see that the spin–orbit interaction is the same and is responsible for both processes, albeit at considerably different rates.

### 3.7.2 Spin–spin coupling

The magnetic field that arises from the spin of an electron interacts with the magnetic moment of a second spin, resulting in a spin–spin interaction

energy of  $E_{SS} = -\mathbf{m} \cdot \mathbf{B}$  (see Eq. 3.167). For singlet states, the two spins are  $180^\circ$  out of phase, and hence  $E_{SS} = 0$ . For triplets, the spins are in phase leading to an energy splitting even when the external field,  $\mathbf{B} = 0$ . This *zero-field splitting* (ZFS) of the triplet state is resolved in the fine structure of the molecular spectral features. Other interactions between the electron and nuclear spins (giving rise to *hyperfine interactions*), or between the nuclei themselves (nuclear *Overhauser effects*) are comparatively small and hence do not play a significant role in the spectra of molecular electronic materials.

Analogous to the electric dipole interactions in Eq. 2.39, magnetic dipole field due to a spin of angular momentum,  $\mathbf{s}_i$ , is given by (Jackson, 1998)

$$\mathbf{B}(\mathbf{r}) = - \left( \frac{g\mu_B}{8\pi m_e r^3} \right) \left( \mathbf{s}_i - \frac{3\mathbf{r}(\mathbf{r} \cdot \mathbf{s}_i)}{r^2} \right) = \left( \frac{g\mu_B \gamma_e}{4\pi r^3} \right) \left( \mathbf{s}_i - \frac{3\mathbf{r}(\mathbf{r} \cdot \mathbf{s}_i)}{r^2} \right). \quad (3.192)$$

It follows that the Hamiltonian for the interaction of two spins summed over all electrons in the molecule is

$$H_{SS} = \left( \frac{g^2 \mu_B^2 \gamma_e^2}{4\pi} \right) \sum_{i>j}^N \left( \frac{\mathbf{s}_i \cdot \mathbf{s}_j}{r_{ij}^3} - \frac{3(\mathbf{r}_{ij} \cdot \mathbf{s}_i)(\mathbf{r}_{ij} \cdot \mathbf{s}_j)}{r_{ij}^5} \right), \quad (3.193)$$

where  $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$  is the relative coordinate of spins  $\mathbf{s}_i$  and  $\mathbf{s}_j$ . The energy splitting between states is calculated by diagonalizing the matrix consisting of the three elements  $\langle S, m_S | H_{SS} | S, m_S \rangle$  (corresponding to  $S = 1$  and  $m_S = 0, \pm 1$ ). The ZFS energy terms for interacting electrons,  $i \neq j$  are thus (McGlynn et al., 1969)

$$D_{ij} = \left( \frac{3}{4} \right) \frac{\mu_0 g^2 \gamma_e^2}{4\pi} \langle \phi_e(i, j) | \frac{1}{r_{ij}^3} - \frac{3z_{ij}^2}{r_{ij}^5} | \phi_e(i, j) \rangle \quad (3.194a)$$

and

$$E_{ij} = \left( \frac{3}{4} \right) \frac{\mu_0 g^2 \gamma_e^2}{4\pi} \langle \phi_e(i, j) | \frac{3\{y_{ij}^2 - x_{ij}^2\}}{r_{ij}^5} | \phi_e(i, j) \rangle, \quad (3.194b)$$

where  $\phi_e(i, j)$  is the spatial part of the wavefunction. The energies for the three terms are found by solving the secular determinant:

$$\begin{vmatrix} \frac{1}{3}D_{ij} - E_{SS} & 0 & E_{ij} \\ 0 & -\frac{2}{3}D_{ij} - E_{SS} & 0 \\ E_{ij} & 0 & \frac{1}{3}D_{ij} - E_{SS} \end{vmatrix} = 0, \quad (3.195)$$

yielding the roots

$$E_{SS}(0) = -\frac{2}{3}D_{ij}, \quad (3.196a)$$

$$E_{SS}(\pm) = -\frac{1}{3}D_{ij} \mp E_{ij}. \quad (3.196b)$$

Here, we have used the notation  $E_{SS}(0)$  corresponding to the  $m_s = 0$  state  $|0\rangle$ , and energies  $E_{SS}(\pm)$  to the symmetric (+) and antisymmetric (-) mixing of the  $|1\rangle = |a_1a_2\rangle$  and  $|-1\rangle = |\beta_1\beta_2\rangle$  states (cf. Eqs. 3.3a and 3.3c), as illustrated in Fig. 3.70a. Indeed, the extent of ZFS and the relative sizes of  $E_{ij}$  and  $D_{ij}$  is a direct consequence of the overlap of electronic orbitals within a molecule; as the overlap increases so does the splitting (see Eq. 3.194).

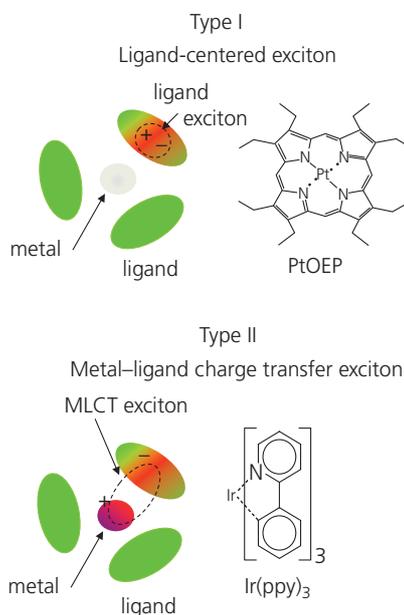

Absent spin-spin interactions, the three triplet states are degenerate and there is no ZFS. A first order approximation applies to  $E_{ij} = 0$ , where interactions between states  $|1\rangle$  and  $|-1\rangle$  vanish. In this limit, state  $|0\rangle$  has the lowest energy ( $-2D_{ij}/3$ ) since its spin dipoles are antiparallel and hence are attractive, whereas  $|1\rangle$  and  $|-1\rangle$  have their dipoles pointing in the same direction, thus raising the total system energy, as shown in Fig. 3.70b. When the full interaction is turned on, there is an additional splitting due to mixing of the otherwise degenerate  $|1\rangle$  and  $|-1\rangle$  states (Fig. 3.70c). Applying an external field lifts this degeneracy even further via the *Zeeman effect*, giving rise to well-resolved triplet energies.

### 3.7.3 Metal–ligand and ligand-centered interactions in organic–transition metal complexes

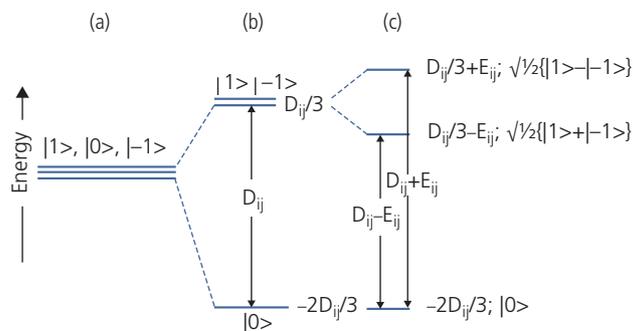

An important class of organic electronic compounds that exhibit high efficiency emission via the triplet state are the organic-transition metal complexes based on heavy metal atoms such as Ir(III), Os(III), and Ru(II), Pt(II), Pd(II), etc. In this section, we discuss two major classes of these transition metal complexes,

the quasi-octahedral chelating complexes, and the di-hedral, distorted square planar complexes. Here, *chelate* refers to a compound containing an organic ligand that is attached to a central metal atom at two or more points. While so-called *metal–ligand charge transfer* (MLCT) in the former systems leads to strong spin–orbit coupling, and consequently very fast and efficient  $T_1 \rightarrow S_0$  transitions, similar transitions in the latter compounds are due to the somewhat weaker *ligand-centered* (LC) couplings.

Spin–orbit interactions leading to efficient phosphorescence in transition metal complexes are classified into two categories illustrated in Fig. 3.71 with example molecules that support these processes. Type I molecules are based on ligand-centered triplet ( ${}^3LC$ ) states. Although Type I triplet emitting molecules can

**Figure 3.71** Two types of triplet excitons formed on metal complexes, with example molecules supporting these excited states.

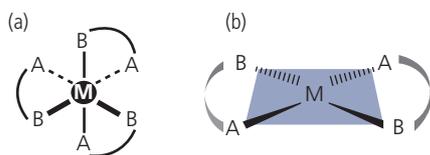

**Figure 3.70** Zero-field splitting of the triplet state for (a) no spin–spin interactions, (b) spin–spin interactions due only to diagonal terms, and (c) a full solution to the secular determinant in Eq. 3.195. From McGlynn et al. (1969).

have very high quantum yield as is the case for PtOEP, the radiative decay rate of  $k_{ph} \sim 10^5 \text{ s}^{-1}$  competes with parasitic non-radiative down-conversion processes that occur at approximately the same rates.

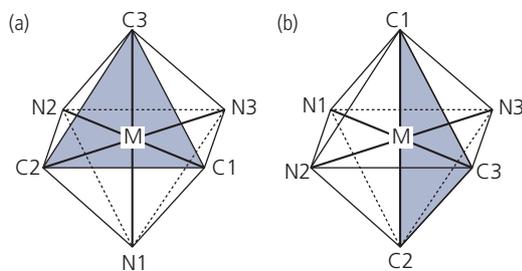

In Type II phosphors, the electron density in the ligand is shared with the heavy metal atom forming a triplet  $^3\text{MLCT}$  state. The sharing of the electron density in complexes such as  $\text{Ir}(\text{ppy})_3$  leads to a large  $H_{SO}$ , and hence rapid ISC that results in highly efficient phosphorescent emission (Lamansky et al., 2001).

The symmetries of the chelating M(III) and square planar M(II) complexes ( $M = \text{metal}$ ) are illustrated in Fig. 3.72. The M(III) complexes such as the  $\text{Ir}(\text{C}^{\wedge}\text{N})_3$  tris-bidentate phosphors have quasi- or distorted octahedral symmetry ( $O_h$ ) of their  $d$ -orbitals, and depending on the atoms A, B can form a facial (*fac*) or meridional (*mer*) isomer. For example, the  $\text{C}^{\wedge}\text{N}$  cyclo-metalating ligand in  $\text{Ir}(\text{ppy})_3$ , has  $A = \text{C}$  and  $B = \text{N}$ . In the *fac*-isomer, the N-atoms lie in a plane. However, by exchanging N and C on one of the three ligands, the three N atoms now lie on two different, intersecting planes in the *mer*-isomer. The octahedral symmetry is apparent from the four A, B atoms around the equator, capped by A and B at opposite molecular azimuths. In contrast, the distorted square molecule has a fourfold dihedral symmetry ( $D_{4h}$ ) characteristic of the planar Pt(II) and Pd(II) complexes.

The pseudo-octahedral symmetry of metalorganic the *fac*- and *mer*-isomers is illustrated in more detail in Fig. 3.73. The overlap of the metal and ligand wavefunctions is distinct for the isomers. The *fac*-isomer

**Figure 3.72** (a) Structure of quasi-octahedral,  $O_h$ , and (b) square planar dihedral,  $D_{4h}$ , transition metal–organic complexes. Here A and B represent atoms that coordinate with the transition metal atom M. A, B may be the same or different atoms such as C, N, O, etc.

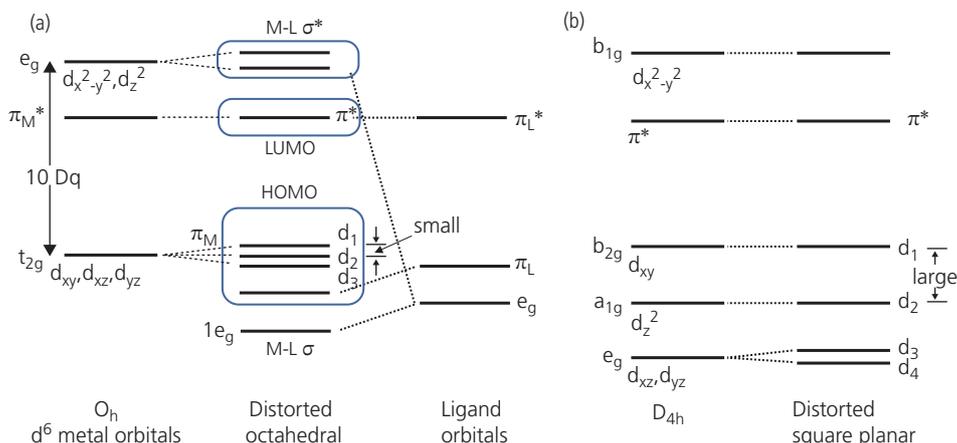

**Figure 3.73** (a) *Fac* and (b) *mer* isomer crystal structural symmetries for pseudo-octahedral  $M(\text{III})(\text{C}^{\wedge}\text{N})_3$  complexes.

has the three identical ligands occupying the face of the octahedron. There are three symmetry-equivalent positions for the ligands that transform into each other by rotations of  $2\pi/3$ , resulting in  $C_3$  symmetry. The ligand plane of the *mer*-isomer intersects the metal atom, resulting in significant overlap of the metal and ligand orbitals. It lacks the rotational symmetry of the *fac*-complex, having a  $C_1$  symmetry. Overlap of the metal and organic orbitals result in a broad, red-shifted spectrum which contrasts with the vibronically distinct, blue-shifted emission features characteristic of *fac*-isomers.

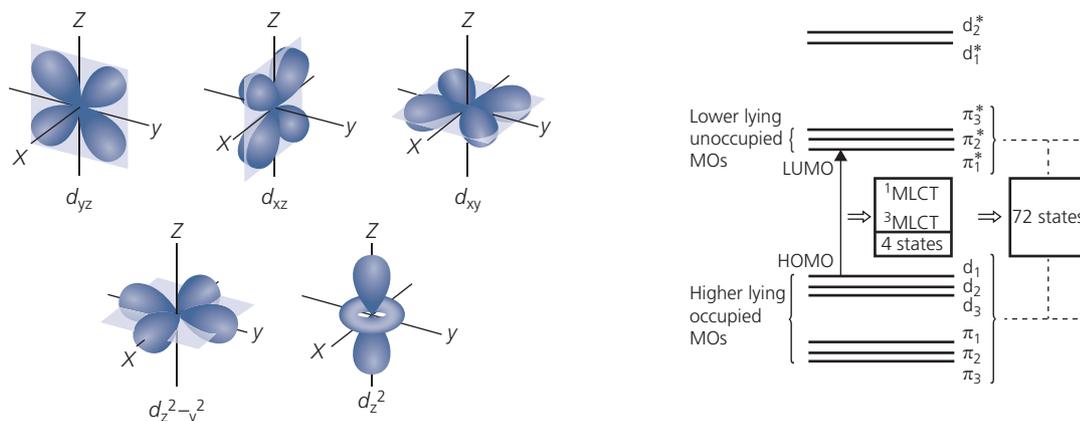

To understand the relationship between spin–orbit coupling and emission efficiency in transition metal complexes, and moreover the relationship between this coupling and the magnitude of the ZFS, we begin by considering a simplified energy landscape of the M(III) chelates. Figure 3.74a shows that the  $d$ -orbitals of an undistorted  $O_h$  compound are split into the three low energy, bonding ( $\sigma$ )  $d_{xy}$ ,  $d_{yz}$ , and  $d_{xz}$ ,  $t_{2g}$  symmetry states (labeled  $\pi_M$ ), and two higher lying antibonding  $e_g$ ,  $\sigma^*$  orbitals labeled  $d_{x^2-y^2}$  and  $d_{z^2}$ . The electronic spatial distribution of the orbitals are illustrated in Fig. 3.75. The low lying  $t_{2g}$  orbitals are triply degenerate, whereas the  $e_g$  orbitals are twofold degenerate. They both have even spatial symmetry under inversion, that is, they are both *gerade* states. Hence, electric dipole transitions between them ( $t_{2g} \leftrightarrow e_g$ ) are symmetry forbidden by the Laporte selection rule. The difference in energy,  $10Dq$ , between the  $t_{2g}$  and  $e_g$  substates results since the latter states are located closer to the ligand. Consequently, there is increased Coulomb repulsion that raises their relative energies. Here,  $Dq$  is known as the *ligand field parameter*. The excited antibonding ligand state,  $\pi_L^*$ , is also shown. In contrast, the  $\pi_M \leftrightarrow \pi_L^*$  and  $\pi_L \leftrightarrow \pi_L^*$  correspond to  $^3\text{MLCT}$  and  $^3\text{LC}$  transitions, respectively, and are spin allowed.

The degeneracy of the  $d$ -orbitals is lifted in the distorted octahedral transition metal chelates, resulting in a small energy splitting ( $\sim 10\text{--}100 \text{ cm}^{-1}$ ) of the  $t_{2g}$  states into the relabeled substates,  $d_1$ ,  $d_2$ , and  $d_3$ . Similarly,  $d_{x^2-y^2}$  and  $d_{z^2}$  are split in the distorted molecule.

In Fig. 3.74b we show that even larger ZFS of the  $d$ -orbitals occur by distortion of square-planar dihedral  $D_{4h}$  molecules; a characteristic feature of Ir(I), Pt(II), and Pd(II). Initially, the lowest  $d$ -orbitals correspond to the degenerate  $d_{xz}$  and  $d_{yz}$  in the  $e_g$  state,  $d_{z^2}$  in the  $a_{1g}$ , and  $d_{xy}$  in  $b_{2g}$ . Finally,  $d_{x^2-y^2}$  lies in the upper  $b_{1g}$  orbital. The distortion then results in lifting the degeneracy in  $e_g$ , giving rise to four lowest lying  $d$ -orbitals,  $d_1, \dots, d_4$ . Note that the splittings are far larger ( $\sim 1000\text{--}4000 \text{ cm}^{-1}$ ) than in the octahedral compounds, resulting in reduced mixing between  $d_1$  and

**Figure 3.74** Zero-field splitting (ZFS) of the  $d$ -orbitals in (a) distorted octahedral and (b) distorted dihedral transition metal complexes. The distorted octahedral molecule has an energetic landscape that combines the metal plus the ligand energetics. The bonding and antibonding orbitals are  $\sigma$  and  $\sigma^*$ , respectively, and the  $\pi^*$  orbital is a linear combination of similar states in the metal ( $\pi_M^*$ ) and the ligand ( $\pi_L^*$ ). The ZFS is small compared to the distorted square planar ZFS between the  $d_1$  and  $d_2$  orbitals (Rausch et al., 2010).

**Figure 3.75** Electron distributions in the 5d orbitals. Note the different rotational positions of  $d_{xy}$  and  $d_{x^2-y^2}$ .

the other  $d$ -orbitals. This, ultimately, reduces the ZFS, giving a weaker  ${}^3\text{LC}$  character to the transitions compared with  ${}^3\text{MLCT}$ .

To understand spin-orbit interactions in the quasi-octahedral transition metal complexes, we turn to a simplified set of diagrams that single out the energy levels responsible for the lowest energy transitions in Fig. 3.76 (Yersin et al., 2011). The primary  $\text{LUMO} \leftarrow \text{HOMO}$  MLCT transitions occur from occupied metal  $d$ - and occupied molecular orbitals to one of three unoccupied ligand  $\pi^*$  substates localized on each of the three equivalent ligands. Each of these transitions share oscillator strength with 3 triplets or one singlet state. Hence there are a total of six initial  $d + \pi$ -orbitals, times three  $\pi^*$  states, times four possible spin combinations between the initial and final state, equaling 72 total states that can

**Figure 3.76** Highest molecular orbitals  $\pi_1$ ,  $\pi_2$ ,  $\pi_3$  corresponding to the three ligands, and the three lowest metal  $d$ -orbitals,  $d_1$ ,  $d_2$ ,  $d_3$  that support the  $\text{LUMO} \leftarrow \text{HOMO}$  MLCT transitions to the three lowest unoccupied molecular orbitals,  $\pi_1^*$ ,  $\pi_2^*$ ,  $\pi_3^*$ . Higher lying  $e_g$  orbitals are also shown (Yersin et al., 2011).

intermix via spin-orbit interactions. We neglect higher lying  $d$ -orbitals and even lower lying (non-frontier) molecular orbitals. While these too may mix with the lowest lying states, it was already noted that those states lying closest to the one supporting the transition result in the largest perturbation of the final state (Eq. 3.184).

Since the spin-orbit Hamiltonian in Section 3.7.1 is a single electron operator, the *Slater-Condon selection rule* requires that the final and initial states differ by only one spinorbital (Atkins and de Paula, 2006). Furthermore, the operator imposes the selection rule that the final and initial states can differ by a change of spin quantum number of  $\Delta m_s = 0, \pm 1$ . One further simplifying assumption is that the exponential decay of the wavefunction with distance allows us to consider

interactions with only a single ligand, and hence a single  $\pi$ -orbital. With these conditions, we can limit our consideration of  $LUMO \rightarrow HOMO$  transitions affected by spin-orbit interactions to those shown in Fig. 3.77. Both singlet and triplet LC and MLCT transitions to  $\pi^*$  are shown from the upper two  $d$  or  $\pi$  orbitals. Admixtures from  $d_3$  and orbitals not shown are also possible, although they become increasingly unlikely as the energy denominator in Eq. 3.184 increases due to the increased energy difference with the radiative state.

Since the closed shell configuration of the complexes is  $d_1^2 d_2^2 \pi^2$ , we will consider, for example, only the  $m_S = +1$ , triplet substate denoted  $|^3(d_1\pi^*)_{+1}\rangle$ , shown in the second row of Fig. 3.77 (Yersin et al., 2011). The notation used is  $|^S(\text{state})_{m_S}\rangle$ . First, we can ignore coupling between  $|^3(d_1\pi^*)_{+1}\rangle$  and the ligand-centered substates,  $|^{1,3}(\pi\pi^*)\rangle$  since these two- and three-centered integrals are small due to the spatial separation of orbitals on different ligands. Furthermore, a  $d$ -orbital cannot couple to itself according to the Slater–Condon selection rule. Hence, we are left with the couplings of  $|^3(d_1\pi^*)_{+1}\rangle$  to the  $d_2$  triplet and singlet substates, that

is,  $|^3(d_2\pi^*)_{+1}\rangle$ ,  $|^3(d_2\pi^*)_0\rangle$  and  $|^1(d_2\pi^*)\rangle$ . Note that the  $m_S = 0$  subscript is ignored in writing  $|^1(d_2\pi^*)\rangle$  since it is the only possibility for a singlet state, and hence is redundant.

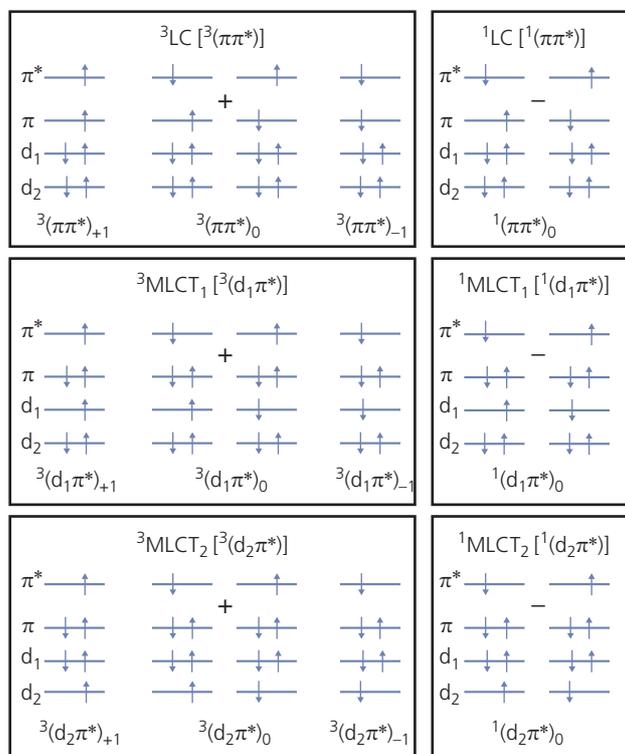

Returning to Section 3.7.1, using perturbation theory, and Eq. 3.182, we write the modified eigenstate as:

$$\begin{aligned} |^3(d_1\pi^*)'_{+1}\rangle &= |^3(d_1\pi^*)_{+1}\rangle + |^1(d_2\pi^*)\rangle \\ &\times \frac{\langle ^1(d_2\pi^*) | H_{SO} | ^3(d_1\pi^*)_{+1}\rangle}{E(^3(d_1\pi^*)_{+1}) - E(^1(d_2\pi^*))} \\ &+ |^3(d_2\pi^*)_0\rangle \frac{\langle ^3(d_2\pi^*)_0 | H_{SO} | ^3(d_1\pi^*)_{+1}\rangle}{E(^3(d_1\pi^*)_{+1}) - E(^3(d_2\pi^*)_0)} \end{aligned} \quad (3.197)$$

or, taking only contributions from the nearest singlet state,

$$\begin{aligned} |^3(d_1\pi^*)'_{+1}\rangle &\approx |^3(d_1\pi^*)_{+1}\rangle + |^1(d_2\pi^*)\rangle \\ &\times \frac{\langle ^1(d_2\pi^*) | H_{SO} | ^3(d_1\pi^*)_{+1}\rangle}{E(^3(d_1\pi^*)_{+1}) - E(^1(d_2\pi^*))}. \end{aligned} \quad (3.198)$$

Ignoring the second triplet term in Eq. 3.197 is justified since its transition dipole oscillator

**Figure 3.77** Lowest energy single electron ligand-centered (LC) and metal ligand charge transfer (MLCT) states in a pseudo-octahedral transition metal-organic system (Yersin et al., 2011).

Reprinted from Coordination Chem. Rev., 255, 2622, Yersin, H., Rausch, A. F., Czerwiecniak, R., Hofbeck, T. & Fischer, T., The triplet state of organo-transition metal compounds. Triplet harvesting and singlet harvesting for efficient OLEDs copyright 2011 with permission from Elsevier.

strength to the ground state,  $S_0$ , is negligible. This latter expression is equivalent to the approximation of Eq. 3.184 that assumes the spin-orbit coupling is dominated by a lone singlet state,  $|^1(d_1\pi^*)\rangle$ . Following this same treatment, we derive the orbital stabilization energy due to spin-orbit interactions from Eq. 3.186:

$$E'(^3(d_1\pi^*)_{+1}) = E(^3(d_1\pi^*)_{+1}) + \frac{|\langle ^1(d_2\pi^*)|H_{SO}|^3(d_1\pi^*)_{+1}\rangle|^2}{E(^3(d_1\pi^*)_{+1}) - E(^1(d_2\pi^*))}, \quad (3.199)$$

where once again, we note that the triplet lies at a lower energy than the singlet, such that  $E'(^3(d_1\pi^*)_{+1}) < E(^3(d_1\pi^*)_{+1})$ . This treatment has been simplified to ignore interactions with other  $d$ - and  $\pi$ -orbitals.

As noted, the magnitudes of the couplings are expected to decrease rapidly as their separations in energy and distance increase. Hence, the approximations employed are adequate to describe the observed effects without unnecessarily complicating the discussion. Finally, we obtain the triplet or phosphorescent radiative rate from  $|^3(d_2\pi^*)_{+1}\rangle$  in Eq. 3.189:

$$k_{ph} = \frac{8\pi\omega^3}{3hc^3} \left| \frac{\langle ^1(d_2\pi^*)|H_{SO}|^3(d_1\pi^*)'_{+1}\rangle}{E(^3(d_1\pi^*)_{+1}) - E(^1(d_2\pi^*))} \right|^2 \times |\langle S_0|q\mathbf{r}|^1(d_2\pi^*)\rangle|^2. \quad (3.200)$$

Clearly, a smaller energy denominator, and hence small exchange energy splitting of  $T_1$  and  $S_1$  in Eq. 3.200 leads to an increased radiative triplet rate. Furthermore,  $k_{ph}$  also depends on the strength of the singlet transition dipole moment, as seen by the last term in this expression. And most importantly, in the absence of spin-orbit coupling the first term in Eq. 3.200 vanishes, and the triplet state is non-radiative. Note that Eq. 3.199 considers contributions from only a *single* substate interaction. Of course, there are additional states that intermix, which only increase ISC and the radiative rate,  $k_{ph}$ .

The last step in our analysis is to consider transitions from the lowest ligand centered triplet,  $|^3(\pi\pi^*)\rangle$ , shown in the top row of Fig. 3.76. We have already seen that two- and three-centered integrals are small compared to single-centered integrals that characterize MLCT transitions. However, MLCT interactions are small in dihedral molecules such as the square planar PtOEP, due to the large energy gap between  $d$ -orbitals in these complexes (see Fig. 3.74). Treating the LC transitions is considerably more complex than MLCT interactions in distorted octahedral complexes since it involves both MLCT and LC couplings. We can understand this via

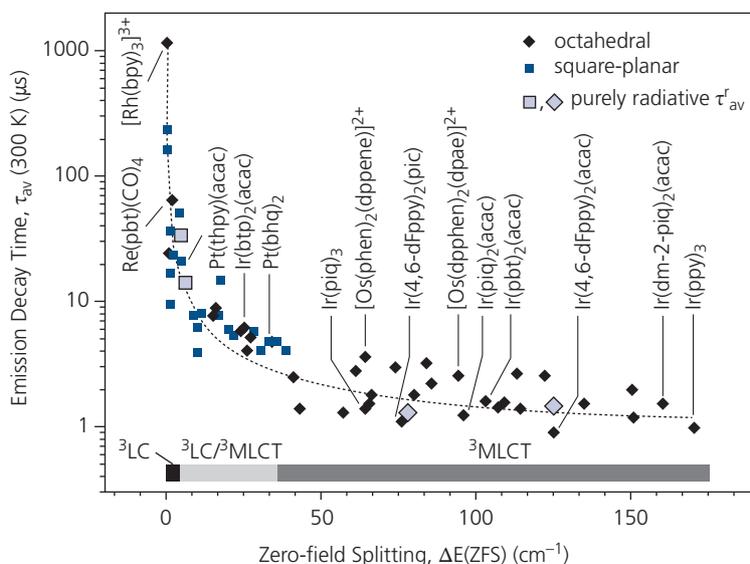

the following arguments: Following the selection rules outlined above,  $|^3(\pi\pi^*)\rangle$  cannot mix with itself; hence it necessarily involves two and three center integrals that are weaker than the one-center integrals employed to describe MLCT. To estimate the ZFS from LC states, we once again focus on a single substate:  $|^3(\pi\pi^*)_{+1}\rangle$ . This can couple to the MLCT<sub>1</sub> and MLCT<sub>2</sub> states  $|^3(d_1\pi^*)_{+1}\rangle$  and  $|^3(d_2\pi^*)_{+1}\rangle$ , respectively (see Fig. 3.77) (Yersin et al., 2011). The mixing with  $|^3(d_1\pi^*)_{+1}\rangle$  is due to *electronic configuration interactions* (CI), whose selection rules are  $\Delta S = \Delta m_S = 0$ . As discussed in Section 3.4.1, CI are used in the calculation of changes in energies of  $n$ -electron systems that arise from reorganization of the  $\pi$ -orbitals with the addition of a single electron.

Hence, CI lead to a perturbation from each of the three <sup>3</sup>MLCT states of the same magnitude:

$$|^3(\pi\pi^*)'_{+1}\rangle \approx |^3(\pi\pi^*)_{+1}\rangle + |^3(d_1\pi^*)_{+1}\rangle \frac{\langle ^3(d_1\pi^*)_{+1}|H_{CI}|^3(\pi\pi^*)_{+1}\rangle}{E(^3(\pi\pi^*)_{+1}) - E(^3(d_1\pi^*)_{+1})}. \quad (3.201)$$

where  $H_{CI}$  is the configuration Hamiltonian. Now the admixed  $|^3(d_1\pi^*)_{+1}\rangle$  can, in turn, interact with the singlet  $|^1(d_1\pi^*)\rangle$  as we have seen in the foregoing discussion of MLCT. Thus, LC interactions involve two processes: the first due to CI with the ligand electron system, and the second via interaction of the CI-perturbed  $\pi$ -system with the  $d$ -orbitals via MLCT. Given that this requires a hybridization of two orbital systems, its intensity (and hence resulting ZFS) is weaker. For this reason, <sup>3</sup>LC transitions in distorted square planar systems are generally weaker, and their transition rates slower than <sup>3</sup>MLCT transitions in M(III) transition metal complexes.

The importance of ZFS on the luminescent properties of triplet emitting materials should be apparent from Eqs. 3.199 and 3.200. The calculated dependence of the average lifetime,  $\tau_{av} \approx k_{ph}^{-1}$  on ZFS energy,  $\Delta E$ , is shown in Fig. 3.78. The energies range from  $>200 \text{ cm}^{-1}$  (25 meV) for Os- and Ir-based phosphors with strong <sup>3</sup>MLCT transitions, to  $<1 \text{ cm}^{-1}$  for <sup>3</sup>LC-dominated Pd, Re, and Rh complexes. This energy range corresponds to three orders of magnitude change in  $\tau_{av}$ , from  $\sim 400 \text{ ns}$  for octahedral, to milliseconds for square planar complexes. Indeed, a key observation from these data are that the square planar molecules are dominated by <sup>3</sup>LC behavior with longer lifetimes, whereas the octahedral compounds exhibit rapid decay due to the large <sup>3</sup>MLCT content of the spin-orbit coupling.

**Figure 3.78** Measured triplet emission decay time vs. calculated ZFS for a number of transition metal organic compounds with differing  ${}^3\text{MLCT}$  and  ${}^3\text{LC}$  excited state content. The larger ZFS energy results in a decrease in triplet radiative lifetime, which in turn generally leads to a higher luminescent efficiency due to more favorable competition of radiative with non-radiative recombination (Yersin et al., 2011).

The emission efficiency generally is higher for materials with a smaller radiative lifetimes. This is due to two principal reasons. The first is that the PLQY depends on the competition between radiative and non-radiative recombination according to Eq. 3.119. Thus,  $\Phi_{\text{PL}} \rightarrow 1$  for  $k_r = k_{\text{ph}} \gg k_{\text{nr}}$ . The second is that the density of triplets increases with increasing lifetime under constant illumination. Thus, the probability for triplet–triplet annihilation, which is a mechanism for non-radiative loss, increases with  $\tau_{\text{av}}$ , thus resulting in a decrease in  $\Phi_{\text{PL}}$ , particularly at high intensities (see Section 3.10). For these reasons, the highest emission efficiencies are from phosphors based on either Ir or Pt with strongly  ${}^3\text{MLCT}$  character and ZFS energies typically  $> 10 \text{ cm}^{-1}$ .

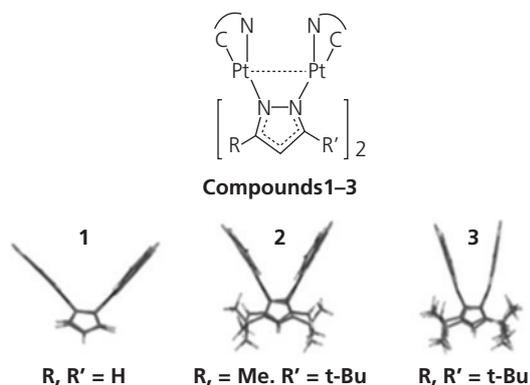

It is noteworthy that the increase of ZFS  $> 100 \text{ cm}^{-1}$  does not result in a further decrease in  $\tau_{\text{av}}$ . We have shown that there is a clear correlation between the magnitude of the spin–orbit coupling and the ZFS energy, which in turn results in a higher  $k_{\text{ph}}$  according to Eq. 3.200. Recall, however, that *total* ZFS results from the sum over all  $T_1$  substates in Eq. 3.185. We have seen that spin–orbit coupling lifts the degeneracy of these three states that are separated by energies  $\Delta E_{ij}$ , where  $i, j$  denote the two states that are mixed. Hence, the emission rate is determined by the Boltzmann factors for each substate. The average emission rate,  $\bar{k}_{\text{ph}}$ , is the sum of several rates, each weighted by its activation energy following (Yersin et al., 2011):

$$\bar{k}_{\text{ph}} = \frac{k_1 + k_2 \exp(-\Delta E_{12}/k_B T) + k_3 \exp(-\Delta E_{13}/k_B T)}{1 + \exp(-\Delta E_{12}/k_B T) + \exp(-\Delta E_{13}/k_B T)}, \quad (3.202)$$

where we have labeled the participating substates  $i = 1, 2, 3$ . Hence, the rate is ultimately limited by that substate that has the greatest energy separation from the lowest energy level  $i = 1$  (corresponding to  $m_S = 0$ , see Fig. 3.70), giving rise to the asymptotic dependence of  $\tau_{\text{av}}$  on ZFS in Fig. 3.78.

Measurement of ZFS energies and the corresponding transition rates is primarily done via high resolution spectroscopy (Yersin, 2004). However, the temperature dependence of the PL transients using Eq. 3.202 presents an alternative method for obtaining the energies, transition rates and  $\Phi_{\text{PL}}$ . While this expression has several variables, it is simplified by measuring the rates at low and high temperatures. Thus, in the limit,  $k_B T \gg \Delta E_{12}, \Delta E_{13}$ , we have  $\bar{k}_{\text{ph}} = k_1$ , and in the high temperature limit,  $\bar{k}_{\text{ph}} = (k_1 + k_2 + k_3)/3$ .

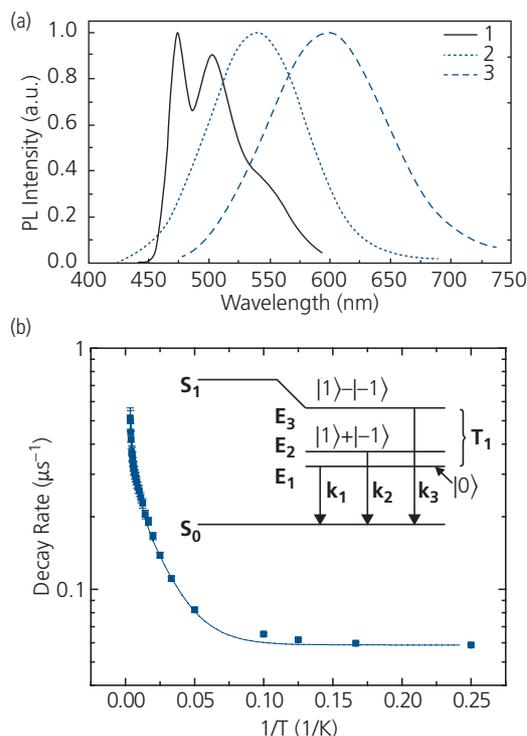

This approach has been used to characterize a series of phosphorescent pyrazolate-bridged cyclometalated platinum(II) complexes with the general formula:  $\text{C}^{\wedge}\text{N} \text{Pt}(\mu\text{-pz})_2 \text{PtC}^{\wedge}\text{N}$  shown in **Scheme 2**, where  $\text{C}^{\wedge}\text{N}$  represents the cyclometalating ligand (Qi et al., 2008). The pyrazolate (pz) ligand controls the degree of metal–metal interaction by adjusting the angle between opposing ligands, and thus the emission spectra.

**Scheme 2** Binuclear C<sup>N</sup>Pt(μ-pz)<sub>2</sub>PtC<sup>N</sup> complexes.

Compounds **1**, **2**, and **3** have Pt···Pt spacings of 3.19 Å, 3.05 Å, and 2.83 Å, respectively (Ma et al., 2005). Their phosphorescence spectra in the blue, green and red, are shown in Fig. 3.79a. The bridging ligands rigidly link the two metal centers on opposing pyridyl rings. For compound **1**, the well resolved vibronic progression in the emission spectrum indicates only weak interaction between the two metal centers. In contrast, broad and featureless emission spectra of compounds **2** and **3** are observed due to a mixed <sup>3</sup>LC/<sup>3</sup>MLCT state, and are assigned to strong triplet metal-metal ligand charge transfer (<sup>3</sup>MMLCT) enhanced by the proximity of the emissive ligands (Lai et al., 2002). Note that the phosphorescent efficiencies of OLEDs at low current whose active region employs these compounds doped into a wide energy gap UGH2 matrix are 3.8%, 6.6% and 6.6% for compounds **1**, **2**, and **3**, respectively. The electroluminescent efficiencies are functions of Φ<sub>PL</sub> (among other factors arising from the OLED current injection and emission properties, see Chapter 6). Hence, the differences in OLED efficiencies suggest that the blue emitting compound **1** has the lowest Φ<sub>PL</sub> of the three phosphors.

Transient PL data in Fig. 3.79b were obtained by exciting a film consisting of compound **3** doped at 8 wt% in an UGH2 matrix using a N<sub>2</sub> laser with a wavelength of λ = 337 nm. A fit to the data using Eq. 3.202 is shown by the line. The resulting transition rates, *k*<sub>1</sub>, *k*<sub>2</sub>, and *k*<sub>3</sub> obtained from the fits to these and similar data for compounds **1** and **2** are provided in Table 3.4. The large ZFS of compounds **2** and **3** is apparent from values of Δ*E*<sub>13</sub> and Δ*E*<sub>12</sub> that are 4–8 times higher than that from compound **1**. This leads to correspondingly larger decay rates for the latter compounds, which is consistent with differences in their quantum yields. The large ZFS energies of these

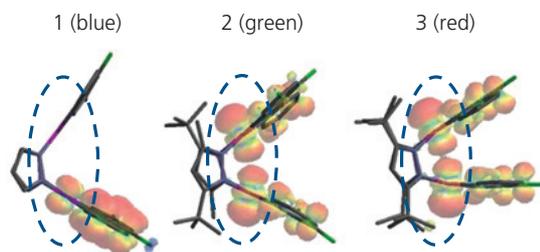

**Figure 3.79** (a) Room temperature photoluminescence (PL) spectra of compounds **1**, **2**, and **3**. (b) Measured PL decay rate (data points) vs. 1/*T* for 8 wt% compound **3** doped into UGH2. The line is a fit to Eq. 3.202 in text. Inset: Energy level scheme of the triplet manifold indicating the ZFS energies and corresponding decay rates. Also indicated are the substate wavefunctions where the number in the ket vectors correspond to the *m<sub>z</sub>* values (Qi et al., 2008).

<b>1</b>	28±3	<4	0.12	0.11	0.25
<b>2</b>	142±9	31±5	0.07	0.42	0.81
<b>3</b>	113±10	33±6	0.06	0.32	1.12

binuclear complexes are more characteristic of octahedral than dihedral compounds, as inferred from Fig. 3.78, providing support for the strong <sup>3</sup>MMLCT coupling of these complexes.

The metal participation in the triplet state, which is expected to influence the magnitude of the ZFS, is estimated from the simulated electron orbital distributions in Fig. 3.80. No pronounced change in triplet spin density takes place at the pyridyl ring, whereas the spin density surfaces at the Pt–Pt center for compounds **2** and **3** are double that of **1**. According to calculation, the complexes exhibit significant overlap

**Figure 3.80** DFT simulations of the triplet spin density surfaces for compounds **1**, **2** and **3**. The spin density at the Pt...Pt centers is double for the latter two compounds compared to that of compound **1**. The dashed oval approximately locates the region of Pt...Pt interactions between the ligands. After Qi et al. (2008).

Reprinted from Chem. Phys. Lett., 458, 323 Qi, X., Djurovich, P. I., Giebink, N. C., Thompson, M. E. & Forrest, S. R., Evidence for enhanced interactions between Pt centers in binuclear phosphorescent complexes copyright 2008 with permission from Elsevier.

of the *d*-orbitals of the individual metal atoms. The strong interactions lift the triplet energy degeneracy, leading to the pronounced ZFS and high PL efficiencies.

The relationship between ZFS for  ${}^3\text{MLCT}$  vs.  ${}^3\text{LC}$  dominated transitions is also apparent from the comparison of  $(\text{N}^{\wedge}\text{C})\text{Pt}(\text{acac})$  and  $(\text{N}^{\wedge}\text{C})_2\text{Ir}(\text{acac})$  analogs in Table 3.5. Here, acac is the ancillary, acetylacetonate ligand. The effects of strong  ${}^3\text{MLCT}$  character in the Ir-complexes compared with the  ${}^3\text{LC}$  dominance of the square planar Pt complexes are striking. The red shift in  $\lambda_{\text{peak}}$  is higher for  ${}^3\text{MLCT}$  vs.  ${}^3\text{LC}$  transitions. From Eq. 3.199, the energy stabilization is larger in the former than in the latter case. Furthermore, the ZFS energy shift is considerably larger for Ir complexes, where  $ZFS \approx 20\text{--}100\text{ cm}^{-1}$  compared with typically ten times smaller shifts for the Pt analogs. All of these characteristics are consistent with the much larger triplet emission rate (again, often by a factor of ten) for the octahedral vs. the dihedral complexes.

Finally, we note that only subtle differences in structure of the same molecule can also alter its excitonic character from  ${}^3\text{LC}$  to  ${}^3\text{MLCT}$  with dramatic consequences to the photophysical characteristics of a molecular species. The facial (*fac*-) and meridional (*mer*-) isomers of  $\text{Ir}(\text{pmp})_3$ , respectively shown in Fig. 3.81 provide a striking illustration of the effects of the charge transfer character of the triplet excited state (Lee et al., 2016). Based on DFT calculations, the HOMO and LUMO of the *fac*-isomer are formed on the same ligand due to its  $\text{C}_3$  symmetry, resulting in considerable localization of the triplet state. In contrast, the HOMO of *mer*- $\text{Ir}(\text{pmp})_3$  is formed on two oppositely-disposed ligands, and the LUMO is on the third. This leads to more delocalized excited state that efficiently couples to the metal atomic orbitals.

**Table 3.5** Peak emission wavelength ( $\lambda_{\text{peak}}$ ), zero-field splitting energy (ZFS), and radiative lifetimes ( $k_{\text{ph}}$ ) of analogous Pt(II) and Ir(III) transition metal complexes. From Yersin et al. (2011)

Compound <sup>a</sup>	$\lambda_{\text{peak}}$ (nm)	ZFS ( $\text{cm}^{-1}$ )	$k_{\text{ph}}$ ( $\times 10^4\text{ s}^{-1}$ )
$\text{Ir}(4,6\text{-dFppy})_2(\text{acac})$	484	109	64
$\text{Pt}(4,6\text{-dFppy})(\text{acac})$	467	8	8.0
$\text{Ir}(\text{thpy})_2(\text{acac})$	567	33	12
$\text{Pt}(\text{thpy})(\text{acac})$	558	4	2.4
$\text{Ir}(\text{s1-thpy})_2(\text{acac})$	586	16	9.8
$\text{Pt}(\text{s1-thpy})(\text{acac})$	577	<1	2.1
$\text{Ir}(\text{bt})_2(\text{acac})$	557	100	14
$\text{Pt}(\text{bt})(\text{acac})$	539	10	6.0

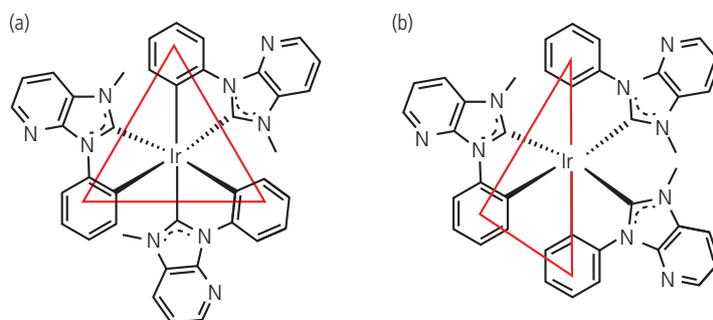

<sup>a</sup>  $(4,6\text{-dFppy})_2(\text{acac})$  = bis(4',6'-difluorophenyl)pyridinate, acac = acetylacetonate; thpy = 2-(2-thienyl)pyridinatoN,C<sup>3</sup>; s1-thpy = 5,2-bis(2-thienyl)pyridinate; bt = bis(2-phenylbenzo-thiozolato-N,C2')

Several photophysical characteristics of this pair of isomers confirm that the *fac*-isomer phosphorescence is predominantly of  ${}^3\text{LC}$  (Type I phosphor) character, whereas emission from *mer*- $\text{Ir}(\text{pmp})_3$  is from the  ${}^3\text{MLCT}$  (Type II) state. Due to the lower  $E_{\text{SO}}$  of  ${}^3\text{LC}$  states, the photoluminescence of *fac*- $\text{Ir}(\text{pmp})_3$  is considerably blue-shifted from that of the *mer*-isomer (see Fig. 3.82a). Their room temperature decay rates in Fig. 3.82b are equal to within a factor of two, while at low temperature the decay rate of *fac*- $\text{Ir}(\text{pmp})_3$  is  $\sim 10$  times smaller than for *mer*- $\text{Ir}(\text{pmp})_3$ , ( $k_{\text{ph}} = 6.4 \times 10^5\text{ s}^{-1}$  vs.  $10 \times 10^5\text{ s}^{-1}$  at 295 K;  $1.1 \times 10^5\text{ s}^{-1}$  vs.  $1.0 \times 10^6\text{ s}^{-1}$  at 77 K for *fac* and *mer*- $\text{Ir}(\text{pmp})_3$ , respectively) as is characteristic of Type I vs. Type II phosphors.

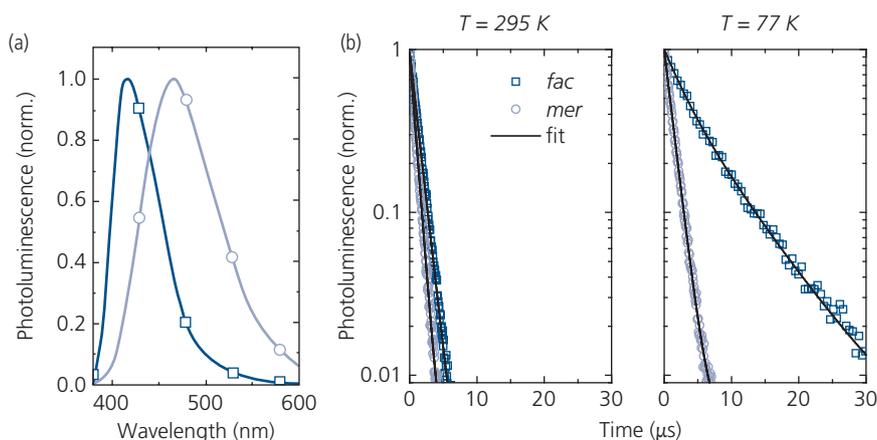

A further indication of the more polar nature expected for the  ${}^3\text{MLCT}$  state is found in the relative solvatochromatic shifts in a solvents of different polarity in Fig. 3.83. The larger excited state dipole moment of *mer*- $\text{Ir}(\text{pmp})_3$  is a consequence of the spatially extended  ${}^3\text{MLCT}$  state compared to that of the more compact  ${}^3\text{LC}$  state localized onto a single ligand. This leads to a significantly larger bathochromic shift for *mer*- $\text{Ir}(\text{pmp})_3$  as the polarity of the three solvents is increased (see Section 3.6.7). The dipole moments of the solvents used are 0 D, 0.375 D, and 1.6D for PMMA, toluene, and DCM, respectively. We summarize these differences between Type I and II  $\text{Ir}(\text{pmp})_3$  phosphors in Table 3.6.

### 3.7.4 Relative phosphorescent and fluorescent rates and efficiencies

Phosphorescence is formally defined as emission observed after a “perceptible” time has elapsed from the end of the excitation. A more reasonable definition, however, is emission that is controlled by triplets. The

relatively low phosphorescent emission rate depends primarily on two factors: the strength of electric dipole transitions between the dominant singlet excited

**Table 3.6** Comparison of the properties of Type I (*fac*), and Type II (*mer*- $\text{Ir}(\text{pmp})_3$ )

Property	Type I ( ${}^3\text{LC}$ )	Type II ( ${}^3\text{MLCT}$ )
Isomer	<i>fac</i> - $\text{Ir}(\text{pmp})_3$	<i>mer</i> - $\text{Ir}(\text{pmp})_3$
Excited state dipole	small (localized excited state)	large (extended excited state)
Red shift in DCM (1.6 D)	0.19 eV	0.33 eV
Emission energy	high (3.1 eV, deep blue)	moderate (2.7 eV, light blue)
Emission rate (295 K)	$6.4 \times 10^5 \text{ s}^{-1}$	$10 \times 10^5 \text{ s}^{-1}$
Emission rate (77 K)	$1.1 \times 10^5 \text{ s}^{-1}$	$1.0 \times 10^6 \text{ s}^{-1}$

state to  $S_0$ , and the atomic number of the heavy atom or electronic system that governs the magnitude of the spin-orbit interaction,  $H_{\text{SO}}$ . Phosphorescent emission depends on the ISC rate ( $k_{\text{ISC}}$ ) of  $S_1 \rightarrow T_1$ , followed by radiative decay (rate  $k_{\text{Ph}}$ ) from  $T_1 \rightarrow S_0$ . Efficient

phosphorescence requires that these rates are larger than competing processes, particularly non-radiative decay pathways via defects or impurities, such that  $k_{nr} \ll k_{ISC}, k_{Ph}$ . Spin-orbit coupling also leads to rapid ISC from  $S_D$  to  $T_1$  which suppresses fluorescence from singlets (i.e. the fluorescence lifetime is  $\tau_F \sim 1\text{--}10$  ns compared with the phosphorescence lifetime for heavy metal complexes of  $\tau_{Ph} \sim 1\text{--}10$   $\mu$ s). The hierarchy of transition rates that govern radiative and non-radiative transitions in organics are shown in Fig. 3.84. Note that  $k_{ISC}$  covers a broad range, approaching the rate of internal conversion ( $k_{IC}$ ) for heavy metal complexes where  $H_{SO}$  is large, that is,  $k_{ISC} > 10^{10} \text{ s}^{-1} > k_F$ . In contrast,  $k_{ISC} < 10^5 \text{ s}^{-1}$  for low molecular weight fluorescent materials (e.g. naphthalene) where  $H_{SO} \rightarrow 0$  (Beljonne et al., 2001, Forster, 2006).

We can understand the relative importance of the processes in Fig. 3.84 by comparing expressions for their *photoluminescence quantum yields*, which is defined as the ratio of the number of photons emitted into  $4\pi$  solid angle, to the total number of exciting photons that are absorbed in the sample. The fluorescent quantum yield is (cf. Eq. 3.119)

$$\Phi_F = \frac{k_F}{k_F + k_{nrS} + k_{ISC}} \quad (3.203)$$

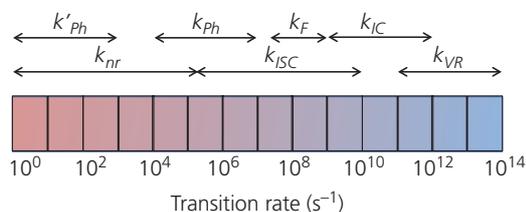

with an analogous expression for phosphorescence:

$$\Phi_P = \frac{\Phi_{ISC} k_{Ph}}{k_{Ph} + k_{nrT}}, \quad (3.204)$$

where  $k_{nrS}$  ( $k_{nrT}$ ) is the non-radiative decay rate from the singlet (triplet) state, and  $\Phi_{ISC}$  is the ISC quantum yield:

$$\Phi_{ISC} = \frac{k_{ISC}}{k_{ISC} + k_F + k_{nrS}} \quad (3.205)$$

That is, a condition for strong phosphorescent emission is that  $k_{ISC} \gg k_F$ , such that  $\Phi_{ISC} \rightarrow 1$  and  $\Phi_F \rightarrow 0$ . It follows that for a small non-radiative rate from the triplet state (which is often the case for heavy-metal-

**Figure 3.84** Characteristic transition rates in organic molecules. Here,  $k'_{Ph}$  is the phosphorescence transition rate in the absence of heavy-metal-induced spin-orbit coupling,  $k_{Ph}$  is the phosphorescence rate for heavy metal complexes. Other rates include fluorescence ( $k_F$ ), ISC for heavy metal complexes ( $k_{ISC}$ ), vibrational relaxation ( $k_{VR}$ ), internal conversion ( $k_{IC}$ ), and non-radiative relaxation ( $k_{nr}$ ). See Fig. 3.33.

based triplet emitting molecules), then we arrive at *Kasha's intersystem crossing ratio*:

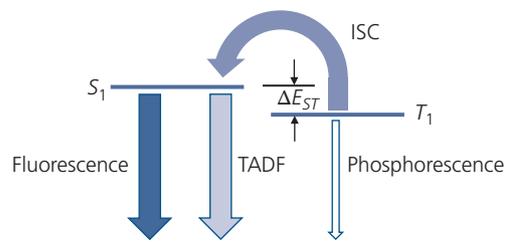

$$\frac{\Phi_{Ph}}{\Phi_F} = \frac{k_{ISC}}{k_F}. \quad (3.206)$$

While we have concentrated our discussion on Frenkel excitons, charge transfer excitons also have either a singlet or triplet spin multiplicity, and the same is true for excimers and exciplexes. The notations used to denote the multiplicities of CT states are  $^1\text{CT}$  and  $^3\text{CT}$  for singlets and triplets, respectively.

### 3.7.5 Delayed fluorescence

Rapid ISC occurs when the singlet and triplet energies are approximately in resonance. Based on first order perturbation theory,  $k_{ISC}$  becomes large when  $E(T_1) - E(S_D) \rightarrow 0$  in the energy denominator in Eq. 3.189. We caution that in this situation, first order perturbation theory is no longer strictly valid. Nevertheless, in near resonance, a triplet is *endothermically* promoted into the singlet manifold, followed by fluorescent emission. Since the direct emission from the triplet is electric dipole forbidden, the fluorescence emission rate is limited by the thermally activated transfer rate of the long-lived triplets, as illustrated in the Jablonski diagram in Fig. 3.85. This phenomenon is known as E-type delayed fluorescence, first observed in the molecule, eosin (Parker and Hatchard, 1961). More commonly, the process is termed *thermally activated delayed fluorescence* (TADF). TADF is one of two processes leading to delayed fluorescence; the other is due to lossy *triplet-triplet annihilation* (TTA) involving the participation of two triplets (see Section 3.10). Formation of a singlet via TTA is sometimes referred to as P-type delayed fluorescence due to its first observation in pyrene (Parker, 1963).

While spin-orbit coupling is required to mix the spin states in compounds undergoing TADF, the molecules do not require a heavy metal atom since the near-

**Figure 3.85** The TADF process due to endothermic conversion from  $T_1$  to  $S_1$ , separated by a small activation energy  $\Delta E_{ST}$ .

resonance between  $S_1$  and  $T_1$  reduces the reliance of the transition on the magnitude of  $E_{SO}$ . However, in the absence of strong spin-orbit coupling,  $k_{ph} \ll k_F$ . Hence, while back transfer from  $S_1$  to  $T_1$  is also rapid and exothermic, as long as the non-radiative vibronic relaxation rate is  $k_{nr} < k_{ph}$ , the excited state will be repeatedly thermionically excited into  $S_1$  until a fluorescent  $S_1 \rightarrow S_0$  transition occurs. The emission cycle of  $T_1 \rightarrow S_1 \rightarrow T_1$  persists for the duration of

$$\frac{1}{\tau_{TADF}} \approx k_{nr} + k_{ph}, \quad (3.207)$$

which is approximately equal to the natural phosphorescent lifetime.

The kinetic scheme leading to S-T mixing and ultimately to TADF is illustrated in Fig. 3.86. Here, the ISC rate,  $k_{ISC,T}$ , from  $T_1 \rightarrow S_1$  is thermally activated, following:

$$k_{ISC,T} = k_{ISC,T}^{\infty} \exp(-\Delta E_{ST}/k_B T), \quad (3.208)$$

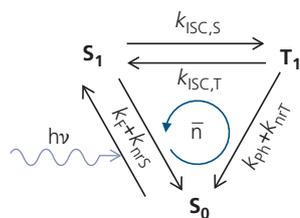

where  $\Delta E_{ST}$  is the singlet-triplet exchange energy, and  $k_{ISC,T}^{\infty}$  is the value of  $k_{ISC,T}$  as  $T \rightarrow \infty$ . Since the opposite rate,  $k_{ISC,S}$ , is exothermic, it is much larger than  $k_{ISC,T}$ . A closer energy match of  $S_1$  to  $T_1$ , and a longer triplet lifetime ( $\tau_{ph} = 1/k_{ph}$ ) leads to more efficient TADF, which in some circumstances can approach 100%. The probability that higher order vibronics in  $T_1$  are occupied at higher temperatures follows the Boltzmann distribution in Eq. 3.208. Hence, as temperature increases, the transfer between  $T_1$  and  $S_1$  becomes increasingly more efficient.

The average number of cycles,  $\bar{n}$ , between  $S_1$  and  $T_1$  prior to emission via  $T_1 \rightarrow S_0$  (Fig. 3.86) depends on the relative magnitudes of the radiative and non-radiative rates, as well as on  $k_{ISC,T}$ . Defining the quantum yields for singlet and triplet formation as:

$$\Phi_S = \frac{k_{ISC,T}}{k_{ISC,T} + k_{ph} + k_{nrT}} \quad (3.209)$$

and

$$\Phi_T = \frac{k_{ISC,S}}{k_{ISC,S} + k_F + k_{nrS}}, \quad (3.210)$$

**Figure 3.86** The cyclic TADF process. Adapted from Baleizao and Berberan-Santos (2008).

respectively, then it can be shown that the number of cycles is

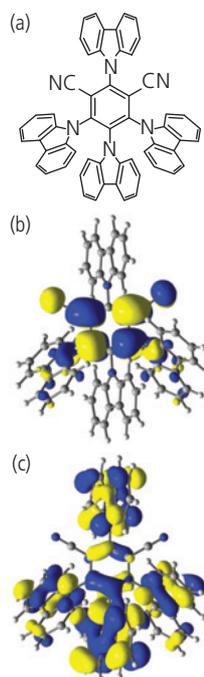

$$\bar{n} = \frac{\Phi_T \Phi_S}{1 - \Phi_T \Phi_S}. \quad (3.211)$$

The kinetics of TADF have been studied in the fullerenes,  $C_{60}$  and  $C_{70}$ . Astonishingly, for  $C_{60}$   $\bar{n} \approx 100$  at  $150^\circ\text{C}$  (Baleizao and Berberan-Santos, 2008). However, due to the activation energy barrier between  $S_1$  and  $T_1$ , the contribution of TADF to the emission intensity falls off rapidly as temperature is reduced.

More recently TADF has been employed in very high efficiency OLEDs (Uoyama et al., 2012), a topic discussed further in Section 6.3.4. For this purpose, fluorescent molecules with a minimal  $\Delta E_{ST}$  are required for high efficiency emission. As noted in Section 3.7.1, the exchange energy is typically from 0.5 eV to 1.0 eV, in which case,  $\Delta E_{ST} \gg k_B T$  and hence the reverse transfer rate,  $k_{ISC,T}$  is small. The key to reducing the exchange energy,  $K_j$  in Eq. 3.49b, is to design molecules that minimize the overlap between orbitals in  $S_1$  and  $S_0$ , while keeping the molecular structure sufficiently rigid to inhibit rapid  $T_1 \rightarrow S_0$  non-radiative decay.

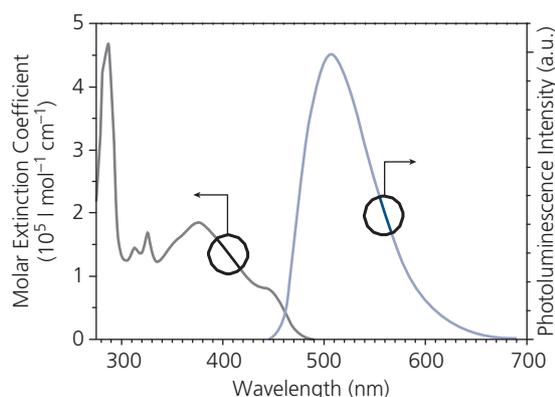

Metal-free TADF compounds with high efficiency emission across the visible spectrum are exemplified by the archetype green fluorescent compound 4CzIPN shown in Fig. 3.87a (Uoyama et al., 2012). Time dependent DFT calculations show in Fig. 3.87b that the lowest unoccupied natural transition orbital (LUNTO) is centered on the dicyanobenzene group at the molecular core, with little overlap with the highest occupied NTO (HONTO) that is delocalized over the four carbazoyl groups (see Fig. 3.87c). In these calculations, the NTO is obtained from a weighted sum over all empty HOMO and filled LUMO states to obtain an estimate of the most likely  $S_1 \rightarrow S_0$  transition probability density distribution (Martin, 2003). The limited orbital overlap between the excited and ground states results in a small  $\Delta E_{ST} = 83$  meV, thereby introducing a substantial oscillator strength to the intersystem  $S_1 \leftarrow T_1$  transition. These molecules also exhibit a relatively small Stokes shift, suggesting minimal reconfiguration during transition that is enforced by steric effects introduced by the cyano groups. Taken along with suppressed  $k_{nr}$ , a quantum yield of  $\Phi_S = 94\%$  is observed.

A feature of TADF emission is the absence of vibronic overtones typically observed in monomeric  $S_1 \rightarrow S_0$  spectra. Indeed, TADF spectra are comparatively broad and featureless, as shown in Fig. 3.88. This results from the lack of overlap of the HOMO and LUMO on the same molecule, creating a situation similar to that found for excimer transitions. In that

**Figure 3.88** Absorption and photoluminescence spectra of 4CzIPN in Fig. 3.87. Note the broad, featureless emission spectrum of the molecule characteristic of TADF (Uoyama et al., 2012).

case, the absence of a bound ground state is responsible for the featureless shape of the emission spectra.

Thermally activated delayed fluorescence is also commonly observed in metal–organic complexes such as the Cu carbenes in **Scheme 1**, Section 3.6.1. Indeed, TADF in Cu complexes have been extensively studied due to their high emission efficiencies that are useful in OLEDs (Wallesch et al., 2014, Shi et al., 2017,

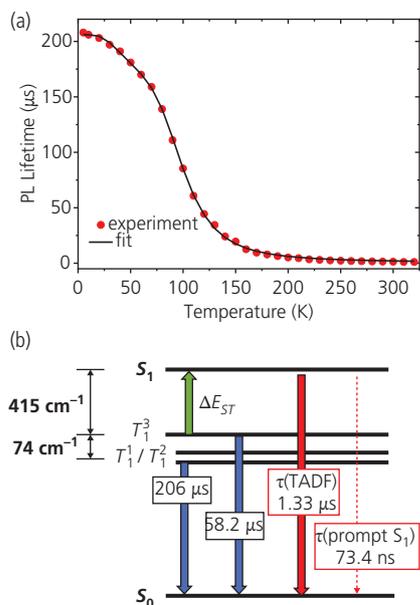

**Figure 3.89** Frontier orbitals. LUMO (left) and HOMO (right) of compounds **3** (top) and **6** (bottom), **Scheme 1** (Shi et al., 2019).

E., Highly Efficient Photo and Electroluminescence from Two Coordinate Cu(I) Complexes Featuring Non conventional N heterocyclic Carbenes. Copyright 2019 American Chemical Society.

Yersin et al., 2017). The frontier molecular orbitals of Compounds **3** and **6** in **Scheme 1** calculated by DFT and TD-DFT and shown in Fig. 3.89 provide insight into the effectiveness of this molecular motif in promoting high efficiency delayed fluorescence (Shi et al., 2019). The Cu linkage between the carbazoyl (to the right) and the carbene (MAC or DAC) separates the electron densities of the HOMOs and LUMOs such that there is little or no overlap between them. Transitions thus require intramolecular charge transfer across a small  $\Delta E_{ST}$ , as required for efficient TADF at room temperature. The Cu-complexes show featureless emission (see Fig. 3.40) and absorption spectra that are due to excimer-like charge transfer between the excited and ground state orbitals.

The photophysics of the Cu–carbene complexes have been investigated to understand the mechanisms and energetics leading to highly efficient TADF. The measured transient PL decay vs. temperature of compound **3** is shown in Fig. 3.90a (data points). The lifetime changes rapidly from a plateau of  $> 200 \mu\text{s}$  at low temperature, to approximately  $1 \mu\text{s}$  as temperature is increased above 175 K. The data are fit by assuming that the lower triplet levels are populated according to Boltzmann statistics. Then, following Eq. 3.202, we can write an analogous expression for the TADF PL lifetime:

$$\bar{k}_{TADF} = \frac{2k_{12} + k_3 \exp(-\Delta E_{13}/k_B T) + k_F \exp(-\Delta E_{S_{1,1}}/k_B T)}{2 + \exp(-\Delta E_{13}/k_B T) + \exp(-\Delta E_{S_{1,1}}/k_B T)}, \quad (3.212)$$

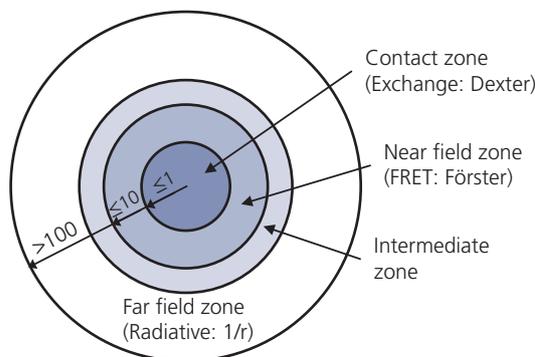

**Figure 3.90** (a) Photoluminescent transient decay vs. temperature of Cu–carbene compound **3** in Fig. 3.89. Measurements shown as circles, fit to theory in text as lines. (b) Energy level scheme inferred from the fit in (a). After Shi et al. (2019).

E., Highly Efficient Photo and Electroluminescence from Two Coordinate Cu(I) Complexes Featuring Non conventional N heterocyclic Carbenes. Copyright 2019 American Chemical Society.

where the factors of 2 are due to the twofold degeneracy of states  $T_1^1$  and  $T_1^2$ . The PL rate is determined by the rates at which  $S_1$  is populated via excitations from the three triplet substates, 1, 2, and 3. This must compete against direct fluorescence from  $S_1$  at rate  $k_F = 1.2 \times 10^7 \text{ s}^{-1}$  which is weighted by the factor,  $\exp(-\Delta E_{S_1,1}/k_B T)$ . A fit to the data in Fig. 3.90a (solid line) using this expression yields the energies in Fig. 3.90b. A substantial ZFS energy of  $74 \text{ cm}^{-1}$  and an exchange energy splitting of  $415 \text{ cm}^{-1}$  ( $51.5 \text{ meV}$ ) leads to a high room temperature photoluminescent quantum yield of 90% (Shi et al., 2019).

### 3.8 Energy transfer

The mobile character of the exciton arises from dispersion,  $E(\mathbf{k})$ , in its energy band structure discussed in Section 3.6. Hence, the effective mass of the exciton is finite, resulting in kinetic energy,  $\hbar^2 k^2 / 2m_r^*$ , where  $\hbar k$  is the momentum. That is, if the bands are dispersionless, as is the case for isolated atoms and molecules, then  $\partial^2 E / \partial k^2 \rightarrow 0$ , in which case  $m^* \rightarrow \infty$  which prohibits exciton motion. Its ability to move freely about the solid implies that exciton migration occurs via energy transfer from molecule to molecule.

**Figure 3.91** Interaction zones and approximate distances (in nm) over which they occur (shown as numbers) for  $D^* \rightarrow A^0$  intermolecular energy transfer transitions. The contact zone is where  $D^*$  and  $A^0$  are in physical contact, radiationless dipole–dipole transfer occurs in the near field zone where Förster theory is valid, the intermediate zone is a transition region between radiationless and radiative transfer, and in the far field zone, emission by  $D^*$  is absorbed by  $A^0$ . In this zone, interactions scale as  $1/r$ , where  $r$  is the intermolecular distance. After Förster (1959) and van der Meer (2014).

Energy transfer is governed by three principal processes, depending on the distance over which it occurs. These are: (i) long range *radiative transfer* (also known as *trivial energy transfer*), (ii) near field *Förster* (or *fluorescent*) *resonant energy transfer* (or FRET), and (iii) *exchange transfer* (or *Dexter transfer*) between molecules that are in direct physical contact. The interaction zones and characteristic interaction distances are shown in Fig. 3.91. In the transfer process, one molecule is a donor in its excited state,  $D^*$ , which delivers its energy to an acceptor in its ground state,  $A^0$  (terminology is the same as used for excimers and exciplexes in Section 3.6.3). Sometimes, the donor is referred to as the *sensitizer molecule*, and the acceptor is called the *activator*, but here we will use the former and more common terminology. Furthermore, the donor and acceptor can be molecules of similar or different compositions.

Following the Second Law of Thermodynamics, the transfer from  $D^*$  to  $A^0$  is always accompanied by energy loss. That is, if the exciton energy of  $D^*$  is  $E_{D^*}$  and of  $A$  is  $E_{A^0}$ , then efficient transfer requires  $E_{D^*} > E_{A^0}$ . This corresponds to exothermic transfer. The energy loss arises from relaxation of the molecule following excitation, for example, via internal conversion or lattice distortions that result in a Stokes shift. Furthermore, in the subsequent transfer step, the acceptor molecule becomes the donor, that once more undergoes the same relaxation process, lowering the energy even further from that of the original excitation. Nevertheless, if these losses are not excessive, energy can be extracted from the

system (e.g. in the form of heat via phonon absorption) to enable endothermic energy transfer even when  $E_D^* < E_{A^0}$ .

The primary objective of this section is to determine the energy transfer rates,  $k_{ET}$ , for each process. These are calculated using Fermi's Golden Rule (Eq. 3.69), where the interaction is Coulombic: that is the transition multipole expansion can be used for  $H_{int}$ , with different terms in the expansion dominating at different distances. The full quantum mechanical treatment used to describe these several process in a unified way is useful but complicated, for which the reader is referred to Andrews (1989). Here, we focus on the three primary regions of interest, omitting a discussion of transfer within the intermediate zone. It is convenient to begin our discussion with FRET in the near field region, and then move to exchange interactions, finishing up with radiative transfer. In addition to providing a derivation based on quantum mechanics, where necessary we will provide a semi-classical description that may be more useful in the practical understanding of energy transfer.

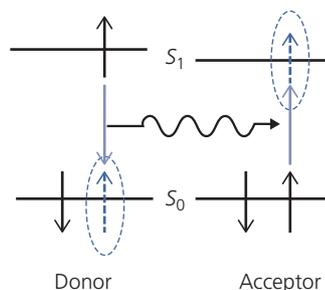

### 3.8.1 Near field radiationless energy transfer: FRET

In Chapter 2 we showed how induced dipole-induced dipole interactions provide the adhesive force for van der Waals solids. This same interaction is responsible for radiationless coupling of the excitation of a donor molecule to a nearby, unexcited acceptor. The first treatment of this widely observed phenomenon is attributed to J. Perrin (Perrin, 1927) and F. Perrin (Perrin, 1932). While their work introduced the concept of energy exchange between coupled oscillators, errors in their treatments led to a considerable overestimation of the distances over which transfer occurs: ~20–100 nm compared to actual distances of only ~5 nm. These inconsistencies were corrected in a landmark paper by T. Förster that presented the first comprehensive and accurate analysis of radiationless energy transfer in the near field (Förster, 1948).

In FRET, an excited singlet donor ( $^1D^*$ ) is coupled to an unexcited acceptor ( $^1A^0$ ) via dipole-dipole interactions. After a time  $\tau_{ET} = 1/k_{ET}$  the excitation is transferred according to

a process illustrated in Fig. 3.92. That is, the excited singlet donor transfers its energy to a nearby (~1–10 nm) ground state acceptor. This process requires that the D and A transitions be quantum

**Figure 3.92** Förster resonant energy transfer from a singlet excited state donor to a ground state acceptor. The small solid and dashed arrows are the electron and hole spins, respectively, and the large arrows show the transitions.

mechanically allowed, and therefore the initial and final spin states of the D and A must be identical. However, transfer to an acceptor between triplet manifolds is also allowed via

where  $1 \leq m < n$  are the indexes of the initial and final acceptor triplet states (e.g.  $T_2 \leftarrow T_1$  or  $T_3 \leftarrow T_1$ ). This transition requires that  $^3A_m$  is already populated, that is, it is already in an excited state. Finally, we note that when the donor molecule is capable of efficient triplet emission (e.g. it contains a heavy metal atom), then process Eq. 3.213 is modified as follows:

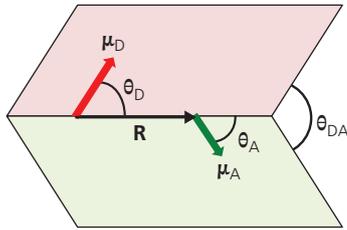

This process, known as *phosphor sensitized fluorescence*, was predicted by Förster (1959) and has been demonstrated as a route to high efficiency fluorescent OLEDs (Baldo et al., 2000) (see Chapter 6.3).

The transfer process is governed by electrostatic multipole interactions between the neutral  $D^*$  and A molecules (Eq. 2.39 ff.), viz.

$$H_{int} = \frac{q^2}{4\pi\epsilon_0\epsilon_r R^3} \left\{ \mathbf{r}_D \cdot \mathbf{r}_A - \frac{3(\mathbf{r}_D \cdot \mathbf{R})(\mathbf{r}_A \cdot \mathbf{R})}{R^2} \right\} + O\left(\frac{1}{R^4}\right) + \dots \quad (3.216)$$

Here,  $R$  is the distance between D and A, and  $\mathbf{r}_D$  and  $\mathbf{r}_A$  are the positions of dipoles of moment  $\boldsymbol{\mu} = -q\mathbf{r}$ . The term in brackets is due to dipole-dipole interactions. The higher order terms represent dipole-quadrupole and higher multipole interactions, which due to their very short range, can be safely ignored. The vector relationships between these quantities are illustrated in Fig. 3.93. It follows from Eq. 3.69 that the energy transfer rate is:

$$k_{ET}(E) = \frac{2\pi}{\hbar} |\langle \Phi_f | H_{int} | \Phi_i \rangle|^2 \rho(E) = \frac{2\pi}{\hbar} |M_{fi}|^2 \rho(E) \quad (3.217)$$

**Figure 3.93** Vector relationships between the donor and acceptor electric dipole moments,  $\mu_D$  and  $\mu_A$ , respectively, and their separation,  $R$ .

where  $\Phi_{if}$  are the wavefunctions, including both electronic and nuclear components in the initial ( $i$ ) and final ( $f$ ) states.

In the very weak coupling limit of Förster transfer, there is no unique correspondence between the vibronic levels of the initial and final states. That is, due to numerous degrees of freedom, the vibronic levels are inhomogeneously broadened, resulting in a distribution of transition densities across the excited donor and ground state acceptor electronic manifolds. This must be considered when we determine  $\rho(E)$ . A graphical representation of this situation is shown in Fig. 3.94.

To determine  $k_{ET}$ , we first calculate the matrix element in Eq. 3.216. The wavefunctions explicitly include both the nuclear ( $\phi_N$ ) and electronic parts ( $\phi_e$ ), such that

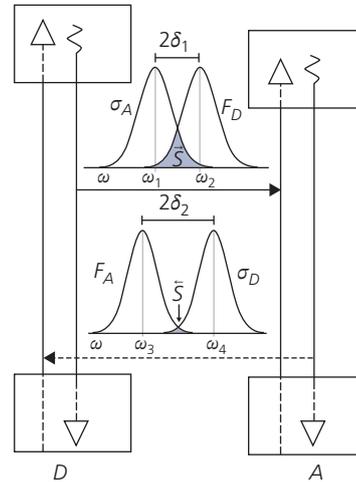

$$\Phi_i(E_{D^*}, E_{A^0}) = \phi_e^{D^*} \phi_e^{A^0} \phi_N^{D^*}(E_{D^*}) \phi_N^{A^0}(E_{A^0}) \quad (3.218)$$

and

$$\Phi_f(E_{D^0}, E_{A^*}) = \phi_e^{D^0} \phi_e^{A^*} \phi_N^{D^0}(E_{D^*} - E) \phi_N^{A^*}(E_{A^0} + E), \quad (3.219)$$

where the energy transferred from  $D^*$  to  $A^0$  is  $E$ , and the other energies correspond to the molecular states as denoted in their subscripts. Then,

$$\begin{aligned} |M_{fi}|^2 &= |\langle \Phi_f | H_{\text{int}} | \Phi_i \rangle|^2 = \left| \left\langle \phi_e^{D^0} \phi_e^{A^*} \left| H_{\text{int}} \right| \phi_e^{D^*} \phi_e^{A^0} \right\rangle \right|^2 \\ &\times \left| \left\langle \phi_N^{D^0}(E_{D^*} - E) \left| \phi_N^{D^*}(E_{D^*}) \right\rangle \right|^2 \\ &\times \left| \left\langle \phi_N^{A^*}(E_{A^0} + E) \left| \phi_N^{A^0}(E_{A^0}) \right\rangle \right|^2 \\ &= |M_{efi}|^2 FC_D(E_{D^*}; E_{D^*} - E) \times FC_A(E_{A^0}; E_{A^0} + E), \end{aligned} \quad (3.220)$$

**Figure 3.94** Coupling between the broad donor ( $D$ ) and acceptor ( $A$ ) bands involved in FRET. Here,  $F_{A,D}(\omega)$  are the emission spectra, and  $\sigma_{A,D}(\omega)$  the absorption spectra of the (acceptor, donor) molecules. Their respective Stokes shifts are  $2\delta_1$  and  $2\delta_2$ .  $S$  is the overlap between the two (Andrews and Rodriguez, 2007).

where the overlap integrals of the ground and excited state vibronic levels are given by their respective Franck-Condon factors. Also, we have used  $M_{efi}$  for the Coulomb integral resulting from the dipole-dipole interaction in Eq. 3.216.

The next step is to calculate the Coulomb integral. For this, we refer to the vector relationships of  $\mathbf{r}_A$  and  $\mathbf{r}_B$  in Fig. 3.93, to rewrite the second term in Eq. 3.216 as follows:

$$q^2 \left\{ \mathbf{r}_D \cdot \mathbf{r}_A - \frac{3(\mathbf{r}_D \cdot \mathbf{R})(\mathbf{r}_A \cdot \mathbf{R})}{R^2} \right\}^2 = \kappa_F^2 \mu_D^2 \mu_A^2. \quad (3.221)$$

Here,  $\kappa_F$  is the *orientation factor* that relates to the coupling between dipoles:

$$\kappa_F^2 = (\cos\theta_{DA} - 3\cos\theta_D\cos\theta_A)^2. \quad (3.222)$$

This quantity has a value between 0 and 4, depending on the relative angles between dipoles. It is apparent that if the dipoles are orthogonal to each other, no energy transfer can occur. In a medium in which the dipoles are uncorrelated and hence randomly oriented, the spatial average is  $\kappa_F^2 = \frac{2}{3}$ . Thus, the efficiency of FRET can be used to determine the degree of orientational correlation between donor and acceptor. Specifically, the transfer efficiency in a solid can be measured as a function polarization of the incident radiation that is used to induce the transition  $D^* \leftarrow D^0$  (Andrews and Bradshaw, 1999).

Using Eqs. 3.216 and 3.220, we obtain

$$|M_{fi}|^2 = \frac{\kappa_F^2 \mu_D^2 \mu_A^2}{(4\pi\epsilon_0)^2 n_r^4 R_{DA}^6} FC(E_{D^*}; E_{D^*} - \hbar\omega) \times FC(E_{A^0}; E_{A^0} + \hbar\omega), \quad (3.223)$$

where  $R_{DA}$  is the distance between dipoles, and the real part of the index of refraction is related to the permittivity via  $n_r = \sqrt{\epsilon_r}$ . Finally, integrating over the density of initial and final states within the electronic manifolds of  $D^*$  and  $A^0$ , we obtain the total, energy-independent rate of:

$$k_{ET} = \frac{\kappa^2 \mu_D^2 \mu_A^2}{(2\pi)^3 (4\pi\epsilon_0)^2 n_r^4 \hbar^2 R_{DA}^6} \times \int g_{D^*}^*(E_{D^*}) g_A^0(E_{A^0}) FC_D(E_{D^*}; E_{D^*} - \hbar\omega) \times FC_A(E_{A^0}; E_{A^0} + \hbar\omega) d\omega. \quad (3.224)$$

In this expression, we have introduced the Boltzmann factors,  $g_{D^*}^*$  and  $g_A^0$ , that account for the distribution of excitations over the several vibronic levels within the particular electronic manifold (i.e.  $D^*$  or  $A^0$ ). The dipole overlap integrals are conveniently expressed via

$$M_D(\omega) = \mu_D^2 \int g_{D^*}^*(E_{D^*}) FC_D d(E_{D^*}) \quad (3.225a)$$

and

$$L_A(\omega) = \mu_A^2 \int g_A^0(E_{A^0}) FC_A d(E_{A^0}). \quad (3.225b)$$

The integral Eq. 3.224 is proportional to the overlap of the normalized emission spectrum of the donor ( $f_D(\omega)$ ) with the molar absorption spectrum of the acceptor. Thus, in terms of the un-normalized donor fluorescence spectrum,  $F_D(\nu)$ :

$$f_D(\nu) = \frac{F_D(\nu)}{\int F_D(\nu) d\nu} = \frac{F_D(\nu)}{\Phi_D}, \quad (3.226)$$

where  $\Phi_D$  is the total fluorescence quantum yield of the donor. To obtain the exact expressions for these terms, Förster has shown (Förster, 1951) from the Einstein coefficients for spontaneous emission,  $A_{fi}$ , and stimulated absorption,  $B_{if}$  that:

$$M_D(\nu) = \frac{3 \epsilon_0 \hbar c^3 \Phi_D f_D(\nu)}{4 \pi n_r \tau_D \nu^3} \quad (3.227)$$

and

$$L_A(\nu) = \frac{6 \epsilon_0 \alpha_A(\nu) n_r \hbar c M_{wA}}{N_A \nu \rho_{MA}}. \quad (3.228)$$

Here,  $M_{wA}$  is the molar molecular mass,  $\rho_{MA}$  is the mass density of the acceptor in the mixture, and  $\tau_D$  is the total radiative lifetime (including non-radiative transitions) of the donor in the absence of the acceptor molecule. Then combining Eqs. 3.224, 3.225, 3.227, and 3.228 we arrive at the so-called Förster integral:

$$k_{ET} = \frac{9c^4}{128\pi^5} \frac{\kappa^2 \Phi_D}{N_A n_r^4 \tau_D R_{DA}^6} \frac{M_{wA}}{\rho_{MA}} \int \frac{f_D(\nu) \alpha_A(\nu)}{\nu^4} d\nu. \quad (3.229)$$

Often, it is convenient to use the imaginary part of the complex refractive index,

$$\tilde{n} = n_r + ik, \quad (3.230)$$

instead of the absorption coefficient, in which case we substitute  $\alpha_A(\nu) = 4\pi k_A(\nu)/\lambda$  in Eq. 3.229. (Here,  $k$  is the extinction coefficient that should not be mistaken for a rate, Boltzmann's constant or any number of other confusing assignments used for this variable!) Alternatively, Eq. 3.229 can be restated in terms of the decadic molar extinction coefficient (cf. Eq. 3.97):

$$k_{ET} = \frac{9(2303)c^4}{128\pi^5} \frac{\kappa^2 \Phi_D}{n_r^4 \tau_D N_A R_{DA}^6} \int \frac{f_D(\nu) \epsilon_A(\nu)}{\nu^4} d\nu. \quad (3.231)$$

Finally, we can write this expression in terms of the acceptor absorption cross section,  $\sigma_A = \frac{4\pi k_A}{\lambda} \frac{M_{wA}}{N_A \rho_{MA}}$  to obtain

$$k_{ET} = \frac{9c^4}{8\pi} \frac{\kappa^2 \Phi_D}{n_r^4 \tau_D R_{DA}^6} \int \frac{f_D(\omega) \sigma_A(\omega)}{\omega^4} d\omega. \quad (3.232)$$

Equation 3.229 (and its other versions) has several notable features. First, it is independent of  $\hbar$ , even though our treatment has been based on the quantum mechanical interaction of the donor and acceptor molecules! Indeed, the premise of Förster's original treatment of this phenomenon was that it is completely classical (Förster, 1948), although at a later date he came to an identical formulation based on quantum mechanics. A review and comparison of these various approaches has been summarized by B. Wieb van der Meer (2014). A further important feature of FRET is its dependence on  $1/R_{DA}^6$  as is characteristic of very short range induced dipole-induced dipole interactions. Finally, the transfer rate follows  $\sim \Phi_D/\tau_D$ , that is, it scales proportionately with the ratio of quantum yield to fluorescence lifetime of the donor. As the quantum yield increases and lifetime decreases, the transfer becomes increasingly efficient. This is a consequence of the fact that the coupling involves the exchange of quanta, and hence the efficiency of this exchange must be proportional to the radiative quantum yield. The inverse proportionality with lifetime implies that

other competing processes can reduce the transfer efficiency. If  $\tau_D$  is sufficiently short, FRET will dominate.

Finally, and most importantly, the integral is proportional to the degree of *overlap* between the donor fluorescence and acceptor absorption spectra. This, in effect, expresses the extent that the energy levels of these states are in resonance. The Förster integrals can be simplified if we rearrange Eq. 3.229 as follows:

$$k_{ET} = \frac{1}{\tau_D} \left( \frac{R_0}{R_{DA}} \right)^6 \quad (3.233)$$

where

$$R_0^6 = \frac{9c^4}{128\pi^5} \frac{\kappa^2 \Phi_D M_{DA}}{N_A n_r^4 \rho_{MA}} \int \frac{f_D(v) a_A(v)}{v^4} dv = A_v J_v \quad (3.234)$$

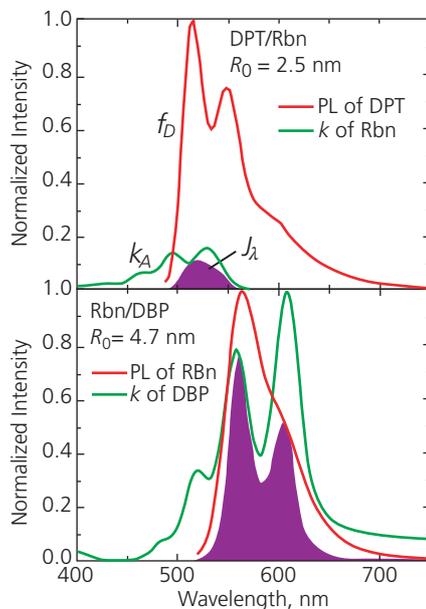

is the *Förster radius* or the *transfer distance*, which is proportional to the spectral overlap integral,  $J_v$ . Thus, when  $R_{DA} = R_0$ , then  $k_{ET} = 1/\tau_D$ . In this circumstance, the transfer time is equal to the radiative lifetime, reducing the transfer efficiency by 50%:

$$\eta_{ET} = \frac{\tau_D}{\tau_{ET} + \tau_D} \rightarrow \frac{1}{2}. \quad (3.235)$$

Here,  $1/\tau_D = 1/\tau_F + 1/\tau_{NR}$  where  $\tau_F$  is the natural fluorescence lifetime of the donor, and  $\tau_{NR}$  is the time for non-radiative decay via parasitic loss channels. The Förster radius is thus strongly dependent on the spectral overlap integral.

An example of overlap, and the resulting calculated values of  $R_0$  using Eq. 3.234 are the emission and absorption spectra shown in Fig. 3.95 for a layer of a DPT film in contact with rubrene (Rbn), as well as Rbn in contact with DBP. The spectral overlap region is shaded. Clearly,  $J_v$  for Rbn–DBP is much larger than for the DPT–Rbn system, yet the Förster radius differs by less than a factor of two ( $R_0 = 2.5$  nm vs. 4.7 nm). This seeming contradiction points to the fact that  $R_0 \sim J_v^{1/6}$ , and hence is very insensitive to the degree of overlap and the other physical and optical properties of the molecular system. Most effective molecular species that exhibit efficient FRET have Förster radii between 3 nm and 5 nm (van der Meer et al., 1994).

It is worth discussing the effects of the orientation factor,  $\kappa_F^2$ , that carries a wealth of information about the morphology of the D–A blend, since the degree of coupling between molecules depends on their relative angles,  $\theta_{DA}$ ,  $\theta_D$ , and  $\theta_A$  (Fig. 3.93). Recovery of this information is complicated by the many other parameters in the prefactor to the overlap integral.

**Figure 3.95** Normalized photoluminescence spectrum (corresponding to the fluorescence spectrum  $f_D$ ) and extinction coefficient ( $k$ ) for the (a) DPT/Rbn and (b) Rbn/DBP D–A pairs. The overlap between spectra are shaded, along with the calculated Förster radii ( $R_0$  shown in legends) (Griffith and Forrest, 2014).

However, the coupling of polarized light to the donor molecule is proportional to  $\cos^2\theta$ , where  $\theta$  is the angle between the incident light and the dipole moment,  $\mu_D$ . Hence, polarized light selectively excites only those molecules aligned to the incident polarization. If energy transfer occurs on a time scale less than the time to randomize the excited donors, then information about the polarization state is passed on to the acceptor population with an efficiency proportional to  $\kappa_F^2$ . We then can determine if there is a preferred orientation between D and A by measuring the polarization of light emitted by the acceptor. The degree of polarization of the emitted light is

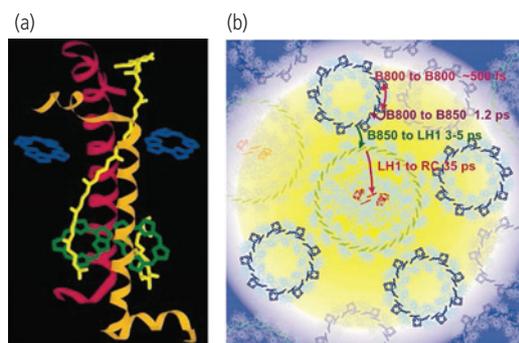

$$P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}}, \quad (3.236)$$

where  $I_{\parallel}$  and  $I_{\perp}$  are the polarized emission intensities parallel and perpendicular to the excitation polarization. If all absorbing dipoles are aligned parallel to the incident polarization, then  $P = 0.5$ . Further, for a sample where all emitting dipoles are perfectly aligned, the 3D rotational average should have a ratio of  $I_{\parallel} : I_{\perp} = 3 : 1$ . Differences from this ratio provide information about the degree of misalignment, or of the rate of randomization of the dipoles on time scales comparable to  $k_{ET}$  (Andrews and Bradshaw, 1999). Furthermore, the time dependence of this

ratio can be used to study the dynamics of molecular orientation and motion within the solid or liquid that hosts the D and A molecules.

As noted above, FRET plays a significant role in the diffusion of excitons, and hence has been studied and exploited in OLEDs, OPVs, lasers, and many other organic devices. These phenomena will be discussed in the context of those devices in Part II. Also, we would be remiss in omitting the essential role that FRET plays in living organisms, most notably in the process of photosynthesis. The literature abounds with detailed studies of FRET in proteins, cells, nucleic acids, nanoparticles and so on (see, for example, Medintz and Hildebrandt, 2014). For example, the light harvesting complexes in purple bacteria comprise ring structures that contain optical absorbing porphyrins. The photogenerated exciton is transferred from porphyrin to porphyrin, eventually finding its way to a reaction center (RC) in the middle of the ring that transforms the excitation into free charge. Hence, the rings serve as optical antennas that funnel excitons to the charge separation center. An example system comprised of two light harvesting complexes, LH1 and LH2 that serve as coupled antennae in *Rhodobacter sphaeroides* is shown in Fig. 3.96 (Sundström et al., 1999).

The complex has been optimized to assure that the path from light absorption to charge generation is nearly 100% efficient. Its properties include: (i)

**Figure 3.96** The photosynthetic light harvesting complex found in *Rhodobacter sphaeroides*. (a) A detail of one unit of the nine-sided light harvesting complex, LH2, shown as ring structures in (b). The red and orange ribbons are the *a* and *b* polypeptide helices, respectively, that form a scaffold to support the light absorbing B800 (blue) and B850 (green) bacteriochlorophylls (BChl). Carotenoids are shown in yellow. (b) The BChl are precisely positioned to maximize FRET from the LH2 antennae to the LH1 ring centered on the reaction complex (RC) where the excitons are separated into free charge. The transfer times ( $\tau_{ET}$ ) between moieties are indicated (Sundström et al., 1999).

Reprinted with permission from J. Phys. Chem. B, 103, 2327, Sundström, V., Pullerits, T. & Grondelle, R. v. Photosynthetic light-harvesting: Reconciling dynamics and structure of purple bacterial LH2 reveals function of photosynthetic unit. Copyright 1999 American Chemical Society

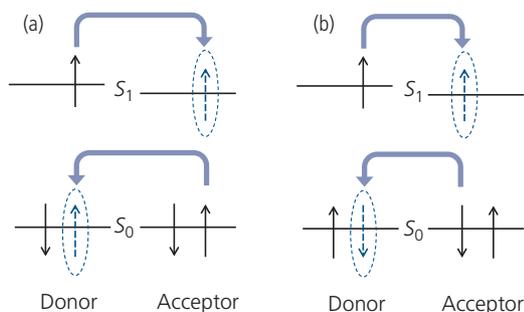

optimization of the spectral characteristics of the donor–acceptor bacteriochlorophyll (BChl) pair B800 and B850 (with absorption between wavelengths of 800 nm to 850 nm, respectively) to assure resonant coupling between molecular units. (ii) Precise positioning of molecules involved in the transfer to less than a Förster radius. The spacing is maintained by a peptide scaffold that also forms two concentric rings to accurately positions the BChl molecules. The separation between B800 and B850 is estimated to be only 1.5 nm to 1.9 nm (see Fig. 3.96a). (iii) Extremely fast and nearly lossless transfer between molecular units around the nine-membered (nonomer) LH2 ring structure, and between LH2 and LH1 and the RC at the central axis of the antenna assembly. Indeed, dipole–dipole coupling energies of  $\sim 15 \text{ cm}^{-1}$  between B800 and B850 ensure almost no energy loss during each transfer step.

In Fig. 3.96b, we find that the rates of transfer around the rings, and between rings and RC range from 500 fs to 35 ps. There are no other processes in this photosynthetic unit that can compete on these time scales, resulting in near unity quantum yield. Finally, (iv) the carotenoid molecules are extremely tightly coupled ( $< 1 \text{ nm}$  spacing) with the pigments, particularly B850 in Fig. 3.96a. The carotenoids (Crt) perform two functions, one in energy transfer and the other in stabilizing the pigment molecules by scavenging damaging triplet states and reactive singlet oxygen. The Crt,  $S_2$  state is very short lived, and hence it efficiently transfers energy to the Q-band absorption of B850, thus broadening the spectral sensitivity of the antenna system. Due to the very close intermolecular spacings, transfer occurs in only  $\sim 200 \text{ fs}$ , thus competing favorably with parasitic non-radiative processes.

Fluorescent resonant energy transfer plays a central role in this complex antenna network that has been optimized by evolution to ensure rapid and highly efficient energy harvesting in plants and microbial organisms. The foundations to our understanding of energy transfer laid by Förster nearly 70 years ago has opened many new fields in the biological and physical sciences.

### 3.8.2 Energy transfer in the contact zone: Dexter transfer by electron exchange

When the excited donor is in physical contact with an acceptor molecule, the electron from the donor can be directly transferred to the acceptor simultaneously with the transfer of an electron between their ground states. The exchange can occur between states of either the same or different spin

**Figure 3.97** (a) Singlet-singlet and (b) triplet-triplet electron exchange energy transfer in the contact zone.

multiplicities, as long as the excited and ground states do not change multiplicity during transfer. In Fig. 3.97 we illustrate that charge exchange, or Dexter transfer, occurs via

with obvious variations where the triplet and singlet states are interchanged. Reactions in Eq. 3.237a and b are analogous to those in Fig. 3.97a and b, respectively.

Exchange transfer was first considered by Dexter who extended the work of Förster to include both the exchange and Coulomb integrals in the analysis (Dexter, 1953). We can derive the transfer rate by starting with the initial (*i*) and final (*f*) state antisymmetrized donor-acceptor spinorbital wavefunctions as follows:

$$\Psi_i = \frac{1}{\sqrt{2}} [\Psi_{D^*}(\mathbf{r}_1, \mathbf{Q}_1; S_{1D^*}) \Psi_{A^0}(\mathbf{r}_2, \mathbf{Q}_2; S_{2A^0}) - \Psi_{D^*}(\mathbf{r}_2, \mathbf{Q}_2; S_{2D^*}) \Psi_{A^0}(\mathbf{r}_1, \mathbf{Q}_1; S_{1A^0})] \quad (3.238)$$

and

$$\Psi_f = \frac{1}{\sqrt{2}} [\Psi_{D^0}(\mathbf{r}_1, \mathbf{Q}_1; S_{1D^0}) \Psi_{A^*}(\mathbf{r}_2, \mathbf{Q}_2; S_{2A^*}) - \Psi_{D^0}(\mathbf{r}_2, \mathbf{Q}_2; S_{2D^0}) \Psi_{A^*}(\mathbf{r}_1, \mathbf{Q}_1; S_{1A^*})]. \quad (3.239)$$

The coupling matrix element,  $M_{fi}$ , Eq. 3.220, is then:

$$M_{fi} = \frac{1}{2} \left[ \langle \Phi_{D^0}(\mathbf{r}_1, \mathbf{Q}_1) \Phi_{A^*}(\mathbf{r}_2, \mathbf{Q}_2) \times |H_{int}| \Phi_{D^*}(\mathbf{r}_1, \mathbf{Q}_1) \Phi_{A^0}(\mathbf{r}_2, \mathbf{Q}_2) \rangle \times \langle \sigma_{D^0}(S_{1D^0}) \sigma_{A^*}(S_{2A^*}) | \sigma_{D^*}(S_{1D^*}) \sigma_{A^0}(S_{2A^0}) \rangle - \langle \Phi_{D^0}(\mathbf{r}_1, \mathbf{Q}_1) \Phi_{A^*}(\mathbf{r}_2, \mathbf{Q}_2) | H_{int} | \Phi_{D^*}(\mathbf{r}_2, \mathbf{Q}_2) \Phi_{A^0}(\mathbf{r}_1, \mathbf{Q}_1) \rangle \times \langle \sigma_{D^0}(S_{2D^0}) \sigma_{A^*}(S_{1A^*}) | \sigma_{D^*}(S_{1D^*}) \sigma_{A^0}(S_{2A^0}) \rangle \right] \quad (3.240)$$

The first term is the Coulomb integral that couples the excited and ground states of the donor and acceptor pair. It is the same integral that leads to Förster transfer in the previous section. Since the spin eigenfunctions,  $\sigma$ , are orthogonal, the spin integral in the first term vanishes unless  $S_{1D^0} = S_{1D^*}$  and  $S_{2A^0} = S_{2A^*}$ ; that is the spin multiplicity on a given site must be conserved in a Coulomb-mediated interaction between the initial and final states. Thus, there can be no spin-flip between the initial and final states of either the donor or acceptor. Indeed, this is a condition of Förster transfer, as discussed in Section 3.8.1, except for situations where there is strong mixing between states of different multiplicities (e.g. in triplet-emitting metalorganic complexes).

The second term in Eq. 3.240 is the exchange integral: its magnitude depends on the spatial overlap of the wavefunctions,  $\Phi_D$  and  $\Phi_A$  between sites  $\mathbf{r}_1$  and  $\mathbf{r}_2$ . This integral is only significant when the donor and acceptor molecules are in close contact. The interaction is purely Coulombic, that is,

$$H_{int} = -q^2/4\pi\epsilon_0\epsilon_r|\mathbf{r}_1 - \mathbf{r}_2| = -q^2/4\pi\epsilon_0\epsilon_r R_{DA}. \quad (3.241)$$

In contrast to near-field interactions, the spin integral in the second term in Eq. 3.240 places no prohibition on spin-flip during transfer. That is, the integral is non-vanishing when  $S_{1A^*} = S_{1D^*}$  and  $S_{2D^0} = S_{2A^0}$ , where the spins are exchanged between molecular sites. Then, the spin of the excited acceptor is equal to the spin of the excited donor, and likewise the initial states of the donor and acceptor also have the same spin. These spins must therefore transfer simultaneously between donor and acceptor, as illustrated in Fig. 3.97.

Now that the transfer matrix element is defined, we once more use Fermi's Golden Rule along with the procedure used to calculate the Förster integral (e.g. Eq. 3.232) to obtain (Dexter, 1953)

$$k_{ET} = \frac{2\pi}{\hbar} \Gamma^2 \int f_D(\omega) \sigma_A(\omega) d\omega. \quad (3.242)$$

(Note: consistent with spectroscopic notation in Eq. 3.232,  $\sigma_A$  is the absorption cross section of the acceptor, as opposed to its spin wavefunctions.) Here,  $\Gamma^2$  is the overlap integral of the second term in Eq. 3.240 by summing  $|M_{fi}|^2$  over all final and initial states, weighted by the appropriate Boltzmann factors that account for the state occupancies. Also, the  $1/\omega^4$  dependence in the Förster integral is absent in the denominator of Eq. 3.242 as a result of the  $1/R_{DA}$  Coulomb interaction in the latter, in contrast to dipole-dipole coupling with its  $1/R_{DA}^3$  dependence in FRET. In the simplest

approximation, the wavefunctions of the initial and final states are hydrogenic, such that:

$$\Gamma^2 \propto \frac{q^2}{(4\pi\epsilon_0)^2 n_r R_{DA}^2} \exp(-2R_{DA}/L), \quad (3.243)$$

where  $L$  is the effective Bohr radius (or more accurately the distance of closest molecular spacing as determined by van der Waals forces, see Section 2.3.3) of the contacting molecules. The exponential is proportional to the probability for an electron on the donor to tunnel to a neighboring acceptor. Combining Eq. 3.242 and 3.243 results in the approximate expression for exchange transfer in the contact zone:

$$k_{ET} = K \frac{q^2}{8\pi\epsilon_0^2 \hbar n_r R_{DA}^2} \left\{ \int f_D(\omega) \sigma_A(\omega) d\omega \right\} \times \exp(-2R_{DA}/L) = \frac{K' J_\omega}{R_{DA}^2} \exp(-2R_{DA}/L). \quad (3.244)$$

Here,  $K$  and  $K'$  are numerical constants that account for the degeneracy of the donor and acceptor molecules, the quantum yield of the donor, and other quantum mechanical effects, and  $J_\omega$  is the spectral overlap integral given by the term in brackets. In contrast to the Förster process, Dexter transfer is a purely quantum mechanical phenomenon, which is clear from the appearance of  $\hbar$  in Eq. 3.244. Similar to FRET, we see that exchange transfer also depends on energetic resonance between the donor and acceptor states expressed by the non-vanishing overlap ( $J_\omega$ ) between their emission and absorption spectra, respectively. We further note that there is no dependence on the orientation factor,  $\kappa^2$ . In the spherical wavefunction approximation, there can be no preferred direction of transfer. In realistic molecular systems, however, the transfer occurs preferentially along directions of closest intermolecular contact. Hence, we expect that the exchange transfer will be dependent on the molecular shape, steric influences, crystal structure (and hence anisotropy), direction, and film morphology. Since the orbital overlap between molecules can be small, depending on whether the material is crystalline, polycrystalline or amorphous, and since the rate decreases exponentially with distance, we expect the maximum transfer distance to extend to only one or a few lattice constants from the donor molecule in almost all circumstances.

The rate of exchange is comparable to the tunneling time, which for transfer between nearest neighbors is  $k_{ET} \sim 10^{10} - 10^{11} \text{ s}^{-1}$ . We will show in Section 3.9 that both FRET and exchange interactions play a crucial role in exciton diffusion in molecular solids. Whereas

FRET is the prevalent means for energy migration in fluorescent (singlet) systems, exchange processes dominate for triplets. There are exceptions to this situation when highly emissive phosphorescent molecules are involved.

### 3.8.3 Radiative energy transfer

Radiative, or trivial, energy transfer is a long range process whereby the excited donor radiates a photon of energy  $\hbar\omega$  that is subsequently absorbed by the acceptor after travelling a distance,  $R_{DA}$ , through the medium (see Fig. 3.98). Radiative transfer occurs at distances  $>50 \text{ \AA}$  where neither exchange nor FRET are active. In this limit, the donor and acceptor are decoupled; hence there are no spin selection rules that govern the interaction although it is most likely to occur between a radiative donor (which can be a fluorescent or heavy metal containing phosphorescent molecule) and the singlet state of the acceptor. Note that  $T_n \leftarrow T_m$  ( $n > m \geq 1$ ) transitions are also possible in radiative transfer, although the acceptor must already be prepared in its excited triplet state,  $T_m$ , by, for example, strong optical pumping.

The two-step radiative transfer process follows

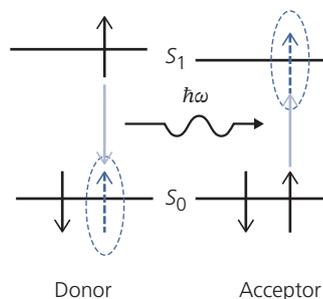

and

The isotropic Coulomb interaction between donor and acceptor is once again found via the same method as used for FRET, giving the transfer rate (Andrews and Juzeliūnas, 1992):

$$k_{ET} = \frac{9\kappa_{rad}^2 \Phi_D}{8\pi n_r \tau_D R_{DA}^2} \int f_D(\omega) \sigma_A(\omega) d\omega, \quad (3.246)$$

**Figure 3.98** Radiative energy transfer involving emission of a photon by the donor and absorption by the acceptor in the far field zone.

where

$$\kappa_{rad}^2 = (\cos\theta_{DA} - \cos\theta_D \cos\theta_A)^2 \quad (3.247)$$

is the orientation factor between donor and acceptor dipoles that accounts for the spherically symmetric radiation field of the Coulomb potential.

Equation 3.246 assumes that a particular donor-acceptor pair at distance  $R_{DA}$  is involved in the transfer. This transfer rate scales as  $1/R_{DA}^2$ , but the number of acceptor molecules contained in a volume centered on the donor increases as  $R_{DA}^3$ , which implies that the transfer rate is a linearly increasing function of the size of the sample. This, of course is not the case since the probability of finding a photon at distance  $R$  is decreased by the probability that it has been absorbed by acceptors in the intervening volume with radius  $<R$ . We resolve this problem by weighting the cross section by the absorption factor  $\exp(-\alpha_A(\omega)R_{DA})$ , using  $\alpha_A(\omega) = N_A \rho_{MA} \sigma_A(\omega) / M_{wA} = \sigma_A(\omega) \rho_{NA}$  where  $\rho_{NA}$  is the number density of acceptors. Thus Eq. 3.246 is corrected to yield

$$k_{ET} = \frac{9\kappa_{rad}^2 \Phi_D}{8\pi n_r \tau_D R_{DA}^2} \int f_D(\omega) \sigma_A(\omega) \exp(-\sigma_A(\omega) \rho_{NA} R_{DA}) d\omega. \quad (3.248)$$

The transfer efficiency ( $\eta_{rad}$ ) is obtained by calculating the total number of photons emitted to those absorbed in the sample:

$$\eta_{rad} = \frac{1}{\Phi_D} \int f_D(\omega) [1 - \exp(-\sigma_A(\omega) \rho_{NA} d)] d\omega, \quad (3.249)$$

which scales with the inverse exponential of the total sample thickness,  $d$ .

Trivial energy transfer typically occurs over distances  $1/a_A \sim 10\text{--}50$  nm. This lossy exothermic process implies only a few transfers typically occur before the photon escapes from the sample, and hence it does not significantly contribute to exciton migration.

The rate for radiative energy transfer is determined by the emission rate, that is,  $k_{ET} \sim k_r$  which is typically  $10^8\text{--}10^9$  s<sup>-1</sup> for fluorescence (cf. Fig. 3.84), although  $k_r$  for metalorganic triplet emitters are in the range

$10^7\text{--}10^5$  s<sup>-1</sup>. Hence, its presence is detected by measuring the increase in radiative lifetime in a sample compared to the natural lifetime of the emitting molecule, and the dependence of this lifetime on sample size.

To summarize, we note that the total energy transfer rate is the sum of all active processes. Therefore, the total rate is given by

$$k_{ET,tot} = k_{ET,exch} + k_{ET,FRET} + k_{ET,rad}. \quad (3.250)$$

The functional dependencies of each of these transfer rates are summarized in Table 3.7.

### 3.9 Exciton diffusion

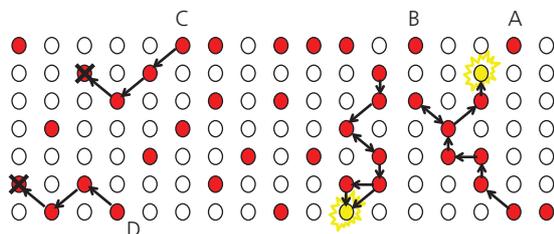

Multiple, sequential exciton transfers between individual molecules prior to recombination results in the migration of energy across macroscopic distances within the solid. The transfer from  $D^*$  to  $A^0$  by one of the several processes in Section 3.8 is the shortest step taken in what is ultimately a random walk of the exciton, resulting in transport of energy over a characteristic distance,  $L_D$ , known as the *exciton diffusion length*. After a *diffusion time*,  $\tau_D$ , the exciton recombines. We define the *diffusivity* (or *diffusion constant*) of the material as

$$D = \frac{L_D^2}{\tau_D}. \quad (3.251)$$

Whether or not diffusion over extended distances is efficient or even possible ultimately depends on the distance over which transfer must occur between donor and acceptor molecules. In homogeneous thin films, the donor is surrounded by acceptor molecules, and provided that the transfer process is not significantly exothermic (i.e. there is not a large energy loss in the  $D^* \rightarrow A^0$  process), transfer occurs by simple diffusion for a time,  $\tau_D = \tau_r$ , the natural recombination lifetime of the exciton. However, if the donor and acceptor molecules are mixed into a matrix consisting of *host* molecules that have an energy gap larger than that of the donor (or *guest*), then the diffusion length is shorter than predicted in Eq. 3.251 if the separation

**Table 3.7** Energy transfer processes and their properties

Process	Transfer rate	Distance dependence	Zone	Characteristic transfer distance
Exchange (Dexter)	$k_{ET,exch}$	$\frac{1}{R_{DA}^2} \exp(-2R_{DA}/L)$	Contact	<1 nm
FRET	$k_{ET,FRET}$	$\frac{1}{R_{DA}^6}$	Near	<10 nm
Radiative	$k_{ET,rad}$	$\frac{1}{R_{DA}^2} \exp(-\alpha_A R_{DA})$	Far	>100 nm

**Figure 3.99** Diffusion of an excited state via sequential transfer from donor to acceptor molecules (filled circles) in a wide energy gap host matrix (open circles). The wide energy gap of the matrix prevents energy transfer from the host. Paths A and B are examples of percolation, resulting in radiative recombination (starbursts) of the guest after a diffusion length,  $L_D$ , is reached. Paths C and D are too short for the exciton radiate before it non-radiatively recombines (denoted by X).

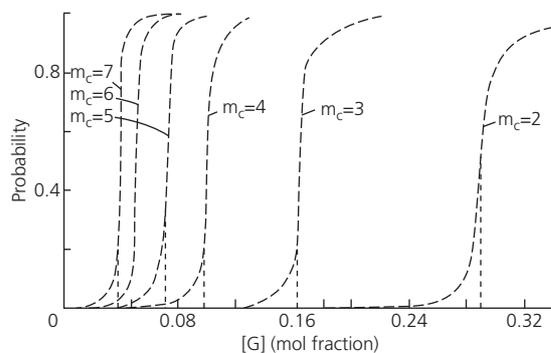

between guest molecules exceeds a critical distance beyond which the exciton has a greater probability for recombination than transfer. In this case,  $\tau_D < \tau_r$  for a guest concentration  $[G]$  that is less than a critical value,  $[G_c]$  that allows for an uninterrupted percolating path for diffusion, illustrated in Fig. 3.99. The dependence of diffusion length on  $[G]$  is known as *dynamic percolation* (Monberg and Kopelman, 1978).

The abrupt onset of percolation for triplets governed by Dexter exchange is determined using the exchange integral,  $K$ . Guest molecules that are separated, on average by  $m$  host molecules, gives (Klafter and Jortner, 1977)

$$K = \beta(\beta/\Delta)^m, \quad (3.252)$$

where  $\beta$  is the exchange integral between nearest neighbors, and  $\Delta$  is the energy difference between the guest and host excited states. The process whereby the excitation moves from  $D^*$  to  $A^0$  over a bridge of  $m$  intervening host molecules is known as *superexchange* (Lambert et al., 2002). When the distance between D and A is small, a narrow impurity band develops over which transport (of excitons or charges) can occur, and the exciton is thereby delocalized. Alternatively, the exciton can be trapped within a cluster. In this case, no band exists, and the solid is transformed from a conductor to an insulator. This transition is known as *Anderson localization* (Anderson, 1958), and is observed for a range of physical phenomena including spin waves, acoustic waves, and conductor-to-insulator transitions in disordered media.

For inhomogeneously broadened spectral lines arising from off-diagonal disorder (i.e. the interaction occurs between two spatially separated molecules), the uncertainty principle implies that the hopping time is  $\tau_{hop} = \hbar/K \leq \tau_r$ , where the latter inequality is required for dynamic percolation to occur. Then,

**Figure 3.100** Percolation probability for a square lattice of  $C_{10}H_8$  (guest) molecules doped in  $C_{10}D_8$  (host) as a function of guest concentration,  $[G]$ . The concentration at which the probability that the guest molecule is found in an "infinite cluster," that is, where the exciton diffusion length is not limited by its lifetime, corresponds to the intersection of the straight dashed lines with the  $[G]$  axis. From Monberg and Kopelman (1978).

Reprinted from Chem. Phys. Lett., 58, 492, Monberg, E. M. & Kopelman, R., Critical concentrations for triplet exciton tunneling in binary naphthalene crystals: The case for percolation copyright 1978 with permission from Elsevier

from Eq. 3.252, the number of steps leading to percolation, is

$$m_c = \ln(\beta\tau_r/\hbar)/\ln(\Delta/\beta). \quad (3.253)$$

The relationship between  $m_c$  and  $[G_c]$  depends on the dimensionality of the solid and its lattice structure.

Interestingly,  $m_c$  for triplets is typically larger than for singlets. For example, for the system consisting of guest  $C_{10}H_8$  molecules in a  $C_{10}D_8$  host, the singlet lifetime is  $\tau_r \approx 128$  ns vs. 2.6 s for triplets. For this system,  $\beta \approx 1-10$   $cm^{-1}$ , and  $\Delta \approx 30-100$   $cm^{-1}$ , leading to  $K \approx 10^{-2}-10^{-4}$   $cm^{-1}$  (Klafter and Jortner, 1977). Thus, for singlets,  $m_c \approx 2$ , whereas for triplets,  $m_c \approx 6$ . That is, owing to the significantly longer lifetime of triplets, the number of sites over which superexchange can occur is correspondingly larger, resulting in a concomitant reduction in  $[G_c]$ . The probability for the onset of percolation for a square lattice is shown in Fig. 3.100.

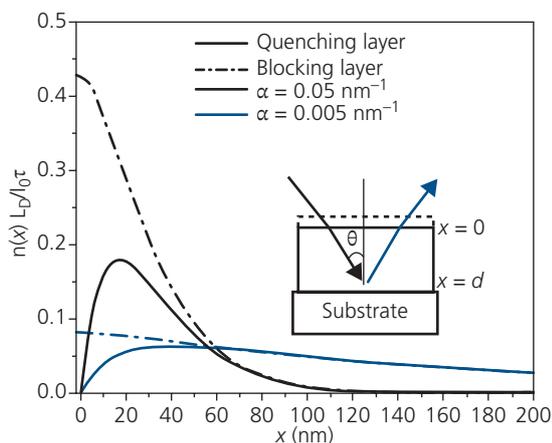

Diffusion is governed by *Fick's law*. Thus, the time-dependent exciton population density of  $n(\mathbf{r}, \lambda)$ , at position  $\mathbf{r}$  due to absorption at wavelength  $\lambda$  is given by the diffusion equation:

$$D\nabla^2 n(\mathbf{r}, \lambda, t) - \frac{n(\mathbf{r}, \lambda, t)}{\tau_D} + G(\mathbf{r}, \lambda, t) = \frac{\partial n(\mathbf{r}, \lambda, t)}{\partial t}, \quad (3.254)$$

where  $G(\mathbf{r}, \lambda, t)$  is the generation rate of excitons in the medium at time,  $t$ . In steady state, the right hand side of Eq. 3.254 is zero.

In Fig. 3.101 we show the solution to Eq. 3.254 for light propagating in the  $+x$  direction with intensity  $I_0$

and incident on the sample surface at  $x = 0$ . From the Beer–Lambert law,  $G(x, \lambda, t) = I_0(\lambda, t)\exp[-\alpha(\lambda)x]$  where  $\alpha(\lambda)$  is the absorption coefficient. The calculations are for two different values of  $\alpha$ , and for the boundary conditions of  $n(x = 0) = 0$ , or  $\frac{\partial n(0)}{\partial x} = 0$ , corresponding to complete, or zero quenching (known as blocking), respectively, of excitons at the surface. For blocking conditions, the exciton density is at a maximum at the light incident surface. Far from the surface, the exciton density simply follows the exponential decay of the generation rate profile. The diffusion length can be accurately measured in luminescent samples possessing one of these two boundary conditions by determining their luminescence intensity as a function of sample thickness. For example, if the excitons are quenched at the surface of incidence, the fluorescence intensity increases with film thickness since an increasing fraction of photons are absorbed deeper in the sample. By fitting the intensity from a series of samples of different thicknesses to the profiles calculated using Eq. 3.254, one can determine  $L_D$ . Alternatively, this same procedure can be applied to a single sample by measuring the luminescent intensity as a function of incident wavelength. Since absorption is wavelength dependent, this allows one to vary the *optical path length* within the sample for each wavelength chosen, from which a fit to the diffusion equation provides  $L_D$ .

**Figure 3.101** Exciton density from the surface at  $x = 0$  as a function of boundary conditions normalized to the incident intensity. The sample thickness is  $d \gg L_D = 15$  nm. The exciton density is given for two different values of absorption coefficient,  $\alpha$ . Here,  $I_0$  is the incident light intensity and  $\tau$  is the exciton lifetime. Inset: Geometry employed in measuring  $L_D$  (Lunt et al., 2009).

Reprinted from Lunt, R. R., Giebink, N. C., Belak, A. A., Benziger, J. B. & Forrest, S. R. 2009. Exciton Diffusion Lengths of Organic Semiconductor Thin Films Measured by Spectrally Resolved Photoluminescence Quenching. *J. Appl. Phys.*, 105, 053711 with the permission of AIP Publishing

A particularly accurate method for measuring  $L_D$  is *spectrally resolved photoluminescence quenching* (SR-PLQ), where the photoluminescence intensity as a function of wavelength is measured using a capping layer that either quenches or blocks excitons at the material surface (Lunt et al., 2009). The experimental configuration for the SR-PLQ measurement is shown in Fig. 3.101 (inset). A wavelength dependent exciton distribution,  $n(x)$ , in a thin film is generated using a monochromatic light source incident at  $x = 0$  through either a transparent exciton blocking or capping layer. For sufficiently thick films,  $n \rightarrow 0$  as  $x \rightarrow d$ , the film thickness. The exciton distribution is then described by Eq. 3.254 modified to take into account the angle of the incident illumination,  $\theta$ :

$$\frac{L_D^2}{\tau_r} \frac{\partial^2 n(x)}{\partial x^2} - \frac{n(x)}{\tau_r} + \frac{I_0 \alpha(\lambda)}{\cos \theta} \exp\left(-\frac{\alpha(\lambda)x}{\cos \theta}\right) = 0. \quad (3.255)$$

By comparing the luminescence intensity of the sample with a blocking ( $PL_B$ ) to that with a quenching layer ( $PL_Q$ ), the normalized quenching ratio,  $\eta$ , is obtained using:

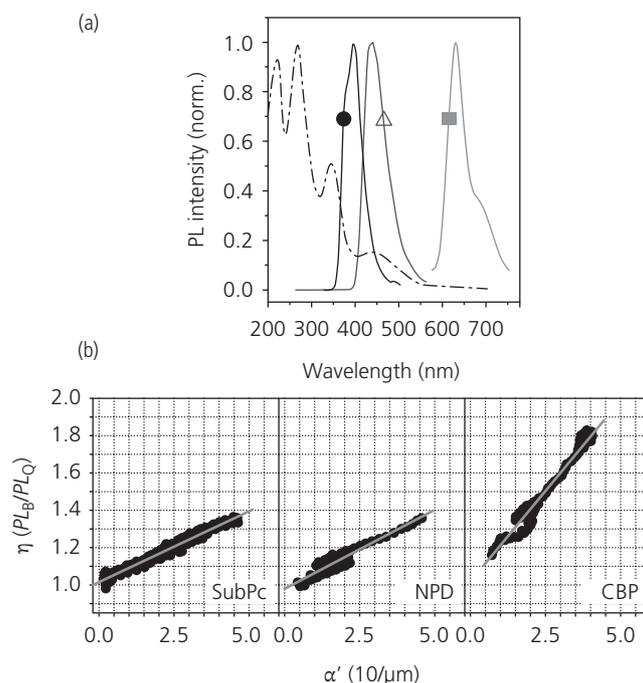

$$\eta(\alpha) = \frac{PL_B(\alpha)}{PL_Q(\alpha)} = \frac{\int_0^\infty n_B(x, \alpha) dx}{\int_0^\infty n_Q(x, \alpha) dx}. \quad (3.256)$$

Here,  $n_Q$  is the exciton density in the film with the quenching layer,  $n_B$  is the density in the film with the blocking layer. Solving for  $n(x)$  in Eqs. 3.255 and 3.256 we obtain

$$\eta(\alpha) = \frac{\alpha(\lambda)L_D}{\cos \theta} + 1 = \alpha'(\lambda)L_D + 1. \quad (3.257)$$

where  $\alpha'(\lambda)$  is the angle-corrected value of the absorption coefficient. Thus, the slope of a plot of  $PL_B/PL_Q$  versus  $\alpha'(\lambda)$  yields the diffusion length in situations where there is negligible energy transfer between the film and the quenching layer. The analysis becomes somewhat more complicated when the films are thin, there is energy transfer between the film and the quenching layer, or there is overlap between the spectra of the sample and the blocking or quenching layers. While these situations can and should be avoided, they can nevertheless be accounted for by optical modelling of the sample structures, and including independent measurements of transfer radii, etc. (Lunt et al., 2009, Bergemann and Forrest, 2011).

Example results from SR-PLQ analysis of three archetype fluorophores used in organic photovoltaics and OLEDs are shown in Fig. 3.102. Excitation spectra

**Figure 3.102** (a) Normalized photoluminescence spectra for CBP (filled circle), NPD (triangle), and SubPc (filled square). The normalized C<sub>60</sub> absorption spectrum (dotted black line) highlights the overlap with CBP and NPD emission that must be considered in the diffusion length analysis. (b) Quenching ratio versus absorption coefficient for the materials in (a). The quenching data were fit using Eq. 3.257 (lines). For NPD and CBP, effects of Förster energy transfer are included (Lunt et al., 2009).

were collected at a fixed wavelength located near a peak in the emission are shown in Fig. 3.102a. Quenching and blocking layers were selected for each material based on the alignments of the HOMO and LUMO energies to the material under test, as well as their absorption characteristics to minimize energy transfer-enhanced quenching. For these samples, C<sub>60</sub> was used for exciton quenching, and either BCP or NTCDA (in the case of CBP) for blocking.

The linear relationship between  $\eta$  and  $\alpha'$  is shown in Fig. 3.102b, suggesting the presence of only a single, resolvable diffusion length (and hence a single excitonic species) that is independent of exciting wavelength. Note that this method is limited to materials with strong oscillator strengths in both absorption and emission, and hence is insensitive to non-radiative triplet or weakly emissive charge transfer states.

Table 3.8 provides diffusion lengths and diffusion coefficients obtained for several archetype organic electronic materials by SR-PLQ (Lunt et al., 2009). From these data we make two observations. In most cases, the diffusion length in crystals is longer than in amorphous solids. This is not surprising, since excitons are easily trapped and quenched at grain boundaries or disordered regions where energy transfer to

neighboring molecular sites is impeded. The second, perhaps more surprising finding is that  $L_D$  for triplets in PtOEP is nearly equal to that of singlet excitons in fluorescent materials, even though the triplet lifetime is  $\tau_D \sim 20 \mu\text{s}$  compared to the more than three orders of magnitude smaller singlet lifetime. While the ratio of the triplet to singlet lifetime is not always this large, the triplet diffusion constant is nevertheless several orders of magnitude smaller than for singlets. This results from the lower energy of the triplet, resulting in self-trapping at molecular sites, thereby impeding transfer (by exchange interactions) to neighboring molecules.

Since diffusion over large distances occurs by a series of random transfer steps from donor to acceptor, the relationship between the acceptor capture rate and the diffusion constant can be obtained using the diffusion equation, Eq. 3.254. The analysis assumes that the probability for capture is unity when the exciton arrives within a distance,  $R_c$ , from the acceptor. Here,  $R_c$  is the *exciton capture radius*.

In the absence of other losses (e.g. recombination at defects or impurities), Eq. 3.254 simplifies to

$$D\nabla^2 n(\mathbf{r}, t) = \frac{\partial n(\mathbf{r}, t)}{\partial t}. \quad (3.258)$$

**Table 3.8** Measured diffusion lengths ( $L_D$ ) for singlet (S) and triplet (T) excitons of crystalline (C) and amorphous (A) films measured by spectrally resolved photoluminescence quenching

<sup>b</sup> Up/flat refers to whether the molecular plane is perpendicular/parallel to the substrate.

<sup>c</sup> Free = no layer.

The unity capture efficiency condition leads to the boundary condition:  $n(r, t)|_{r=R_c} = 0$ . Taking  $n(\mathbf{r}, 0) = n_0$ , in spherical coordinates, the solution to Eq. 3.258 is (Smoluchowski, 1915, Chandrasekhar, 1943)

$$n(r, t) = n_0 \left[ 1 - \frac{R_c}{r} + \frac{2R_c}{r\sqrt{\pi}} \int_0^{x_c} \exp(-x^2) dx \right], \quad (3.259)$$

where  $x_c = (r - R_c)/2\sqrt{Dt}$ . Then the capture rate is

$$k_c = \frac{dn_0}{dt} = 4\pi DR_c^2 \left( \frac{\partial n(r, t)}{\partial r} \right) \Big|_{r=R_c}, \quad (3.260)$$

which finally leads to

$$k_c = 4\pi DR_c \left( 1 + \frac{R_c}{\sqrt{\pi Dt}} \right) \approx 4\pi DR_c. \quad (3.261)$$

The second term in parentheses is rarely considered since the capture radius is  $R_c \leq 1$  nm (corresponding to the Förster radius or Dexter hopping distance) and  $D \sim 10^{-2}$  cm<sup>2</sup>/s (Lunt et al., 2009), with transfer times  $t = 1/k_{ET}$ ,  $t_{ot} \leq 1$  ns (cf. Eq. 3.250). Hence, the second term is  $\lesssim 0.01$ , and can usually be neglected.

Assuming that the donor sits at the corner of a cube of side  $a$ , then for a hop in time,  $\tau_{TH}$ , to any neighboring site, we obtain

$$D = \frac{L_D^2}{\tau} = \frac{a^2}{\tau_H} \theta, \quad (3.262)$$

where

$$\theta^{-1} = \left[ \frac{6}{\sqrt{1}} + \frac{12}{\sqrt{2}} + \frac{8}{\sqrt{3}} + \dots \right]. \quad (3.263)$$

Here, hops to the 6 nearest neighbors, 12 second nearest neighbors, and so on are summed.

If the hopping process is via FRET, then  $k_{FRET} \sim 1/\tau_H$ , and assuming that nearest neighbor transfers are the most likely due to the  $1/R^6$  dependence, then

$$\frac{\tau}{\tau_H} = \left( \frac{R_{DA}}{a} \right)^6. \quad (3.264)$$

Using this and Eq. 3.262, we obtain a relationship between the diffusion length and the Förster radius:

$$L_{D,FRET} = \frac{1}{\sqrt{6}} \frac{R_{DA}^3}{a^2}. \quad (3.265)$$

If the transfer is via exchange interactions (see Eq. 3.244), similar arguments yield:

$$L_{D,exch} = \sqrt{\frac{\tau K' J_\lambda}{6}} \exp(-a/L), \quad (3.266)$$

where we recall that  $L$  is the effective orbital radius of the initial and final electronic states. Comparison of Eqs. 3.265 and 3.266 show a clear distinction between the dependence of the diffusion length on concentration,  $C$  (and hence the mean separation between donor and acceptor molecules,  $a$ ). In FRET, the diffusion length scales as  $C^{2/3}$ , whereas for exchange, the dependence is exponential.

In addition to its dependence on the efficiency of energy transfer between molecules, exciton diffusion also depends on crystalline morphology. As the number of grain boundaries increases, the potential for trapping within the grains increases. The dependence of  $L_D$  on crystallinity has been shown for a series of PTCDA films grown on KBr substrates, where the substrate temperature during growth was varied to achieve morphologies ranging from amorphous (with

a mean grain size of  $\bar{\Sigma} = 0 \pm 5$  nm at  $T_{sub} = 77$  K using vacuum thermal evaporation) to nearly single crystalline (with  $\bar{\Sigma} = 440$  nm at  $T_{sub} = 440$  K using organic vapor phase deposition) (Lunt et al., 2010). Micrographs of three representative films with differing PTCDA grain sizes are shown in Fig. 3.103.

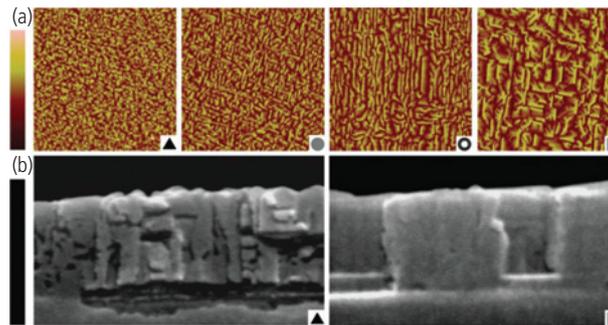

Following the treatment that leads to Eq. 3.265, a fit in Fig. 3.104 to the dependence of  $L_D$  determined by SR-PLQ on  $\bar{\Sigma}$  clearly shows that energy transfer is via FRET. We also find that the fluorescence yield in Fig. 3.104a increases with  $L_D$  as expected, since excitons are non-radiatively quenched at the grain boundaries. Indeed, the quenching is extremely efficient: excitons are  $10^4$  times more likely to be quenched at grain boundaries in PTCDA than from other structural irregularities such as point defects or vacancies.

Interestingly, the maximum diffusion length of 25 nm is achieved only for films whose grain size is  $\bar{\Sigma} = 400$  nm, or nearly 20 times larger. This results

since excitons are optically generated across the grain under uniform illumination across macroscopic sample areas. Excitons generated near a quenching boundary have a greater probability of diffusing to that boundary, and hence their mean diffusion length will be less than excitons generated in the grain center. Boundary effects become negligible only when the grain diameter is much larger than  $L_D$ . The solid line in Fig. 3.104b is a fit to the Förster transfer theory of Eq. 3.265, taking the increase in quantum yield into account for this analysis (Lunt et al., 2010). A transfer radius of  $R_{DA} = 2.8 \pm 0.2$  nm is inferred from these data.

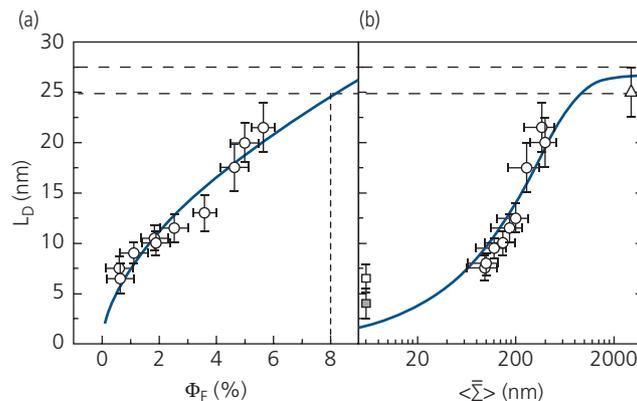

### 3.10 Exciton recombination and annihilation

Thus far we have considered the diffusion of a single exciton. However, it is never the case that only one excited state exists in a solid. Since the states can

**Figure 3.103** (a) Atomic force microscope (AFM) images of 350 nm thick PTCDA films grown under various conditions to control crystal domain diameters. The image widths and heights are 5  $\mu$ m and 50 nm, respectively. (b) Cross-sectional scanning electron microscope (SEM) images of the PTCDA films (left and right SEM images correspond to the left- and right-most AFM images, respectively). The scale bar on the left corresponds to 500 nm. The symbols correspond to different substrate temperatures used during growth: 440 K ( $\square$ ), 430 K ( $\circ$ ), 420 K ( $\bullet$ ), and 295 K ( $\blacktriangle$ ) (Lunt et al., 2010).

migrate, as the excitation density increases, their opportunities for encountering each other or a charge correspondingly increase. These exciton–exciton and exciton–charge (i.e. polaron) encounters often lead to annihilation of one or more of the excitons. That is, the energy of an exciton on one molecule is delivered to an exciton on its neighbor. This is an alternative energy transfer mechanism that results in briefly promoting the neighboring exciton to a high energy state from which it quickly relaxes, while returning the original molecule to its ground state.

This type of interaction is known as exciton annihilation and can occur by one of several routes: singlet–triplet (STA), singlet–polaron (SPA), singlet–singlet (SSA), triplet–triplet annihilation that produces singlets and triplets (TTA-S and TTA-T, respectively), and triplet–polaron annihilation (TPA). Their shared characteristic is that one excited state is the product of a collision between two initial states. Several of the most important reactions and their associated rates (shown above the arrows) are listed here:

The energetics of these several properties are provided in the Jablonski diagrams in Fig. 3.105. Note that TTA can result in either a singlet (Eq. 3.267d) or a triplet (Eq. 3.267e). Here,  $P$  denotes a polaron of either charge polarity, and the superscript,  $n$ , denotes an excited state higher than the lowest,  $n = 1$  electronic manifold. Also, TTA-S constitutes *triplet fusion*. This process occurs when two  $T_1$  triplets, each with half of the energy of the  $S_1$  state, collide to form a singlet. Similarly, a singlet may split into two triplets, each with half of the singlet energy in the complementary process of *singlet fission* (Smith and Michl, 2010). Both fusion and fission are potentially useful in photogeneration of charge in organic photovoltaics and emission in OLEDs. This subject will be discussed further in Chapters 6 and 7.

Since annihilation events involve the encounter of *two* particles, the capture radius is double that for a

**Figure 3.105** Various annihilation processes whereby an exciton in molecule **1** encounters an exciton (top) or polaron (bottom) in molecule **2**. This subsequently de-excites **1** (downward arrow) while promoting **2** into a higher, spin-symmetry-allowed upper state (upward arrow to  $S_n$ ,  $T_n$ , or  $P_n$ ). This excitation rapidly relaxes back to its first excited state ( $S_1$ ,  $T_1$ , or  $P_0$ ) by a combination of internal conversion and vibronic relaxation.

single excited state encountering a trap. For example, the relationship between the rate of TTA and the diffusion constant becomes (cf. Eq. 3.261) (Chandrasekhar, 1943)

$$k_{TTA} = 8\pi DR_c, \quad (3.268)$$

with analogous expressions for the other bimolecular processes.

Cataloging the various transition processes is helpful in writing the time-dependent dynamical expressions for the exciton populations that undergo bimolecular reactions. For example, in an optically and/or electrically pumped film of thickness  $d$ , and current density  $j$ , the triplet  $T$  and singlet  $S$  population densities are expressed by a pair of coupled equations:

$$\frac{dS}{dt} = G_S - k_S S - \frac{1}{2} k_{SSA} S^2 - k_{STA} S T - k_{SPA} S P + k_{TTA-S} T^2, \quad (3.269)$$

$$\frac{dT}{dt} = G_T - k_T T - 2k_{TTA-S} T^2 - \frac{1}{2} k_{TTA-T} T^2 - k_{TPA} T P, \quad (3.270)$$

where all variables are functions of  $(r, \lambda, j, t)$ , as appropriate. If generation occurs by current injection, then  $G_{T,S}(j) = \chi_{T,S} \eta_j j / qd$ , where  $\chi_{T,S}$  is the triplet or singlet generation ratio due to encounters of charges with uncorrelated spins. Also,  $\eta_j$  is the

electron-to-exciton conversion ratio, that is, it is the quantum efficiency for exciton generation. The factor of two in Eq. 3.270 results from the loss of two triplets to produce one singlet. Similarly the factors of  $\frac{1}{2}$  in both expressions arise since two excitons collide to result in a single exciton of the same spin multiplicity.

It has been shown that the singlet/triplet generation ratio via current injection is determined by random statistics. Thus, unless samples are specifically prepared to have a particular singlet/triplet ratio via, for example, the application of a magnetic field, then  $\chi_S = \frac{1}{4}$  for singlets and  $\chi_T = \frac{3}{4}$  for triplets (Baldo et al., 1999). Generally, under optical pumping,  $G_T = 0$  due to the spin forbidden  $T_1 \leftarrow S_0$  transition.

Equations 3.269 and 3.270 represent simple enumerations of exciton sources and sinks indicated by either a + or – sign, respectively, that accompanies each term. Note that the annihilation terms have a square dependence on density (e.g. SSA has a  $S^2$ , TTA has a  $T^2$ , and SPA has a  $SP$  dependence, respectively) since the reaction requires the encounter of two excitons. As expected, therefore, these bimolecular interactions dominate as the excitation density (either via  $j$  or  $I_0$ ) increases.

An example where several of the processes in Eq. 3.267 are active is in fluorescent OLEDs. For exciton generation via electrical pumping, we have  $G = j/qd$ , where  $d$  is the thickness of the optically pumped emission layer. Triplet density dynamics in this case are determined by the processes of triplet non-radiative decay, TTA, and TPA, as described in Eqs. 3.267d–f. Assuming *Langevin recombination* which is due to the random collisions between polarons to form an exciton (see Section 4.5.4), we obtain

$$\frac{dP}{dt} = \frac{j(t)}{qd} - k_{rec}P^2, \quad (3.271)$$

where  $k_{rec}$  is the Langevin recombination rate given by (Langevin, 1903)

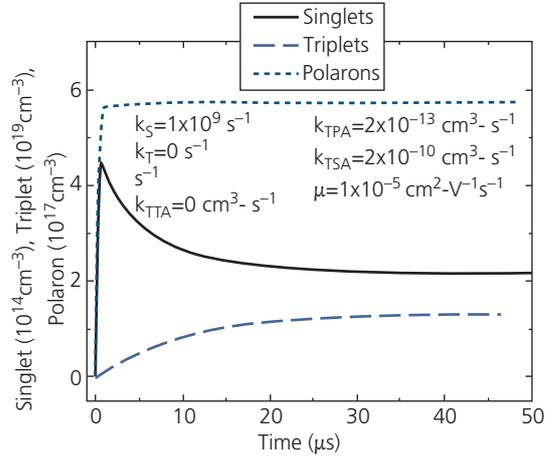

$$k_{rec} = \frac{q}{\epsilon_r \epsilon_0} (\mu_h + \mu_e). \quad (3.272)$$

Here,  $\mu_h$  and  $\mu_e$  are the mobilities of holes and electrons in the layer, respectively. Then, from Eqs. 3.270 and 3.272, the triplet concentration is given by

$$\frac{dT}{dt} = \frac{3}{4}k_{rec}P^2 - k_T T - \frac{5}{4}k_{TTA}T^2 - k_{TPA}TP. \quad (3.273)$$

Here,  $3/4$  and  $5/4$  arise from the spin statistics of triplet generation and TTA, respectively.

The singlet density dynamics are a function of the singlet decay rate as well as STA. Furthermore, in the

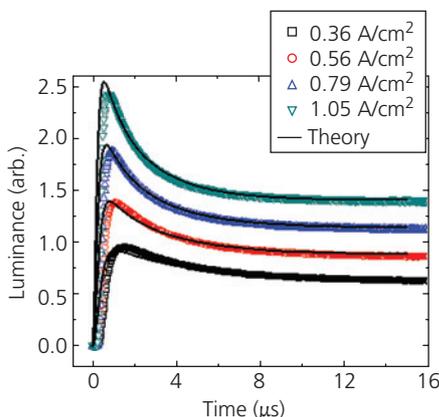

**Figure 3.106** Simulated density dynamics at a current density  $j = 0.8$  A/cm<sup>2</sup> in a film of thickness  $d = 25$  nm, using the parameters listed (Zhang et al., 2010).

presence of STA, the corresponding rate equation for singlets follows:

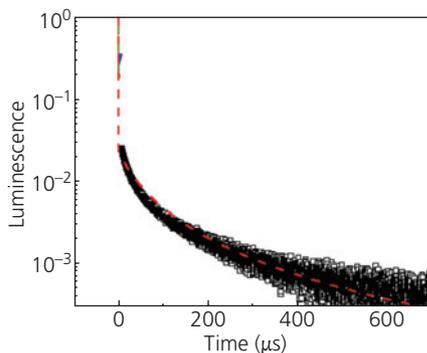

$$\frac{dS}{dt} = \frac{1}{4}k_{rec}P^2 - k_S S + \frac{1}{4}k_{TTA}T^2 - k_{STA}ST. \quad (3.274)$$

The simulated singlet, triplet, and polaron densities under a constant current density of  $j = 0.8$  A/cm<sup>2</sup> using Eqs. 3.271, 3.273, and 3.274 are shown in Fig. 3.106 using parameters typical of many doped fluorescent systems (Zhang et al., 2010). Initially, the singlet density is large since it only depends on the natural singlet decay rate of  $k_S$ . With time, the triplet density increases, leading to an increase in STA that results in a decrease in  $S$  that is proportional to the increase in  $T$ . Since the light output in fluorescent OLEDs is proportional to the singlet density, that is, the luminance intensity follows  $L(t) = k_S S$ , STA leads to a decrease in luminance to a steady state value as the relative concentrations of singlets and triplets approaches equilibrium.

The theory of singlet and triplet dynamics accurately models the transient decay of luminescent intensity in many fluorescent and phosphorescent systems. For example, the luminescence transients in DCM:Alq<sub>3</sub>-based OLEDs are shown as a function of current pulse amplitude in Fig. 3.107. The rise time ( $<1$   $\mu$ s) is significantly shorter than the decay time ( $\sim 20$   $\mu$ s); the former determined by the transit time of electrons and holes into the light emitting layer, while the latter is determined by the triplet decay rate. Fits to the data according to the transient analysis for STA are indicated by solid lines. In this model, only the electron mobility is important since it is considerably higher than holes in the Alq<sub>3</sub> host (Tang et al., 1989, Shi and

**Figure 3.107** Transient electroluminescence of 3% DCM:Alq<sub>3</sub> OLEDs in response to 100 μs current pulses of different amplitudes. The steady state current densities are indicated. Solid lines are the fits to the STA model, with  $k_{STA} = 1.9 \times 10^{-10} \text{ cm}^3/\text{s}$  (Zhang et al., 2010).

**Figure 3.108** Delayed fluorescence from DCM:Alq<sub>3</sub> based OLEDs after the turn-off of the current pulse at  $t = 0$  s. The steady state luminance is normalized at the pulse onset. The fit (dashed line) gives a TTA rate of  $k_{TTA} = (2.2 \pm 0.2) \times 10^{-15} \text{ cm}^3/\text{s}$  (Zhang et al., 2010).

Tang, 2002). Furthermore, non-radiative triplet decay and TTA are neglected since these processes are small compared to TPA during the device turn-on. The predicted  $L(t)$  slightly deviates from the experiment during the initial 1 μs due to neglect of the charge transit time in Eq. 3.271. Nevertheless, it is clear that the simple theory of Eqs. 3.271–3.274 provides an accurate description of the singlet dynamics in electrically pumped organic thin films.

Since TTA results in the generation of singlets, transient solutions to Eq. 3.274 predict that singlet emission should persist long after the singlet natural lifetime,  $1/k_S$ , due to their formation of singlets following the annihilation of very long lived triplets. The delayed, persistent fluorescence (analogous to TADF

in Section 3.7.5) following the DCM:Alq<sub>3</sub> device turn-off is observed in Fig. 3.108. A fit (dashed line) to the clearly non-exponential transient due to the  $T^2$  dependence of TTA gives  $k_{TT} = 2.2 \times 10^{-15} \text{ cm}^3/\text{s}$  (Zhang et al., 2010).

Annihilation processes are particularly important in films where triplet emission dominates over singlets, such as in phosphorescent OLEDs (Baldo and Forrest, 2000). The decay rate of triplets ( $k_T$ ) in metal-organic compounds such as Ir(ppy)<sub>3</sub> is typically three orders smaller than  $k_S$ , indicating that even at modest triplet densities, annihilation depends on the triplet concentration as  $\sim T^2$  for TTA, or  $TP$  for TPA. Hence, optimizing the optical properties of triplet emitting devices requires a complete understanding of the dynamics of the various annihilation, energy transfer and transport processes.

### 3.11 Summing up

The most distinctive properties of organic semiconductors that separates them from the wide diversity of conventional inorganic semiconductors, are their optical characteristics. We have seen that these characteristics are due to the low dielectric constants and lack of chemical bonds between molecules within organic solids. This gives rise to excited states where the electron and hole form an exciton whose binding energy is  $\sim 0.5$  eV which is considerably larger than the thermal energy of 26 meV at room temperature. The stable excitonic states transport energy over relatively long distances, in marked contrast to conventional semiconductors whose much larger dielectric constants result in unstable excitons with binding energies more than an order of magnitude smaller. As a result, excitons dominate the optical properties of organics, that are, consequently, referred to as excitonic materials. In this chapter, we have developed the theory of excitonic materials, starting from individual bonds between atoms forming a molecule, to the properties of the entire molecule, and concluding with the properties of organic solids comprised of large ensembles of molecules or molecular mixtures.

Starting with the eigenstates of the individual orbitals, we have found that the electronic and vibronic (i.e. phonon) structure of molecules can be conveniently described by the linear combination of electronic wavefunctions of the individual atoms of which they are comprised. Once placed in close proximity, the molecular energy levels split to form bands, with the band structure dispersion implying that the excited states are mobile. The mobility is enabled via electrostatic and quantum mechanical coupling between

adjacent molecules due to exchange interactions, to distances of a micron or more via radiative transfer. Further, the Pauli Exclusion Principle gives rise to energy level splitting, revealing a plethora of optical phenomena within solid mixtures. The spin multiplicities (e.g. singlet vs. triplet) of the excited states also play a defining role in organic materials, another clear departure from inorganic semiconductors whose band-like nature tends to obscure these effects.

Ultimately, we observe this rich variety of optical characteristics via the spectroscopic properties of the individual molecules as well as in their collective properties in the solid state. These processes are conveniently quantified in terms of transition rates that are determined using one simple framework of time dependent perturbation theory: Fermi's Golden Rule. Of course we recognize that this framework can be accurately applied to phenomena that only slightly perturb the unexcited system, which is not always the case in excitonic systems.

Unlike conventional semiconductors, the properties of individual molecules are apparent even for molecules bound together in the solid state. This property provides insights as to how the properties of individual units of a solid can lead to the characteristics of the whole. Many of the classic works and advances in our understanding of organics have been developed to describe their fundamental optical processes, including energy transfer and migration. This has formed the foundational knowledge, and application of organics to optoelectronics. It has revealed the properties of diverse systems found in electronics, optics, biology, and so on.

Beyond just providing a laboratory in which one can test the fundamental theories of solid state physics and physical chemistry, the unique optical properties of organics have been extensively exploited in high performance devices such as OLEDs, OPVs, and transistors. Before we can move on to consider these practical applications, we must first lay the foundations for understanding the electrical properties of organics; the subject of the following chapter. Indeed, the transport of energy via exciton diffusion is due among other things, to electron exchange between adjacent molecules. This is similar to the processes of electron and hole transport in the solid.

## Problems

1. If each of the individual spatial and spin wavefunctions in Eqs. 3.2 and 3.3 are normalized, show that the combined wavefunctions are also normalized.
2. Assuming a  $\text{H}_2^+$  molecule with both hydrogen atoms in the 1s states, calculate
  - (a) the Coulomb integral,
  - (b) the resonance integral,
  - (c) the energy eigenvalues of the molecular ground state.
3. For the Morse potential in Eq. 3.16, show that
  - (a) the difference between adjacent energy levels is given by Eq. 3.19,
  - (b) the quantum number of the highest bound state is given by Eq. 3.20.
4. Butadiene is the simple organic molecule  $\text{C}_4\text{H}_6$  shown in the figure below:

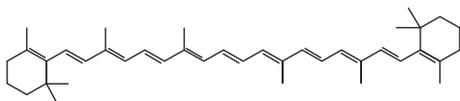

- (a) Construct the  $4 \times 4$  secular determinant and solve for the energy eigenvalues of the  $\pi$ -orbitals of this molecule. The energies can be written in terms of the on- and off-diagonal matrix elements,  $a$ ,  $b$ , respectively.
- (b) Find the four molecular orbitals corresponding to these energies (which is the same as finding the coefficients,  $c_{ni}$ , in  $|\pi\rangle = \sum_{i=1}^4 c_{ni}\phi_i$ , where  $\phi_i$  is the orbital of the  $i$ th carbon atom, and  $n = 1, 2, 3, 4$ ). You may use a computer to calculate the  $c$  values.
- (c) Repeat (a) for cyclobutadiene shown below.

5. One approximation to calculating orbitals that is reasonably accurate for fused ring systems is the perimeter free electron orbital model. One shortcoming of this model is that the energies diverge as the square of the orbital angular momentum quantum number,  $l$  (see Eq. 3.43). A modification of the theory is to use the basis set (Eq. 3.42):

$$\psi_l(\theta) = \frac{1}{\sqrt{2\pi N}} \sum_{k=0}^{N-1} \exp(ik\theta) \phi_k(\theta).$$

- (a) Using this basis set, show that the energy eigenvalues are given by:  $E_l = \alpha + 2\beta \cos(2\pi l/M)$  where  $M$  is the number of atoms,  $\alpha$  is an energy offset and  $\beta$  corresponds to the off-diagonal energy terms.
- (b) Plot  $E_l$  along with that of a simple harmonic oscillator, the solution to the simple PFEQ theory, and a Morse potential. Here, assume that  $l$  is the vibronic quantum number. Which do you think gives the best approximation to actual molecular systems?
6. An alternative and quite simple model of polyenes is the free electron orbital model. In this model, we can take a simple linear molecule such as  $\beta$ -carotene (Scheme P3.6) as a one dimensional quantum mechanical "potential box" consisting of a chain of  $N$  conjugated carbon atoms, with bond length  $R_0$ , as forming a box of length  $L = (N - 1)R_0$ .  $\beta$ -Carotene is a molecule that gives carrots their color.

Scheme P3.6

- (a) Calculate the length of the box.
- (b) Find the wavefunctions and their energies for an electron along the chain.
- (c) Suppose that the electrons enter the states in pairs. Thus, the lowest  $1/2N$  states are occupied. Estimate the wavelength of the lowest energy transition.
- (d) Calculate the expected color of carrots. Is this consistent with your idea of what a carrot should look like?
7. In Section 3.6.1 we showed that the Franck–Condon factor could be written as  $FC_{n,m} = Z^m e^{-Z}/m!$ , where  $Z$  is the Huang–Rhys factor. We want to derive this expression in this problem. We start by assuming that the nuclear positions for 0–0 transitions are expressed by:

$$|0\rangle = \left(\frac{\sigma}{\pi}\right)^{1/4} \exp\left(-\sigma(R - R_0)^2/2\right).$$

- (a) Using this wavefunction, show that the nuclear overlap between the ground and excited state is given by:  $Z_{0-0} = \langle 0|0\rangle = \exp\left(-\sigma(R_0 - R_e)^2/4\right)$  where the excited state equilibrium position is  $R_e$ .
- (b) Similarly, if the first vibronic is given by  $|1\rangle = \sqrt{2\sigma}(R - R_e)|0\rangle$ , calculate  $Z_{0-1}$ .

(c) Continuing along this vein, assuming only the  $|0\rangle$  state is occupied, show that the series of higher orders of  $Z$  results in  $FC_{n,m} = Z^m e^{-Z}/m!$

8. Using the relativistic correction that leads to Thomas precession:

(a) Show that the magnetic field for a moving electron in an electric field  $\mathbf{F}$  at velocity  $\mathbf{v}$  in the laboratory reference frame is given by  $\mathbf{B} = -\frac{\mathbf{v} \times \mathbf{F}}{2c^2}$ , which leads to the spin–orbit Hamiltonian.

(b)  $H_{SO} = -\frac{q}{2m_e^2 c^2} \frac{1}{r} \frac{dV}{dr} \mathbf{l} \cdot \mathbf{s}$ , where  $\mathbf{l}$  and  $\mathbf{s}$  are the orbital and spin angular momentum operators, respectively.

(c) Using this Hamiltonian in the central field of an electron, show for hydrogenic states that the spin–orbit coupling energy is given by:

$$E_{SO} = \frac{Z^4 q^2}{8\pi\epsilon_0 a_0^3 m_e^2 c^2 n^3 l(l + \frac{1}{2})(l + 1)} (\mathbf{l} \cdot \mathbf{s}),$$

where  $Z$  is the atomic number of the atom,  $a_0$  is the Bohr radius,  $n$  is the principal, and  $l$  the orbital angular momentum quantum numbers.

(d) Using the result in (c), plot  $E_{SO}$  vs.  $Z$  for the following atoms commonly found in organic compounds: C, Al, Si, Cu, Ag, Os, Ir, Pt, Pb.

9. The Slater–Condon selection rules introduced in the context of spin–orbit coupling state that two  $n$ -electron spinorbitals can differ by only a single spinorbital when they are coupled via a one-electron Hamiltonian,  $H_{12}$ . Consider two wavefunctions,  $\Phi_1, \Phi_2$  that differ by only a single spinorbital,  $\phi_m \leftrightarrow \phi_p$ . That is,  $\Phi_{1,2} = \sqrt{n!} |\phi_1 \dots \phi_m \dots \phi_p \dots \phi_n|$ . From this, derive the Slater–Condon selection rule:

$$\begin{aligned} \langle \Phi_1 | H_{12} | \Phi_2 \rangle &= \langle \phi_m(1) | H_{12} | \phi_p(1) \rangle \\ &+ \sum_i \left\{ \langle \phi_m(1) \phi_p(1) | H_{12} | \phi_i(2) \phi_i(2) \rangle \right. \\ &\left. - \langle \phi_m(1) \phi_i(1) | H_{12} | \phi_i(2) \phi_p(2) \rangle \right\} \end{aligned}$$

Here, (1) and (2) are the spinorbital coordinates of electrons, 1, 2.

10. Show that the average number of cycles between the  $S_1$  and  $T_1$  states leading to thermally assisted delayed fluorescence is given by:  $\bar{n} = \frac{\Phi_T \Phi_S}{1 - \Phi_T \Phi_S}$ , where  $\Phi_T$  and  $\Phi_S$  are the quantum yields for triplet and singlet emission, respectively.

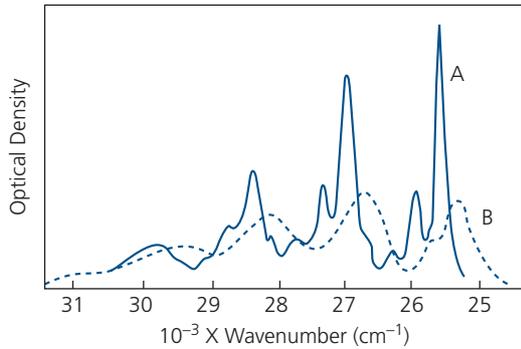

11. Derive the Förster overlap integrals

$$M_D(\nu) = \frac{3 \epsilon_0 \hbar c^3 \Phi_D f_D(\nu)}{4 \pi m_r \tau_D \nu^3} \quad \text{and} \quad L_A(\nu) = \frac{6 \epsilon_0 a_A(\nu) n_r \hbar c M_{wA}}{N_A \nu \rho_{MA}}$$

in Eqs. 3.225a and b using the Einstein  $A$  and  $B$  coefficients for emission and absorption.

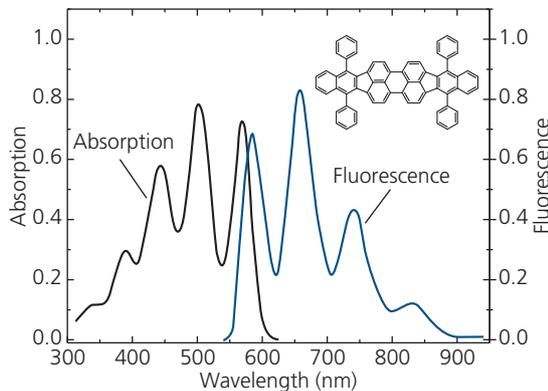

12. Figure P3.12 shows the room temperature absorption spectra of a molecule in solution. In one case the solution is quite dilute, in the other it is more concentrated.

(a) Which of the two spectra (labeled A and B) corresponds to the less and which to the more dilute solution? Explain your reasoning based on the shapes and broadness of the two spectra.

**Figure P3.12** Spectra for a molecule in two solutions.

- (b) Relabel the horizontal axis in terms of energy units. Label each of the peaks using spectroscopic notation in terms of the transition between vibronic levels.
  - (c) Calculate the parabolic energy state that accurately describes spectrum A. That is, specify the spring constant and the energy gap from the ground to excited states.
  - (d) What physical vibrational mode (e.g. a C–H bending mode) do you think these energies correspond to? Is there more than one such mode present?
13. Figure P3.13 shows the room temperature absorption spectrum of the planar aromatic hydrocarbon molecule shown. Also shown is the room temperature emission (i.e. photoluminescence) spectrum of the molecule.

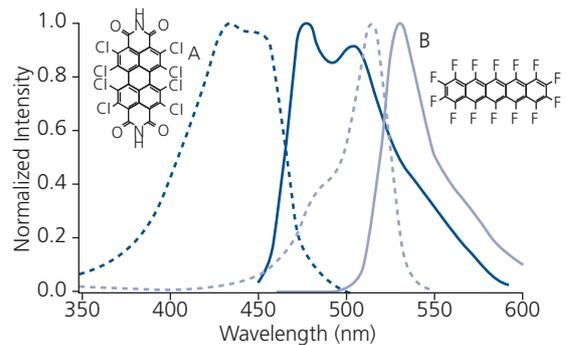

**Figure P3.13** Spectra of the molecule in the inset.

- (a) What is the chemical formula of the molecule?
- (b) Label all of the peaks in the spectrum using standard spectroscopic notation to identify both electronic and vibronic transitions. Also, identify the zero-crossing energy,  $E_{00}$ . Note that the absorption peaks at  $<400$  nm are in a different electronic manifold than at  $>450$  nm. What is the spin multiplicity of the states, and why?
- (c) What is the binding energy of the lowest exciton state assuming  $\epsilon_r = 3.2$ ?
- (d) Plot the vibronic energy vs. quantum number  $n_1$  for the lowest electronic state (subscript 0) as taken from the absorption spectrum. On this plot, fit the progression to

a simple harmonic oscillator and a Morse potential:  $V(r) = V_0(1 - \exp[-\alpha(r - r_0)])^2$  Which fits better?

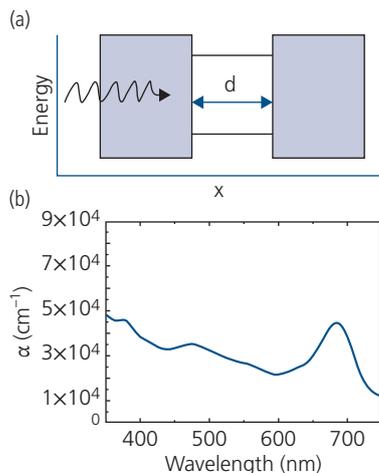

- (e) What is the maximum bound quantum state energy for the Morse potential that provides the best fit to the spectra? What is the force constant?
14. In Fig. P3.14, we show the fluorescence and absorption spectra of two different molecular species (data for molecule **A** in blue, for **B**, in grey). The normalized absorption spectra have maximum absorptions of  $a_A = 5 \times 10^5 \text{ cm}^{-1}$  and  $a_B = 2 \times 10^5 \text{ cm}^{-1}$ . Furthermore, the mass density of **A** is  $1.5 \text{ gm/cm}^3$  and index of refraction of 1.8 in the visible, and for **B** these values are  $2.1 \text{ gm/cm}^3$  and 2.0. Both have quantum yields approaching 100%.

**Figure P3.14** Spectra and molecules of a FRET transfer system.

- (a) If these molecules are blended, which will act as the most effective donor, and which as an acceptor?
  - (b) Calculate the Förster transfer radius,  $R_{DA}$ , for this donor/acceptor system.
  - (c) Given that the natural lifetime of **A** is 3 ns, and that of **B** is 6 ns, plot the FRET transfer rate,  $k_{ET}$  vs. doping concentration of **B** in **A**.
  - (d) What is the diffusion coefficient and diffusion length of each of these molecules when they are undoped in a thin film.
15. Show that a solution to the exciton diffusion equation gives an exciton capture rate of  $k_c = 4\pi DR_c \left(1 + \frac{R_c}{\sqrt{\pi Dt}}\right)$ .
16. Assume that a thin squaraine film of thickness  $d$  is bounded by two, 3 eV energy gap layers to form the structure in Fig. P3.16a. Light is incident normal to the plane of the film from the left and has intensity,  $I_0$ . The recombination lifetime in the film is  $\tau_D = 6$  ns, and the absorbance spectrum is given by Fig. P.16b.
- (a) For  $d = 100$  nm, calculate the steady state exciton density distribution across the entire structure for incident wavelengths of  $\lambda = 400, 550, 675$  nm.
  - (b) The incident illumination at  $\lambda = 675$  nm is switched off at  $t = 0$ . Plot the time evolution of the exciton density distribution across the layer for the next 50 ns.
  - (c) For the conditions in (b), if the quantum yield of the material is  $\Phi_{PL} = 60\%$ , calculate the time evolution of the luminescence intensity emitted in the forward

direction (i.e. toward the right) if the index of refraction of the outermost layer is  $n_r = 1.5$ , and that of the material under investigation is 1.7.

**Figure P3.16** (a) Energy diagram for Problem 16. (b) Absorption spectrum of the material between the barriers of thickness  $d$ .

17. In a fluorescent OLED, excitons are generated by injecting current,  $j$  into an emission region of thickness,  $d$ . Then, the singlets (density  $S$ ) and triplets (density  $T$ ) can undergo many different paths to recombination. In this problem we will only consider triplet–triplet annihilation and singlet–triplet annihilation, and radiation.

- Write down the various singlet and triplet reactions that can occur in this device and label the appropriate rate constants.
- Write down the coupled rate equations for singlets and triplets. Assume that in the active region of the device that all electrons and holes combine to form excitons (i.e. charge balance is unity), and that singlet/triplet formation follows their statistical ratio.
- Solve the coupled equations in (b) for the singlet population vs. time ( $S(t)$ ).
- Calculate the internal quantum efficiency of the device (defined as the ratio of photons emitted to the number of charges injected) as a function of  $j$  from 0.01 to 100 A/cm<sup>2</sup>, assuming that 20% of the triplets that annihilate form singlets, for the parameters shown in the table below:

Parameter	Value	Units
Singlet lifetime	5	ns
Triplet lifetime	60	$\mu$ s
TTA rate	$10^{-13}$	$\text{cm}^{-3} \text{s}^{-1}$
STA rate	$10^{-10}$	$\text{cm}^{-3} \text{s}^{-1}$

- Calculate the electroluminescence turn-on transient (assuming a step function current pulse) over the first 100  $\mu$ s at  $j = 0.01, 1, \text{ and } 100 \text{ A/cm}^2$ .

# Charge transport in organic semiconductors

---

*“When talking about semiconductors, if you can’t draw a band diagram then you don’t know what you’re talking about.”*

**Kroemer’s Lemma, Herbert Kroemer, ca. 1990.**

It is a small step from the optical to the electronic. Indeed, we have seen that all of the optical properties in organic materials emerge from elementary transitions of electrons from one energy state to the next. But electrons and holes, stripped of their binding from each other, contribute to the conductivity of solids. Indeed, it was the conduction of electrons in molecular anthracene that first opened the door to the field of organic electronics. In this chapter, we consider the origin of conductivity in organic semiconductors. We will find that it differs in many ways from inorganic semiconductors. The purely electrostatic and relatively weak van der Waals bonds result in electronic energies in the solid state that are quite similar to that of the individual molecules. Hence, the well-developed band structure that characterizes inorganic semiconductors is absent. But without even narrow bands, the electron mass becomes infinite and there can be no conductivity. That, of course, is the opposite of what we observe.

The links between energy levels, bands and conductivity can be understood in terms of tight binding theory. But the lack of significant energy bandwidths leads to low mobility hopping transport of electrons and holes from molecule to molecule, in contrast to high mobilities due to transport of delocalized charge in bands in inorganics. In fact, charge transport can be incoherent, or dispersive where a single mobility is absent in many solids. The physics of charge transfer between molecules is analogous to exciton transfer, and needs to be considered before we can address the source of the low charge mobility.

Ultimately, the distinguishing characteristics of organic conductivity once again result from the lack of intermolecular chemical bonds. This, in turn leads to structural disorder, an intrinsic property leading to the low charge mobility (and short exciton diffusion lengths) in the solid. Even in the presence of disorder, nearly ideal junctions between dissimilar materials can be formed, resulting in strong rectification of charge across these interfaces.

We start our discussion on junctions with metal–organic contacts. When the injection barrier is considerably larger than the thermal energy, a Schottky diode is formed. When it is small, Ohmic contacts ensue. We continue on to develop ideal diode equations for organic (i.e. excitonic) heterojunctions analogous to treatments used to describe conduction across p-n junctions by Shockley in 1949. However, even though we can derive such an ideal diode equation, it does not mean that all (or even any) excitonic junctions follow such a formulation. Non-idealities such as recombination, lattice defects, disorder, and impurities are always present, and ultimately cause a deviation of behavior from that predicted based only on the most fundamental, irreducible physical processes. We will discuss both the ideal and non-ideal case of conductivity of organic heterojunctions; structures that form the basis of all organic photonic devices such as OLEDs and OPVs.

Beyond purely organic heterojunctions, there is a wealth of exciting and important phenomena found in organic/inorganic semiconductor heterojunctions. Such heterojunctions have long been utilized in such devices as dye sensitized solar cells and colloidal quantum dot emitters and detectors, yet the dynamics of charge transport across such hybrid interfaces has not, until recently, been understood from a first-principles perspective. In the latter part of

this chapter, we will develop the theory of transport across hybrid heterojunctions, and find that it bears striking similarities to both inorganic and fully organic junctions.

We note that photoconductivity forms a bridge between the optical and electronic properties of materials. We leave a full discussion of this topic to Chapter 7, where photodetectors of all varieties are considered.

Earlier, we considered the structural and optical properties of organics. With this chapter on charge transport, we complete our discussion of the fundamental physics of organic semiconductor materials. This leads us directly to their applications that will be the subject of Part II.

## 4.1 From energy levels to energy bands

Due to the intimate bonding between atoms arranged periodically in a crystal, inorganic semiconductors are characterized by a band gap separating broad and continuous conduction and valence bands, themselves characterized by a large *electronic density of states* (DOS). This is illustrated schematically on the left of Fig. 4.1. The bandwidths are typically comparable to the band gap,  $E_G$ , that is, on the order of a few electron volts. The peak densities of states depend on the atomic composition of the lattice, and the lattice symmetry itself. The peak DOS ranges from  $10^{17}$ – $10^{20}$   $\text{eV}^{-1} \text{cm}^{-3}$ , which is significantly less than the atomic density ( $\sim 10^{22} \text{cm}^{-3}$ ). The comparatively low DOS and broad energy bands arise from sharing the outermost bonds between neighboring atoms.

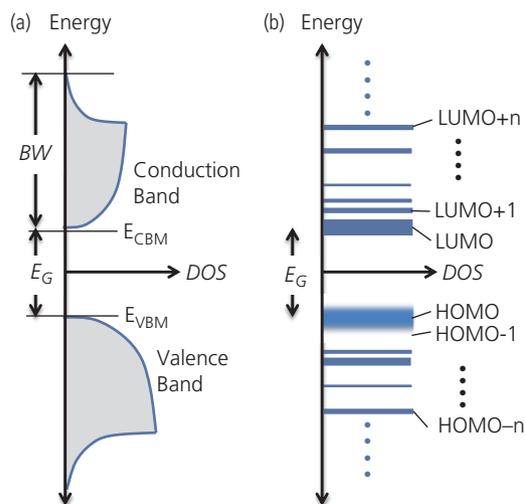

Organic semiconductors do not have broad bands. In this context, it is more precise to call  $E_G$  simply an energy gap rather than a band gap. Then  $E_G$  is the difference between the highest occupied molecular orbital (HOMO) for the most energetic bound valence states, and the lowest unoccupied MO (LUMO) for the least energetic conduction states. Thus, the HOMO is analogous, but not identical to the *valence band maximum* (VBM) of an inorganic semiconductor, and similarly the LUMO is analogous to the *conduction band minimum* (CBM).

In organic materials the DOS is no longer continuous with a wide bandwidth (BW). Near the HOMO and LUMO, the energy levels from nearest-neighbor molecules overlap to a limited degree, leading to a narrow band. Such is the case with tightly packed molecules typified by PTCDA, rubrene, and pentacene, where BW energies approaching a few hundred meV are found. Yet far more frequently, the spacing between molecules, or their mutual orientation leads to only a limited degree of orbital overlap, such that BWs of only a few tens of meV are more the rule than the exception. In the former case, an *incipient energy band* is formed, giving the molecular solid some characteristics of a band-like inorganic semiconductor while preserving many of the properties of a more conventional

organic semiconductor. As temperature is lowered, however, molecular motion is frozen, resulting in increased time-averaged orbital overlap between neighbors that can give a molecular solid with even a small BW at room temperature, band-like characteristics.

The orbitals deeper than the frontier HOMO and LUMO are denoted by HOMO- $i$  and LUMO+ $i$  in Fig. 4.1 (here,  $i$  is the integer orbital index relative to the frontier orbital). These remain comparatively independent in the solid, that is, there is even less overlap with similar levels from adjacent molecules since these orbitals are more tightly bound to the molecular core. Hence, their lack of participation in the electronic properties of the solid further limits the total BW compared to an inorganic material.

Since the character of the frontier orbitals is not significantly changed in the solid, there is approximately one state per molecule: an enormous increase

**Figure 4.1** Characteristic energy level schemes of (a) an inorganic semiconductor with band gap energy,  $E_G$ , and (b) an organic semiconductor with an energy gap of approximately the same magnitude. Here, DOS is the density of electronic states, HOMO is the highest occupied molecular orbital, LUMO is the lowest unoccupied MO, and BW is the width of the corresponding band. The “fuzzy” depiction of the HOMO suggests that in the case of a tightly packed organic crystal, an incipient, or narrow band-like character emerges.

compared with inorganics. One consequence of this is that the optical absorption coefficient of direct band gap inorganic semiconductors is  $\lesssim 10^4 \text{ cm}^{-1}$ , but can be as much as 100 times higher for organics, making even the thinnest films extremely strong absorbers.

The differences in energy level and band structure compared to inorganics play a determining role in their conductive properties. Whereas an electron in an inorganic semiconductor moves relatively effortlessly around the solid within its energy band due to the intimately shared orbitals of adjacent atoms, the reduced intermolecular coupling of molecules results in polarization. The electron therefore self-traps on each molecule as it moves under the influence of an electric field. Given its ability to polarize the surrounding medium, the “free” electron is called a *polaron*, and rather than experiencing band-like transport, it *hops* from molecule to molecule. The immediate consequence is a dramatically reduced mobility: organics have maximum charge mobilities no more than  $1\text{--}5 \text{ cm}^2/\text{V s}$ , whereas inorganic semiconductors have mobilities (and hence conductivities) that can exceed this by a factor to  $10^3\text{--}10^4$ . We will show that both the field and temperature dependence of the charge mobilities in these two systems can also be vastly different, leading to distinctive conductive character.

We begin our discussion by showing how conduction levels emerge when individual molecules are assembled into a solid. While the lack of chemical bonds between molecules allows them to preserve their individual character to some degree, we have shown in Chapter 3 that molecular assemblies have emergent properties of their own that give rise to energy (i.e. exciton) transport within the solid. These same collective effects also allow for charge transport with a semiconductor-like temperature dependence that was discovered for molecular violanthrone (Akamatu and Inokuchi, 1950).

#### 4.1.1 Tight binding method for calculating energy bands

A convenient means for calculating energy bands is the use of the *tight-binding approximation*. It is a somewhat limited method for calculating the very complex situation of molecules in solids, but it has the advantages of providing an intuitive formalism for appreciating the emergence of band-like character that leads to conduction in organic semiconductors.

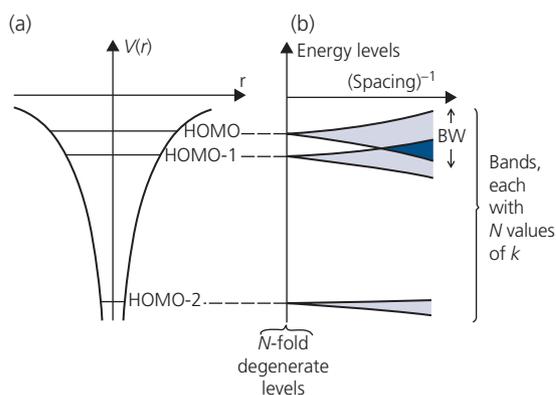

In Chapter 2 we found that bringing two H atoms into close proximity to form an  $\text{H}_2^+$  molecule results in a splitting of the  $1s$  state into a symmetric bonding, and an antisymmetric antibonding state whose energy difference increases with decreasing atomic separation. This splitting is a result of Coulomb repulsion

of the two valence electrons. When  $N$  atoms are brought into proximity in a lattice, the result is a splitting into  $N$  electronic levels. As is the case for a  $\text{H}_2^+$  molecule, the splitting increases as the lattice constant decreases, ultimately resulting in overlap of many adjacent levels to form a continuous band whose width scales with  $N$ .

In molecular systems, the situation is in many ways similar to that of atoms but with a significant difference; in covalently bonded solids, an electron is shared between all  $N$  atoms whereas in molecular systems the orbital overlap between molecules is comparatively small. Hence, the influence on the orbital energies of individual molecules separated by even a few lattice constants is small. When considering an assembly of  $N$  molecules in the solid, therefore, only those molecules within a limited neighborhood need to be considered, and this results in a concomitant reduction in the BW. As for atomic systems, when molecules are brought closer together, the Coulomb interaction between electrons in nearby orbitals increases, broadening the bands even further. Broadening continues until the molecules reach their equilibrium separation distance,  $R_0$ , when the attractive van der Waals force is balanced by the repulsive force of the inner shell electrons.

A schematic representation of the formation of bands as the intermolecular spacing decreases is provided in Fig. 4.2. As the spacing decreases, the BW increases until neighboring orbitals (e.g. HOMO and HOMO-1) begin to interact, resulting in further merging and broadening of the bands.

To calculate the perturbation of the electronic energy levels, we employ the tight binding approximation that has been widely applied to describe inorganic materials such as metals, and was first applied to organic semiconductors by LeBlanc (1961),

**Figure 4.2** Schematic illustration of band formation due to orbital overlap as the molecular spacing is decreased. (a) The orbitals of unperturbed molecules showing the single electron potential,  $V(r)$ . (b) Bands formed due to overlap of orbitals from  $N$  molecules.  $BW$  = electronic bandwidth of the HOMO which increases with decreased spacing.

and then extended by Katz et al. (1963). The important features of this method applied to molecular organic semiconductors are now described.

Each orbital level results in a band. For example, if there are six atoms forming the molecule, there are three resulting electronic states (with two spins per state). The bound orbitals are the HOMO, HOMO-1, and HOMO-2. In a crystal of  $N$  such molecules therefore, three valence bands emerge, one corresponding to each HOMO level. The conduction bands corresponding to the LUMO, LUMO+1, LUMO+2..., extending to the vacuum level, are also generated.

We calculate the BW and shape by assuming that the interaction energy between electrons on separate molecules is small compared to the orbital energies within an individual molecule. Furthermore, we neglect all interactions between electrons within an orbital; this is known as the *single-electron approximation*. Then, using  $H_{mol}$  for the Hamiltonian of a molecular orbital, the total Hamiltonian of the system is

$$H_{tot} = H_{mol} + H_{int}, \quad (4.1)$$

where  $H_{int}(\mathbf{r}) = U(\mathbf{r})$  is the interaction at lattice site,  $\mathbf{r}$ , and has the periodicity of the lattice, that is,

$$U(\mathbf{r} + \mathbf{R}) = U(\mathbf{r}), \quad (4.2)$$

where  $\mathbf{R}$  is the lattice translation vector (Section 2.2). The interaction,  $H_{int}(\mathbf{r})$ , is the perturbation when a molecule is placed into an infinite crystal, and should contain all of the symmetry properties of the lattice. Due to the potential having the same periodicity as the lattice, the *Bloch condition* imposes the same periodicity on the wavefunction, viz.

$$\psi_{\mathbf{k}}(\mathbf{r} + \mathbf{R}) = e^{i\mathbf{k}\cdot\mathbf{R}}\psi_{\mathbf{k}}(\mathbf{r}), \quad (4.3)$$

where  $\mathbf{k}$  is the electronic wavevector.

As in Chapter 3, the electronic wavefunction can be solved by the LCAO method, in which case we expand Eq. 4.3 using

$$\psi_{\mathbf{k}}(\mathbf{r}) = \sum_i^N c_{ki}\psi_n(\mathbf{r} - \mathbf{R}_i), \quad (4.4)$$

where the sum is over all  $N$  lattice points, and  $\psi_n(\mathbf{r} - \mathbf{R}_i)$  is the contribution from the molecule at  $\mathbf{R}_i$  and from the electron in its  $n$ th orbital. The basis functions,  $\psi_n(\mathbf{r})$ , are solutions to the individual (isolated) molecular eigenvalue equations,  $H_{mol}\psi_n(\mathbf{r}) = E_n\psi_n(\mathbf{r})$ . Thus, the lattice wavefunction contains the characteristics of the orbitals of the individual molecules although it must also be consistent with Bloch's theorem for a periodic lattice, as in Eq. 4.3. This requires that the coefficients have the property:

$c_{ki} = N^{-1/2}e^{-i\mathbf{k}\cdot\mathbf{R}_i}$ . We can test that this satisfies the condition for periodicity by translating  $\psi(\mathbf{r})$  through a lattice vector, viz.

$$\begin{aligned} \psi_{\mathbf{k}}(\mathbf{r} + \mathbf{R}) &= \frac{1}{\sqrt{N}} \sum_i^N e^{-i\mathbf{k}\cdot\mathbf{R}_i} \psi_n(\mathbf{r} - \mathbf{R}_i + \mathbf{R}) \\ &= \frac{1}{\sqrt{N}} e^{i\mathbf{k}\cdot\mathbf{R}} \sum_i^N e^{-i\mathbf{k}\cdot(\mathbf{R}_i - \mathbf{R})} \psi_n(\mathbf{r} - \mathbf{R}_i + \mathbf{R}). \end{aligned} \quad (4.5)$$

But  $\tilde{\mathbf{R}}_i = \mathbf{R} - \mathbf{R}_i$  is also a lattice translation vector. Thus,

$$\begin{aligned} \psi_{\mathbf{k}}(\mathbf{r} + \mathbf{R}) &= \frac{1}{\sqrt{N}} e^{i\mathbf{k}\cdot\mathbf{R}} \sum_i^N e^{i\mathbf{k}\cdot\tilde{\mathbf{R}}_i} \psi_n(\mathbf{r} - \tilde{\mathbf{R}}_i) \\ &= e^{i\mathbf{k}\cdot\mathbf{R}} \psi_{\mathbf{k}}(\mathbf{r}), \end{aligned} \quad (4.6)$$

as required by the Bloch boundary condition, Eq. 4.3.

When placed near its neighbors, these functions and the system energy are perturbed. Assuming that the perturbation is small, we write the new wavefunctions as linear combinations of the wavefunctions of the isolated molecules. We allow that the lattice basis can contain more than one molecule, in which case the number of molecules is  $M$ . Then we have

$$\phi(\mathbf{r}) = \sum_j^M a_j \psi_j(\mathbf{r}), \quad (4.7)$$

where, in keeping with only minor perturbations, the coefficients  $a_j$  are small. Then we can rewrite the total wavefunction as

$$\begin{aligned} \psi_{\mathbf{k}}(\mathbf{r}) &= \frac{1}{\sqrt{N}} \sum_i^N e^{i\mathbf{k}\cdot\mathbf{R}_i} \phi(\mathbf{r} - \mathbf{R}_i) \\ &= \frac{1}{\sqrt{N}} \sum_j^N e^{i\mathbf{k}\cdot\mathbf{R}_j} \sum_i^N a_j \psi_{j\mathbf{k}}(\mathbf{r} - \mathbf{R}_i). \end{aligned} \quad (4.8)$$

Using the Hamiltonian for the crystal in Eq. 4.1, we then arrive at

$$H_{tot}\psi_{\mathbf{k}}(\mathbf{r}) = (H_{mol} + H_{int}(\mathbf{r}))\psi_{\mathbf{k}}(\mathbf{r}) = E(\mathbf{k})\psi_{\mathbf{k}}(\mathbf{r}). \quad (4.9)$$

The energy eigenvalues are determined by multiplying Eq. 4.9 by the original, molecular wavefunctions,  $\psi_m(\mathbf{r})$ , which in bracket notation becomes

$$\begin{aligned} \langle \psi_m(\mathbf{r}) | H_{tot} | \psi_{\mathbf{k}}(\mathbf{r}) \rangle &= \langle \psi_m(\mathbf{r}) | (H_{mol} + H_{int}(\mathbf{r})) | \psi_{\mathbf{k}}(\mathbf{r}) \rangle \\ &= \langle \psi_m(\mathbf{r}) | E(\mathbf{k}) | \psi_{\mathbf{k}}(\mathbf{r}) \rangle. \end{aligned} \quad (4.10)$$

Now, the eigenvalues of the unperturbed molecular Hamiltonian,  $H_{mol}$ , are simply  $E_m$ , in which case we can rewrite Eq. 4.10 as

$$(E(\mathbf{k}) - E_m) \langle \psi_m(\mathbf{r}) | \psi_{\mathbf{k}}(\mathbf{r}) \rangle = \langle \psi_m(\mathbf{r}) | H_{int}(\mathbf{r}) | \psi_{\mathbf{k}}(\mathbf{r}) \rangle. \quad (4.11)$$

Substituting Eq. 4.8 into Eq. 4.11, and from the orthogonality of the wavefunctions, we require that  $n = m$ . Then Eq. 4.11 becomes

$$\begin{aligned} (E(\mathbf{k}) - E_m)a_m = & -(E(\mathbf{k}) - E_m) \\ & \times \sum_n^M \left[ \sum_{i \neq 0}^N \int \psi_m^*(\mathbf{r}) \psi_n(\mathbf{r} - \mathbf{R}_i) e^{i\mathbf{k} \cdot \mathbf{R}_i} d^3\mathbf{r} \right] a_n \\ & + \sum_n^M \left[ \int \psi_m^*(\mathbf{r}) H_{int}(\mathbf{r}) \psi_n(\mathbf{r}) \right] a_n \\ & + \sum_n^M \left[ \sum_{i \neq 0}^N \int \psi_m^*(\mathbf{r}) H_{int}(\mathbf{r}) \psi_n(\mathbf{r} - \mathbf{R}_i) e^{i\mathbf{k} \cdot \mathbf{R}_i} d^3\mathbf{r} \right] a_n \end{aligned} \quad (4.12)$$

Since we are assuming the collective effects of the crystal are small and the magnitude of the wavefunctions,  $\psi_n(\mathbf{r} - \mathbf{R}_i)$  must decrease rapidly with  $\mathbf{R}_i$ , only interactions between immediate neighbors (i.e.  $i \approx 1$ ) are included. Hence, terms on both sides of Eq. 4.12 must be small, which means that  $E(\mathbf{k}) \approx E_m$ . This is equivalent to saying that the HOMO energy leads to a broadening of the highest (i.e. valence) band, but it does not influence the energies of the HOMO-1, HOMO-2, etc. levels. Those orbitals themselves are also impacted as the molecules are brought into close proximity but, like the HOMO, are only broadened by other, similar HOMO- $i$  levels, forming the corresponding HOMO- $i$  bands. While the various terms in Eq. 4.12 are small, they are nevertheless finite. If they were not, then we revert to the case of non-interacting molecules, that is,  $E(\mathbf{k}) = E_m$ .

The first term on the right corresponds to contributions to the energy from all of the other molecules in the crystal, although as mentioned above,  $\psi_n(\mathbf{r} - \mathbf{R}_i)$  falls off rapidly with distance. The second and third terms are due to perturbations of the electronic potential due to intermolecular interactions which, in themselves, are assumed to be small. The smallest term in this expression is the last, which is the product of the interaction potential and the wavefunction at distances of one or more lattice constants from the origin. Of course, the interaction may be large far from the origin when  $\psi_n(\mathbf{r} - \mathbf{R}_i)$  is small, or vice versa.

In solving the Eq. 4.12, we must account for the degeneracy of a particular band. That is, if the band has  $s$ -like symmetry, then there is a single equation to be solved, resulting in a single energy band,  $E(\mathbf{k})$ . Likewise, a level with  $p$ -symmetry results in three such expressions (with three  $a_j$  values) that must be solved with a  $3 \times 3$  secular determinant (see Section 3.3). If the energies from two bands are

sufficiently close, or if they are broadened by interactions from nearby molecules such that they overlap with another energy level, then that energy level must also be included. For example, if the HOMO with  $s$ -symmetry interacts with the HOMO-1 with  $p$ -symmetry, then the energy  $E(\mathbf{k})$  of the new HOMO band is calculated via a  $4 \times 4$  secular determinant that considers the contribution from all of the interacting orbitals. Finally, spin must be taken into account if the states are not degenerate. In this case, the number of equations used to calculate the energy levels is doubled yet again.

As an example, we consider an  $s$ -symmetric HOMO level. Then Eq. 4.12 reduces to:

$$\begin{aligned} E(\mathbf{k}) - E_{HOMO} = & -(E(\mathbf{k}) - E_{HOMO}) \sum_{i \neq 0}^N \alpha(\mathbf{R}_i) e^{i\mathbf{k} \cdot \mathbf{R}_i} \\ & + \beta - \sum_{i \neq 0}^N J(\mathbf{R}_i) e^{i\mathbf{k} \cdot \mathbf{R}_i}, \end{aligned} \quad (4.13)$$

which leads to

$$E(\mathbf{k}) - E_{HOMO} = \frac{\beta + \sum_{i \neq 0}^N J(\mathbf{R}_i) e^{i\mathbf{k} \cdot \mathbf{R}_i}}{1 + \sum_{i \neq 0}^N \alpha(\mathbf{R}_i) e^{i\mathbf{k} \cdot \mathbf{R}_i}} \quad (4.14)$$

with

$$\begin{aligned} \alpha(\mathbf{R}_i) = & \int \psi_{HOMO}^*(\mathbf{r}) \psi_n(\mathbf{r} - \mathbf{R}_i) d^3\mathbf{r} \\ = & \langle \psi_{HOMO}(\mathbf{r}) | \psi_n(\mathbf{r} - \mathbf{R}_i) \rangle, \end{aligned} \quad (4.15)$$

$$\beta = \langle \psi_{HOMO}(\mathbf{r}) | H_{int}(\mathbf{r}) | \psi_n(\mathbf{r}) \rangle, \quad (4.16)$$

and

$$J(\mathbf{R}_i) = -\langle \psi_{HOMO}(\mathbf{r}) | H_{int}(\mathbf{r}) | \psi_n(\mathbf{r} - \mathbf{R}_i) \rangle. \quad (4.17)$$

Hence, we have a band centered on the HOMO, but whose width and dependence on  $\mathbf{k}$  are determined by the right hand side of Eq. 4.14. Clearly, a larger overlap between adjacent molecules, and a stronger interaction between molecules leads to an increase in the overlap integral,  $J(\mathbf{R}_i)$ . Since the overlap ultimately is small in the tight binding approximation,  $\alpha(\mathbf{R}_i) \ll 1$ , and hence the properties of the HOMO-band are almost entirely determined by the magnitude and functional form of  $J(\mathbf{R}_i)$ .

Recall from our treatment of excited states in crystals that the energy is perturbed from that of the monomer by nearest neighbor interactions that are modeled as Bloch wavefunctions of the same form

as Eq. 4.3 (c.f. Eq. 3.138). Hence, our solution to Eq. 4.14 should also reduce to the dispersion relation of Eq. 3.139, where (LeBlanc, 1961)

$$E(\mathbf{k}) \sim \Delta E' + 2E_W \cos(\mathbf{k} \cdot \mathbf{R}). \quad (4.18)$$

Here,  $\Delta E'$  is the sum of the ground ( $E_{HOMO}$ ) and excited monomer energies, and  $BW = 4E_W$  is the BW resulting from intermolecular interactions.

It is straightforward to show that Eq. 4.14 follows this familiar form by its solution for the simple case of a face centered cubic (fcc) structure with lattice constant,  $a$ . The molecule at  $(0,0,0)$  has 12 nearest neighbors at positions  $(\pm\frac{1}{2}, \pm\frac{1}{2}, 0)$ ,  $(\pm\frac{1}{2}, 0, \pm\frac{1}{2})$ ,  $(0, \pm\frac{1}{2}, \pm\frac{1}{2})$ . We consider only the  $s$ -states in this example. The inversion symmetry of the cubic lattice implies that the interaction Hamiltonian follows  $H_{int}(\mathbf{R}) = H_{int}(-\mathbf{R})$ . Similarly, the wavefunctions have even parity, i.e.  $\psi(\mathbf{r}) = \psi(-\mathbf{r})$ , from which it follows that the coefficients  $\alpha$ ,  $\beta$ , and  $J$  have this same symmetry. Finally, as noted above,  $\alpha(\mathbf{R}_i)$  is neglected. This leads to a simplified expression for  $E(\mathbf{k})$  in Eq. 4.14 with the sum over only the 12 nearest neighbors:

$$E(\mathbf{k}) - E_{HOMO} = -\beta - \sum_{i=1}^{12} J(\mathbf{R}_i) \cos(\mathbf{k} \cdot \mathbf{R}_i) \quad (4.19)$$

with

$$J(\mathbf{R}_i) = J_{fcc} = - \left\langle \psi_{HOMO}(\mathbf{r}) | H_{int}(\mathbf{r}) | \psi \left( x - \frac{a}{2}, y - \frac{a}{2}, z \right) \right\rangle. \quad (4.20)$$

The expression for  $J(\mathbf{R}_i)$  is identical for all 12 nearest neighbors ( $J_{fcc}$ ); here we have written it explicitly only for the molecule at  $(\frac{1}{2}, \frac{1}{2}, 0)$ . The sum in Eq. 4.19 for the fcc lattice is, therefore:

$$E(\mathbf{k}) - E_{HOMO} = -\beta - 4J_{fcc} \left\{ \cos\left(\frac{1}{2}k_x a\right) \cos\left(\frac{1}{2}k_y a\right) + \cos\left(\frac{1}{2}k_x a\right) \cos\left(\frac{1}{2}k_z a\right) + \cos\left(\frac{1}{2}k_y a\right) \cos\left(\frac{1}{2}k_z a\right) \right\} \quad (4.21)$$

The bands have a cosine shape that is symmetric along all three orthogonal axes, and the BW is determined by  $J_{fcc}$  that is a function of both the overlap of nearest neighbor orbitals and the strength of the interaction potential. In fact,  $H_{int}$  can take any functional form that decays rapidly from the origin. One such function is shown in Fig. 4.3 and follows

$$U(\mathbf{r}) = -U_0 \frac{\sin^2(\pi \mathbf{R}/a)}{(\mathbf{R}/a)^2}. \quad (4.22)$$

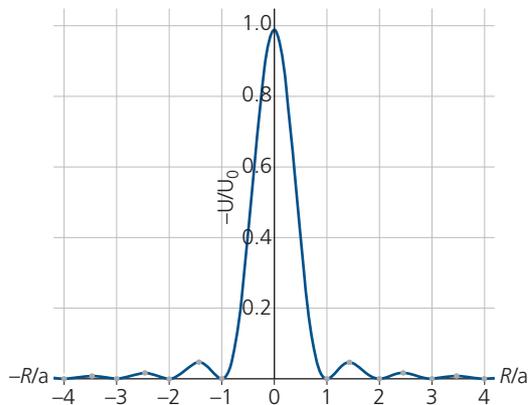

Figure 4.3 Perturbation potential used in tight binding calculation.

One important feature of this potential is that it is large when the wavefunction (and hence the overlap) is small, and vice versa. That is, the potential is maximum midway between the molecular sites (i.e. at  $R/a = (2i + 1)/2$ ,  $i = 1, 2, \dots$ , except the self energy at  $i = 0$ ), and the wavefunction is small at the origin where the  $s$ -state probability density vanishes. This ensures that  $J_{fcc}$  remains a small perturbation of the original crystal structure, as required.

In the limit of  $ka = 1$  (i.e. for electrons near the center of the Brillouin zone), then  $\cos(\frac{1}{2}ka) \approx 1 - \frac{1}{2}(\frac{1}{2}ka)^2$  and Eq. 4.21 becomes

$$E(\mathbf{k}) - E_{HOMO} \approx -\beta - 12J_{fcc} + J_{fcc}(ka)^2. \quad (4.23)$$

Now the slope of the dispersion,  $\partial E(\mathbf{k})/\partial \mathbf{k}$ , toward the zone edge (e.g. along the (100) direction where  $k_x a = 2\pi$ ) is

$$\partial E(k_x)/\partial k_x = 4J_{fcc} a \sin\left(\frac{1}{2}k_x a\right) \rightarrow 0. \quad (4.24)$$

Hence, the band has a cosine shape with width of  $BW = 8 J_{fcc}$  in the (100) direction, and centered on the energy  $E_{HOMO} - \beta$ . Along other directions, the slope may not vanish at the band edge, and the width can differ from  $8 J_{fcc}$ .

Figure 4.2 implies that the deeper orbitals are not as broadened by proximity with neighboring molecules as are the shallower (frontier) orbitals. This is a consequence of the stronger localization of electrons in the deeper valence states of the molecule, and hence their considerably reduced overlap with similar states in adjacent molecules. We also note that the calculation of conduction (i.e. LUMO) states by the tight binding approximation is far less reliable given the considerable spatial extent of such states compared with bound valence states. Hence, the inclusion of

only nearest neighbor interactions becomes dubious as the conduction electron energy increases toward the vacuum level. Finally, the tight binding model as described thus far has only imposed a Coulomb interaction in  $H_{int}$ . However, as we have seen in Chapter 3, many other interactions can play a role, including dipole interactions, and spin-orbit interactions that strongly impact the orbitals of molecules containing heavy metals. As an example, the inclusion of first order singlet–triplet coupling requires solution of a  $4 \times 4$  secular determinant.

A consequence of band structure is that the electron has a velocity given by

$$\mathbf{v}(\mathbf{k}) = \frac{1}{\hbar} \frac{\partial E(\mathbf{k})}{\partial \mathbf{k}}, \quad (4.25)$$

and a corresponding effective mass tensor along crystal directions  $i, j$  of

$$\vec{m}_{ij}(\mathbf{k}) = \left[ \frac{1}{\hbar^2} \frac{\partial^2 E(\mathbf{k})}{\partial k_i \partial k_j} \right]^{-1} = \left[ \frac{1}{\hbar} \frac{\partial v_j(k_i)}{\partial k_i} \right]^{-1}. \quad (4.26)$$

For an isotropic medium, the effective mass reduces to

$$m^* = \left[ \frac{1}{\hbar^2} \frac{\partial^2 E(\mathbf{k})}{\partial k^2} \right]^{-1} = \left[ \frac{1}{\hbar} \frac{\partial v(\mathbf{k})}{\partial k} \right]^{-1}. \quad (4.27)$$

Holes have negative effective masses, but otherwise are determined by the same expressions as Eqs. 4.25–4.27.

The existence of the bands, no matter how narrow, ultimately allows electrons and holes to move from molecule to molecule within the solid. Since bands do not exist in dilute solutions of non-interacting molecules, we conclude that the conductivity of the material depends entirely on the magnitude of the orbital overlap integral,  $J(R)$ . This is easily seen by once more taking the example of an fcc lattice near the Brillouin zone center where

$$v(k) = \frac{2J_{fcc}ka^2}{\hbar} \quad (4.28)$$

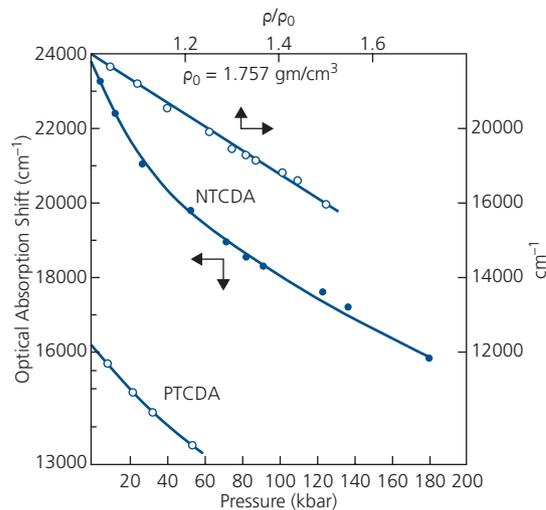

and

$$m^* = \frac{\hbar^2}{2J_{fcc}a^2}. \quad (4.29)$$

That is, the velocity increases and the effective mass decreases with increasing molecular orbital overlap,  $J_{fcc}$ . In contrast, near the (100) zone edge,  $v(k_x) = \frac{1}{\hbar} \frac{\partial E(k_x)}{\partial k_x} \rightarrow 0$ , which leads to the electron effective mass  $m^* \rightarrow \infty$ . That is, the electron slows and is reflected at the zone edge.

An intuitive outcome of the tight binding approximation is that the spacing between molecules should decrease as the crystal is compressed, thereby resulting in a broadening of the bands as well as a decrease in the lowest energy transition from the ground to the excited state. Figure 4.4 shows the energies of the long wavelength absorption edges (which are inversely proportional to  $E_G$ ) of NTCDA and PTCDA as functions of hydrostatic pressure (Jayaraman et al., 1985). The energy gap is reduced with pressure due to a decrease in  $a$ . Indeed, as PTCDA is compressed, its appearance changes from red to black. The change in NTCDA absorption at low pressures is non-linear, with a weaker dependence on pressure. Both responses are functions of the compressibility (i.e. the bulk modulus, Eq. 2.23) of these materials. The more open herringbone structure of NTCDA (with an intermolecular spacing of  $a = 3.506 \text{ \AA}$ ) is more easily compressed than is the very tightly  $\pi$ -stacked PTCDA ( $a = 3.21 \text{ \AA}$ ). Hence, the changes are more pronounced in NTCDA until the molecular core repulsion becomes dominant. However, the dependence of the energy shift on pressure, which is directly proportional to molecular spacing, is linear over the entire range tested in Fig. 4.4.

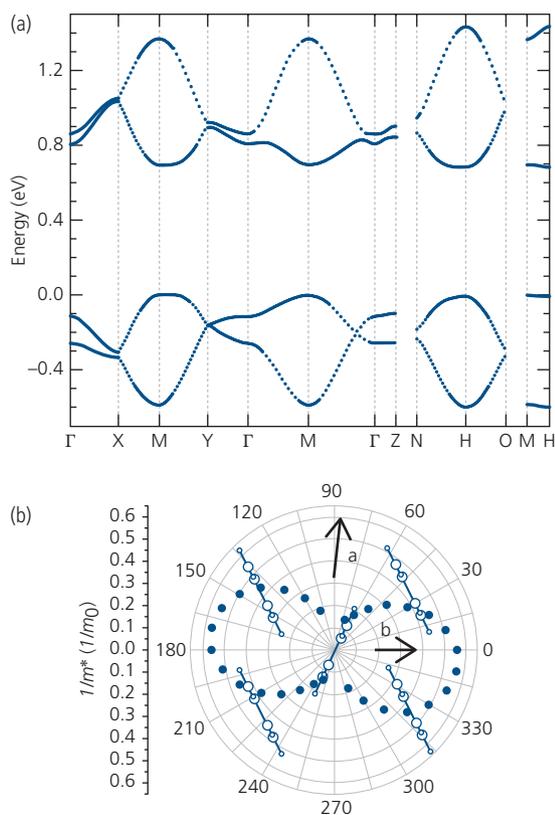

Tight binding approximations have been extensively used to calculate energy band dispersions in a number of molecules. Figure 4.5 shows the excess hole and electron three dimensional band structures for pentacene along several crystal symmetry directions. (Here,  $X = (\mathbf{a}^*/2, 0, 0)$ ,  $M = (\mathbf{a}^*/2, \mathbf{b}^*/2, 0)$ ,

**Figure 4.4** Shift in the low energy absorption edge of NTCDA and PTCDA excitonic features vs. hydrostatic pressure. The upper straight line corresponds to the spectral shift as a function of NTCDA density (Jayaraman et al., 1985).

$Y = (0, \mathbf{b}^*/2, 0)$ ,  $Z = (0, 0, \mathbf{c}^*/2)$ ,  $N = (0, \mathbf{b}^*/2, \mathbf{c}^*/2)$ ,  $H = (\mathbf{a}^*/2, \mathbf{b}^*/2, \mathbf{c}^*/2)$ , and  $O = (\mathbf{a}^*/2, 0, \mathbf{c}^*/2)$ . Also,  $\mathbf{a}^*$ ,  $\mathbf{b}^*$ , and  $\mathbf{c}^*$  are the reciprocal lattice vectors,  $\Gamma$  is the center of the Brillouin zone, and the direction from  $\Gamma$  to M is  $\frac{1}{2}(\mathbf{a}^* + \mathbf{b}^*)$ .) The bands are calculated using both density functional theory and tight binding with almost identical results (de Wijs et al., 2003).

The bands resulting from the crystal structure and the electron density distributions are shown in Fig. 4.5a. The relative position of the wavefunction phases between adjacent molecules in the crystal (see Fig. 3.16) significantly affects the band structure (i.e. the splitting of the bands within the LUMO and HOMO manifolds) and consequently, the charge mobility. There are two branches in both the HOMO and LUMO bands since two symmetry-inequivalent molecules form the unit cell basis. The BWs are  $\sim 600$  meV and  $700$  meV for the HOMO and LUMO, respectively. Note that the calculated band

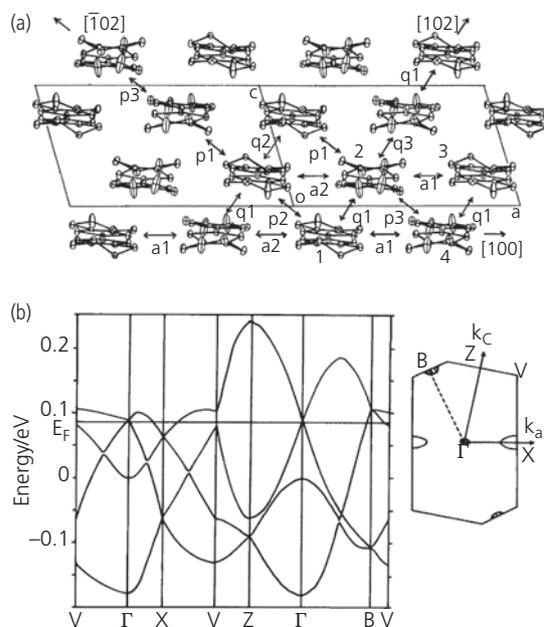

**Figure 4.5** (a) Calculated band structure along several crystal symmetry directions. The upper two lines are the LUMO levels, and the lower two are the HOMO levels. There are two symmetry-inequivalent molecules per unit cell, resulting in a split band along each crystallographic direction. (c) The effective mass,  $m^*$  relative to the free electron mass,  $m_0$ , as a function of direction in the  $\mathbf{a}$ - $\mathbf{b}$  plane. The molecular orientations in this plane are shown for reference (de Wijs et al., 2003).

gap is  $0.7$  eV, which is substantially less than the measured  $E_G = 2.2$  eV (Kang et al., 2006). This difference is sometimes observed in tight binding and DFT calculations (Nabok et al., 2007), although it does not appear to significantly affect other features of the band structure. While the energy band doublets are somewhat distorted due to asymmetries in the transfer integrals,  $J(\mathbf{R})$ , along different symmetry directions, they nevertheless have approximately the cosine shape in Eq. 4.19. This periodicity is particularly apparent for the upper and lowermost bands in the LUMO and HOMO, respectively.

The effective masses in the  $\mathbf{a}$ - $\mathbf{b}$  plane calculated from the band structure are plotted in Fig. 4.5c. The mass varies from approximately  $6.5m_0$  along the  $\hat{\mathbf{a}}$ -axis, to  $1.5m_0$  at approximately  $15^\circ$  from the  $\hat{\mathbf{b}}$ -axis. It is also found that  $m^* = 5.2m_0$  along  $\hat{\mathbf{c}}$ . Here,  $m_0$  is the free electron mass. The asymmetries in  $m^*$  are also due to different magnitudes in the coupling integrals,  $J(\mathbf{R})$ , along different symmetry axes.

The tight binding method has also been used to understand the charge transfer complex, bis(ethylenedithio)tetrathiafulvalene ((BEDT-TTF) $_2$ ClO $_4$  (C $_2$ H $_3$ Cl $_3$ ) $_{0.5}$ ) with the highest four bands shown in Fig. 4.6 (Mori et al., 1984). The bands arise from the four molecules per unit cell, presenting a more

**Figure 4.6** (a) Intermolecular interactions ( $p$ ,  $q$ ) along different crystal directions for (BEDT-TTF) $_2$ ClO $_4$ (C $_2$ H $_3$ Cl $_3$ ) $_{0.5}$ . (b) Four bands arise from the four molecules per unit cell of the molecule along different crystal symmetry directions shown at right. The  $\Gamma$ -point is at the center of the Brillouin zone (Mori et al., 1984).

complex system than polyphenyls such as pentacene. While a small (0.1 eV) band gap around the Fermi energy ( $E_F$ ) opens up between the third and fourth bands along the V-symmetry direction, band overlap along different crystal directions indicates that this is not a semiconductor, but rather a semi-metal with a  $\frac{3}{4}$ -filled frontier orbital. Of particular note is the small BW  $\sim 200$  meV compared to pentacene, resulting from relatively large intermolecular distances of  $R \approx 3.80$  Å.

#### 4.1.2 Experimental dispersion relationships

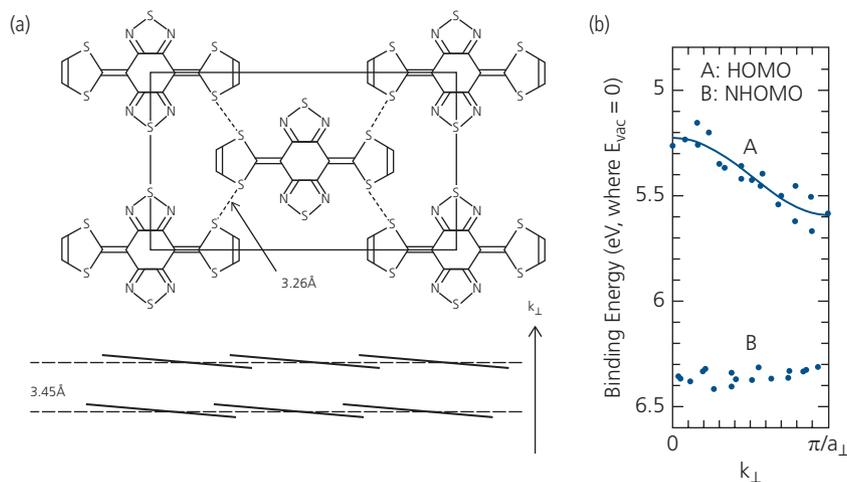

There are several methods for measuring the frontier orbitals of organic semiconductors, most notably *ultraviolet photoelectron spectroscopy* (UPS, also known simply as *photoelectron spectroscopy*, PES) and *cyclic voltammetry* (CV). These methods are described and compared in Appendix C. Here, we will discuss the use of a modified version of UPS, known as *angle resolved ultraviolet photoelectron spectroscopy* (ARUPS) that can resolve the dispersion relation,  $E(\mathbf{k})$ . Briefly, UPS is based on the photoelectric effect, whereby a UV light source illuminates the surface of the sample. The energy difference between the HOMO and the vacuum level (known as the ionization potential, IP) is determined by measuring the kinetic energy of electrons ejected from the sample surface for a given photon energy (Hüfner, 2003). The angular dependence of the kinetic energy yields the component of the electronic wavevector perpendicular to the surface,  $k_{\perp}$ . The parabolic electronic potential (or *mean inner potential*),  $V_0$ , is then determined from ARUPS spectra using

$$k_{\perp} = (2m/\hbar^2)^{1/2}(E_{kin}\cos^2\theta_e + V_0)^{1/2}, \quad (4.30)$$

where  $E_{kin}$  is the kinetic energy determined from the electric field required to retard the motion of the photoemitted electron, and  $\theta_e$  is its emission angle relative to the surface normal. Tight binding theory provides the band shape perpendicular to the substrate via (Mori et al., 1984)

$$E(k_{\perp}) = E_{HOMO} - 2J\cos(a_{\perp}k_{\perp}), \quad (4.31)$$

where the lattice constant perpendicular to the substrate is  $a_{\perp}$ ,  $E_{HOMO}$  is the energy at the band center at  $k_{\perp} = 0$ , and  $BW = 4J$ . ARUPS has been applied to determine the band structure of BTQBT on graphite with results shown in Fig. 4.7 (Hasegawa et al., 1994). The presence of sulfur atoms in BTQBT results in a close in-plane intermolecular contact distance of only 3.26 Å, with a more relaxed interplanar spacing of 3.45 Å which, due to the molecular tilt relative to the substrate, gives  $a_{\perp} \approx 3.4$  Å. Consistent with the tight binding approximation, the HOMO-centered band has a cosine-like dependence with a BW of almost 0.4 eV (corresponding to  $J = 0.092$  eV). This is considerably larger than the next highest HOMO, or NHOMO, centered on HOMO-1 whose BW is  $\sim 0.08$  eV. The narrower BW is a consequence of the more tightly bound inner shell electrons that make up the deeper HOMO levels. Fits to the ARUPS data give a  $V_0 = -12.5$  eV and  $E_{HOMO} = 5.4$  eV. Note that the phase of the NHOMO is opposite to that of the HOMO, suggesting that the velocity and effective masses also have opposite signs in the two bands.

**Figure 4.7** (a) Crystal structure and molecular structural formula of BTQBT. (b) Structure of the HOMO and the next highest HOMO (NHOMO) bands measured by ARUPS (data points), and a fit to the tight binding approximation (lines) (Hasegawa et al., 1994).

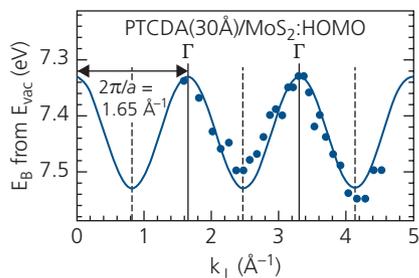

The BW along  $a_{\perp}$  is substantial for an organic solid, and suggests a high charge mobility and low effective mass. Indeed, from the fits to the tight binding model (Fig. 4.7b, solid line), the hole effective mass at the top of the HOMO band is  $m_h^* \approx 3.1m_0$ . Then the charge mobility in the crystal is

$$\mu_h = \frac{q\tau}{m_h^*}, \quad (4.32)$$

where the scattering relaxation time is given by the uncertainty principle to be  $\tau > \hbar/k_B T$  for thermally broadened bands. From this, we find that  $\mu_h > 6.5 \text{ cm}^2/\text{V s}$  (Hasegawa et al., 1994), which is comparable to the measured Hall mobility of  $4 \text{ cm}^2/\text{V s}$ . (Imaeda et al., 1992). There is little question, therefore, that the close intermolecular packing of BTQBT leads to band transport similar to that of inorganic semiconductors.

An even closer  $\pi$ -stacking distance of  $3.21 \text{ \AA}$  for PTCDA suggests an even larger carrier BW. As we have seen in Chapter 3, this close intermolecular spacing results in extended charge transfer states that span several molecules in the stack. In one ARUPS study (Yamane et al., 2003), PTCDA was grown nearly epitaxially onto  $\text{MoS}_2$  to produce large crystalline domains. The spacing of  $a_{\perp} \approx 3.8 \text{ \AA}$  between PTCDA and  $\text{MoS}_2$  is considerably larger than the native intermolecular stacking distance of neat PTCDA crystals. Nevertheless, the fit of the data to a cosine dependence in Fig. 4.8 yields  $m_h^* = 5.28m_0$  and  $\mu_h > 3.8 \text{ cm}^2/\text{V s}$ . These values are expected to differ for bulk crystals with tighter molecular stacking. The data lead us to conclude that, like BTQBT, PTCDA has many band-like properties consistent with inorganic semiconductors.

Similar findings regarding the HOMO energy dispersion have been calculated and measured for high mobility semiconductors such as pentacene (Koch et al., 2006) and rubrene (Yanagisawa et al., 2013). In

**Figure 4.8** Measured HOMO level dispersion of PTCDA deposited on  $\text{MoS}_2$  (data points) giving a bandwidth of  $200 \text{ meV}$ . The solid line is a fit to the cosine-dependent tight binding calculation with an electronic potential of  $V_0 = -5.1 \text{ eV}$  and  $E_{\text{HOMO}} = 7.43 \text{ eV}$  (Yamane et al., 2003).

cases where high mobility is observed, HOMO BWs in the range  $150\text{--}250 \text{ meV}$  are typical, although to date there has not been evidence for a BW higher than  $400 \text{ meV}$ , as observed for BTQBT. The tight binding approximation clearly provides a reasonable estimate of the energy dispersion of high mobility (and thus high conductivity) organic materials, suggesting that Bloch theory applied to inorganic semiconductors can also be adapted to organic materials with a significant orbital overlap between neighbors.

## 4.2 Charge transfer

Now that we have established that the band structure of an organic medium is primarily determined by nearest neighbor interactions, we can develop the theory of charge transfer between molecules. The approaches taken to understand the optical properties of organics (and hence exciton transfer and energy migration) are similar to those needed to understand charge migration and conductivity. Before addressing the process of charge transfer, we define two important macroscopic quantities.

*Charge mobility* ( $\vec{\mu}$ ) is the constant of proportionality between the electric field ( $\mathbf{F}$ ) charge velocity ( $\mathbf{v}$ ). That is,

$$\mathbf{v} = \vec{\mu}\mathbf{F}. \quad (4.33)$$

It is a tensor whose value depends on crystalline direction. The mobility for electrons ( $\mu_e$ ) and holes ( $\mu_h$ ) is different in virtually all semiconductor materials since they each depend separately on their corresponding intermolecular charge transfer (CT) properties that are sensitive to the crystal and molecular structures. As we will show in the ensuing discussion, the mobility is a function of temperature,  $T$ , electric field, and the charge density of states.

*Conductivity*,  $\vec{\sigma}$ , is defined via Ohm's law:

$$\mathbf{j} = q(n\mathbf{v}_e + p\mathbf{v}_h) = \vec{\sigma}\mathbf{F}, \quad (4.34)$$

from which we obtain

$$\vec{\sigma} = q(n\vec{\mu}_e + p\vec{\mu}_p). \quad (4.35)$$

Here,  $\mathbf{j}$  is the current density and  $n$  and  $p$  are the electron and hole densities, respectively.

Given the central importance that  $\mu$  plays in quantifying conductive properties, calculating and measuring this quantity has been a significant focus of studies of organic electronic materials. The remainder of this section is devoted to understanding its origins, and in Section 4.4.3 we discuss how it is accurately measured.

While charge mobilities  $>1 \text{ cm}^2/\text{V s}$  are suggestive of band-like transport, it is far more typical to find organics whose mobilities are  $<0.1 \text{ cm}^2/\text{V s}$ . This is in contrast to mobilities in inorganic solids that are at least 10 times, and even  $>1000$  times larger. The primary difference lies in the strength of the electron–phonon interaction. In inorganics, electron exchange interactions within the bands are dominant. Their large dielectric constants ( $\epsilon_r > 10$ ) lead to electric field screening. Indeed, the large BWs and weak couplings to phonons lead to a charge *mean free path*,  $\lambda \gg a$ , where  $a$  is the lattice constant. Hence, the *mean free time* between scattering events,  $\tau$ , is much longer than the time to move between adjacent atoms in the lattice. The uncertainty principle sets a lower limit to the electronic BW of  $BW > \hbar/\tau$ .

The mobility is related to the diffusion constant,  $D$ , via the *Einstein–Smoluchowski relationship*:

$$\frac{D}{\mu} = \frac{k_B T}{q}. \quad (4.36)$$

Since the charge diffusion length,  $L_D$ , is given by

$$L_D = \sqrt{D\tau}, \quad (4.37)$$

then band-like properties require that  $L_D > a$ . In this case, provided that  $BW > k_B T$  we have the condition that (LeBlanc, 1961),

$$\mu > \frac{qa^2}{\hbar} \left( \frac{BW}{k_B T} \right). \quad (4.38)$$

To estimate the magnitude of this limiting band-like mobility, we assume that  $a \sim 5 \text{ \AA}$ , in which case  $\mu > 5 (BW/k_B T)$  (in units of  $\text{cm}^2/\text{V s}$ ). Thus at room temperature where  $BW \geq 25 \text{ meV}$ , band transport dominates when  $\mu > 5 \text{ cm}^2/\text{V s}$ , a high value that is rarely observed in organic materials.

In contrast to inorganic semiconductors, organic semiconductors have a relatively small dielectric constant ( $\epsilon_r \sim 3$ ), and hence a concomitantly reduced electric field screening. Thus, electron–phonon interactions both within a charged molecule as well as between molecules involved in electron transfer overwhelm the exchange interactions. This leads to charge scattering and localization at each molecular site. In this limit,  $\lambda \sim a$  such that transport is *incoherent*, where the charge trajectories are highly randomized. Band transport gives way to hopping transport of a charge that self-traps on each molecular site due to polarization of the local orbital environment. The polarization energy is “carried” with the charge from molecule to molecule, considerably increasing its effective mass. The charge-plus-polarization is called a *polaron*. Since

the polarization effect is confined to only nearest or next nearest neighbors (i.e. it is on the order of a lattice constant,  $a$ ), the polaron is often referred to as a *small polaron* (Holstein, 1959a).

In contrast to the short range interactions of electrons in organics, interactions in ionic compounds are governed by Coulombic effects whose potential decays as  $1/r$ . Polarization in this case decays slowly with distance, with concomitantly reduced effects on the charge effective mass and other transport properties. This long range lattice distortion is known as a *large polaron*. Since its effects are of relatively minor importance in organic materials, large polarons are not considered further here.

Electron–phonon interactions dominate transport in molecular solids when  $\hbar\omega_0 > BW$ , where  $\hbar\omega_0$  is approximately equal to the highest energy vibration. Thus, mobilities in materials with strong electron–phonon coupling with magnitudes

$$\mu > \frac{qa^2}{\hbar} \left( \frac{\hbar\omega_0}{k_B T} \right) \quad (4.39)$$

suggest the existence of band transport. Typically,  $\hbar\omega_0 \sim 100 \text{ meV}$ . Then at room temperature,  $\mu > 20 \text{ cm}^2/\text{V s}$  is a signature of coherent transport. Such high room temperature mobilities in molecular and polymeric materials are not observed. The transition between hopping and band transport, however, can be observed at far lower mobilities than predicted by the generalities leading to Eqs. 4.38 and 4.39.

Quantitative analysis of intermolecular electron transfer proceeds by solving the Schrödinger equation using the single electron Hamiltonian:

$$H_T = H_e^0 + H_{ph}^0 + H_e^{tr} + H_{e-ph}^{loc} + H_{e-ph}^{non} + H_e^{stat}, \quad (4.40)$$

which is decomposed into the several energetic contributions to the transfer process. The excited electron Hamiltonian for a perfectly ordered lattice is given by (Coropceanu et al., 2007, Bäessler and Köhler, 2012)

$$H_e^0 = \sum_n^N E_n^0 a_n^\dagger a_n, \quad (4.41)$$

where  $E_n^0$  is the electron energy and  $a_n^\dagger(a_n)$  is the creation (annihilation) operator for an electron at the  $n$ th lattice site in the absence of coupling to surrounding molecules. For an  $n$ -particle eigenstate,  $|n\rangle$ , these operators have the following properties:

$$a^\dagger |n-1\rangle = \sqrt{n} |n\rangle \quad (4.42)$$

and

$$a |n\rangle = \sqrt{n} |n-1\rangle \quad (4.43)$$

such that the number operator

$$\mathcal{N}_i = a_i^\dagger a_i \quad (4.44)$$

counts the number of quantum states. Thus,  $\mathcal{N}_i|n\rangle = n|n\rangle$ . Similarly, for phonons we have

$$H_{ph}^0 = \sum_{\mathbf{q},j} \hbar\omega_{\mathbf{q},j} (b_{\mathbf{q},j}^\dagger b_{\mathbf{q},j} + \frac{1}{2}), \quad (4.45)$$

where  $\omega_{\mathbf{q},j}$  is the frequency of the phonon mode with wavevector  $\mathbf{q}$  on the  $j$ th phonon branch. Also  $b_{\mathbf{q},j}^\dagger$  ( $b_{\mathbf{q},j}$ ) is the phonon creation (annihilation) operator. Hence,  $H_e = H_e^0 + H_{ph}^0$  gives the energy of an excited molecule that does not interact with the phonon population. In writing Eqs. 4.41 and 4.45 and the expressions for the various terms in  $H_T$  that follow, for simplicity only first order (linear) interactions are considered.

Electron transfer from the  $m$ th to the  $n$ th molecule is expressed by

$$H_e^{tr} = \sum_{m \neq n}^N J_{nm} a_n^\dagger a_m, \quad (4.46)$$

where the transfer integral,  $J_{nm}$ , gives the electronic interaction, or coupling between molecules  $m$  and  $n$ :

$$J_{nm} = \langle \psi_n(\mathbf{r} - \mathbf{R}_n) | H_e^{tr} | \psi_m(\mathbf{r} - \mathbf{R}_m) \rangle. \quad (4.47)$$

This is in contrast to the *on-site energy*, with expectation value of  $\varepsilon_{nn}$  at site  $n$ :

$$\varepsilon_{nn} = \langle \psi_n(\mathbf{r} - \mathbf{R}_n) | H_e^{tr} | \psi_n(\mathbf{r} - \mathbf{R}_n) \rangle. \quad (4.48)$$

Interactions with the phonon population are expressed by the electron-phonon coupling terms as follows:

$$H_{e-ph}^{loc} = \frac{1}{\sqrt{N}} \sum_{\mathbf{q},j} \sum_m^N \hbar\omega_{\mathbf{q},j} (g_m(\mathbf{q},j) b_{\mathbf{q},j} + g_m^*(\mathbf{q},j) b_{-\mathbf{q},j}^\dagger) a_m^\dagger a_m \quad (4.49)$$

and

$$H_{e-ph}^{non} = \frac{1}{\sqrt{N}} \sum_{\mathbf{q},j} \sum_{\substack{m,n \\ m \neq n}}^N \hbar\omega_{\mathbf{q},j} (g_{nm}(\mathbf{q},j) b_{\mathbf{q},j} + g_{nm}^*(\mathbf{q},j) b_{-\mathbf{q},j}^\dagger) a_n^\dagger a_m. \quad (4.50)$$

Equation 4.49 is the dynamic disorder term due to electron-phonon coupling within the charged molecule. The strength of the coupling is  $g_m(\mathbf{q},j)$ , with complex conjugate  $g_m^*(\mathbf{q},j)$ . Since the interaction only involves intramolecular interactions within the  $m^{\text{th}}$  molecule, the matrix elements lie only on the diagonal ( $m, m$ ), and hence Eq. 4.49 is known as *dynamic diagonal disorder*. Similarly, *dynamic off-diagonal disorder* due to intermolecular interactions with the vibronic manifold, is expressed by Eq. 4.50, with an

electron-phonon coupling strength of  $g_{nm}(\mathbf{q},j)$ . These terms are used to calculate the reduction in electron energy arising from intrinsic or polaronic effects (and hence interaction with the phonon population) during transfer. Importantly, when  $g_m$  or  $g_{nm}$  are large compared to  $J_{nm}$ , the transport is dominated by polarons where the mass of the charge is “dressed” by local lattice distortions. In the opposite circumstance when  $J_{nm} > g_m, g_{nm}$ , the effects of polarons are small, and the transport becomes band-like. This corresponds to the situation in inorganic semiconductors where polaron energies are negligible.

Finally, actual crystal structures always contain a finite number of physical defects, and this is particularly true for weakly bonded organic van der Waals crystals. These imperfections in lattice structure can significantly influence charge transfer between neighboring molecules, and hence the conductivity of the solid. To account for this so-called static disorder, we write

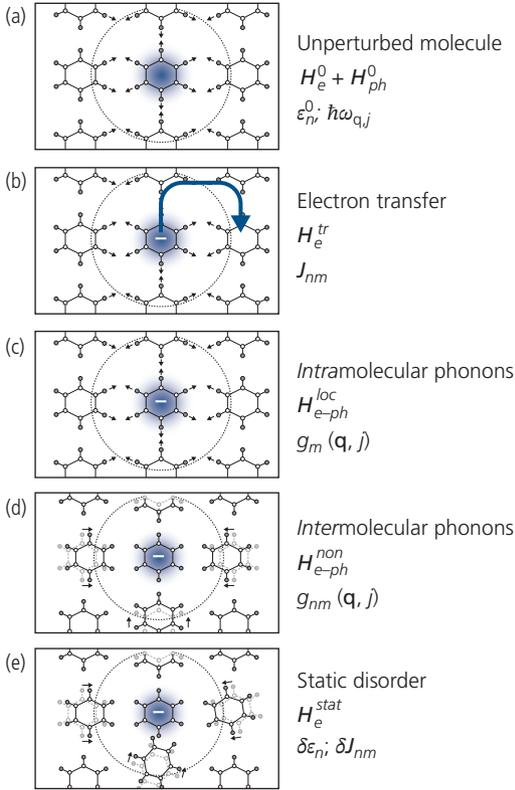

$$H_e^{stat} = \sum_n^N \delta E_n a_n^\dagger a_n + \sum_{\substack{m,n \\ m \neq n}}^N \delta J_{nm} a_n^\dagger a_m. \quad (4.51)$$

The terms  $\delta E_n$  and  $\delta J_{nm}$  are small deviations in the energy and coupling constants due to local variations in the structural morphology. As above, the first term expresses static diagonal disorder and the second is for static off-diagonal disorder. Note that there are no interactions with the phonon population since static disorder is only a property of crystalline morphology. This term is largest in amorphous materials or non-crystalline polymers where there is considerable variation in the molecular environment and configuration from site to site. In sufficiently disordered solids, this term can dominate other effects in Eq. 4.40.

A conceptual illustration of the physical processes and the terms quantifying transfer between molecules in a lattice is shown in Fig. 4.9.

Now that the total Hamiltonian is defined, our task is to calculate the various terms to determine their relative strengths. That is, when  $g_m(\mathbf{q},j)$  and  $g_{nm}(\mathbf{q},j)$  are large, charge transfer (and hence charge mobility) is dominated by polaronic effects, and the primary mechanism for charge transport is via incoherent hopping between nearest neighbor molecules. Conversely, band-like transport occurs when these coupling constants are small.

In the absence of intermolecular coupling (i.e.  $J_{nm} = 0$ ) and considering only local polaron (i.e. on-diagonal terms), the Hamiltonian simplifies to  $H_T = H_e^0 + H_{ph}^0 + H_{e-ph}^{loc}$  which yields the following energy eigenvalues (Coropceanu et al., 2007):

**Figure 4.9** Various processes involved in charge transfer. The relevant Hamiltonians and coupling constants are indicated. The unpaired electron (–) undergoes transfer in the direction indicated by the arrow.

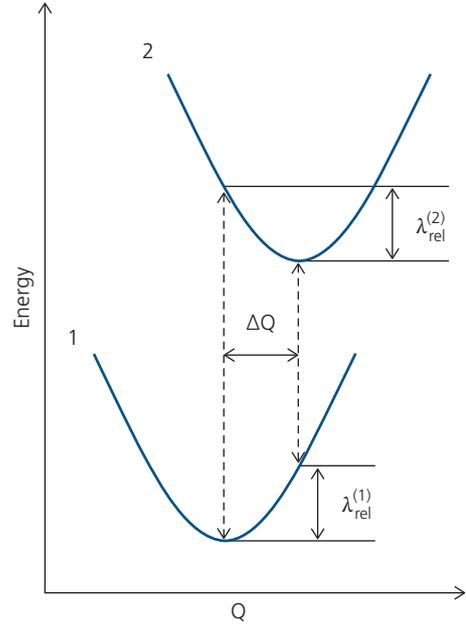

$$E_m = E_m^0 + \sum_{\mathbf{q},j} \hbar\omega_{\mathbf{q},j} \left( n_{\mathbf{q},j} + \frac{1}{2} \right) - \frac{1}{N} \sum_{\mathbf{q},j} \hbar\omega_{\mathbf{q},j} |g_m(\mathbf{q}, j)|^2. \quad (4.52)$$

The first two terms are the familiar solution to the Schrödinger equation using  $H_e$  in Eq. 3.11 ff., whereas the last term results from on-site perturbations of the vibronic modes in response to the excess polaron (Fig. 4.9c). That is, the intramolecular polarization energy which equals the polaron binding energy is

$$E_{pol}^{loc} = -\frac{1}{N} \sum_{\mathbf{q},j} \hbar\omega_{\mathbf{q},j} |g_m(\mathbf{q}, j)|^2. \quad (4.53)$$

To determine the coupling strength, we assume that the transfer of an electron results in only a small distortion of the electronic potential. Then we can expand  $E_m(Q)$  about the equilibrium nuclear coordinates,  $Q(j)$  as defined in Fig. 4.10:

$$E_m(Q) = E_m^0 + \sum_i \left. \frac{\partial E_m}{\partial Q_m(j)} \right|_{Q=0} Q_m(j) + \frac{1}{2} \sum_j M_j \omega_j^2 Q_m^2(j) + \dots \quad (4.54)$$

**Figure 4.10** Relative coordinate shift ( $\Delta Q$ ) between the initial, neutral state (1), and the final charged molecule state (2) involved in charge transfer. The polarization energies are  $\lambda_{rel}^{(1)}$  and  $\lambda_{rel}^{(2)}$ , respectively.

The second term, which is linear in  $Q_m(j)$ , is the restoring force near equilibrium. Here,  $M_j$  is the molecular mass (Holstein, 1959a). This distortion results in a shift in the nuclear coordinates,  $\Delta Q(j)$  that increases the energy by  $M_j \omega_j^2 \Delta Q(j)$ . Assuming that the vibrational modes in the ground and the singly charged excited states are unchanged, and that  $\lambda_{rel}$  is the sum of the energies of the  $j$  vibrational modes,  $\lambda_{rel} = \sum_j \lambda_j$  then the total polarization energy is

$$E_{pol}^{loc} = \lambda_{rel} = \frac{1}{2} \sum_j M_j \omega_j^2 \Delta Q^2(j) \quad (4.55)$$

(see Fig. 4.10). At equilibrium, the first derivative in Eq. 4.54 is zero. It follows that the shift in coordinates by the transfer of charge is (Austin and Mott, 1969)

$$\Delta Q_m(j) = \left[ \frac{1}{2M_j \omega_j^2} \right] \left. \frac{\partial E_m}{\partial Q_m(j)} \right|_{Q=0} \quad (4.56)$$

Then from Eqs. 4.53, 4.54, and 4.56, we obtain a relationship for on-site coupling:

$$|g_m(\mathbf{q}, j)|^2 = \frac{\lambda_j}{\hbar\omega_{\mathbf{q},j}} = \frac{1}{2M_j \hbar\omega_{\mathbf{q},j}^3} \left| \left. \frac{\partial E_m}{\partial Q_m(j)} \right|_{Q=0} \right|^2, \quad (4.57)$$

or

$$|g_m(\mathbf{q}, j)|^2 = \frac{2M_j \omega_{\mathbf{q},j}}{\hbar} |\Delta Q_m(j)|^2. \quad (4.58)$$

The relationship between  $\lambda_{rel}$  and  $\Delta Q$  is shown in the energy diagram of the neutral and ionic molecular states in Fig. 4.10. The coupling constants are proportional to the coordinate displacements,  $\Delta Q$ , that are due to changes in intramolecular vibrational modes in the presence of an excess charge. This change results in a molecular relaxation of the local polarization of magnitude  $\lambda_{rel}^{(1)}$  as the electron is transferred to a neighboring neutral molecule, which in turn relaxes by energy,  $\lambda_{rel}^{(2)}$ . That is, the charge “carries” the polarization from molecule to molecule. The total reorganization energy upon charge transfer is, therefore,

$$\lambda_{reorg} = \lambda_{rel}^{(1)} + \lambda_{rel}^{(2)}, \quad (4.59)$$

and in the special case that the initial and final states of the molecules are the same, then

$$E_{pol}^{loc} = \lambda_{reorg}/2. \quad (4.60)$$

For rigid molecules such as the polyacenes, the reorganization energies have in fact been found to be approximately equal ( $E_{pol} \sim 50\text{--}100$  meV) (Coropceanu et al., 2007). This is not the case for more flexible molecules that can undergo substantial distortion during charge transfer, and where the perturbation approach breaks down.

The reorganization energy was initially introduced by Marcus (1957), who used a classical approach to charge transfer between a donor and acceptor molecule, yielding

$$\lambda_{reorg} = \frac{\Delta q^2}{4\pi\epsilon_0} \left( \frac{1}{2a_D} + \frac{1}{2a_A} - \frac{1}{R_{DA}} \right) \left( \frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_s} \right), \quad (4.61)$$

where  $a_D$  ( $a_A$ ) is the radius of the donor (acceptor) outer sphere electron orbital,  $R_{DA}$  is the distance between acceptor and donor molecules,  $\epsilon_0$  is the permittivity of free space, and  $\epsilon_\infty$  and  $\epsilon_s$  are the optical and static dielectric constants, respectively. The first two terms in Eq. 4.61 are the energies required to charge the donor and acceptor molecules by an amount,  $\Delta q$ , and the third term is the reduction in energy due to the transfer of  $\Delta q$  from D to A. The difference in dielectric constants is a result of the Born–Oppenheimer approximation in that the nuclear degrees of freedom cannot instantaneously adjust during the transfer process. The reorganization energy increases with increasing donor–acceptor separation, as expected.

Calculation of off-diagonal dynamic distortion coupling constants,  $g_{nm}(\mathbf{q}, j)$  follows an analogous procedure to that used for  $g_m(\mathbf{q}, j)$ . This interaction is governed by the generation of acoustic phonons during transfer. The strength of the intermolecular

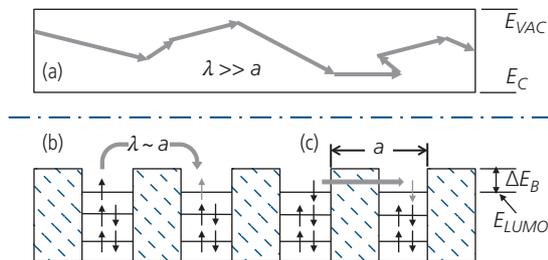

coupling due to off-diagonal dynamic disorder is often lower ( $E_{pol}^{non} \sim 10$  meV), largely as a result of the lower energy of inter vs. intramolecular phonons in organic crystals (Friedman, 1965). The presence of a polaron can result in substantial displacements of the lattice if it is sufficiently soft, leading to contributions as large as 30% to the total polaron energy (Coropceanu et al., 2007).

While the foregoing discussion has focused on electron transfer, the same arguments are made to describe hole transfer, albeit with different values for the coupling constants. The strength of the coupling determines the transfer rate via Fermi’s Golden Rule. Ultimately it is the rate that determines the carrier velocity and hence its mobility. While both electrons and holes apparently follow the same process of charge transfer, it is observed that hole mobilities are often larger than those of electrons. It has been argued that this difference has extrinsic origins; that electrons transported along the LUMO levels are at a higher energy and hence more readily available for oxidation or trapping within the energy gap (Bässler and Köhler, 2012). Intrinsic properties of solids may also lead to a higher mobility for one of the two carrier types: the most important being the orbital overlap between the molecules. In Eq. 4.47 we see that  $J_{nm}$  increases proportionately with the orbital overlap integral. Thus, the overlap of the HOMOs and LUMOs between molecules ultimately determines the probability for charge transfer. The charge mobility is, therefore, intimately related to both the spatial distribution of the respective orbitals, and the relative positions (i.e. stacking habit, distance of closest approach defined by the van der Waals radius, steric hindrance, etc.) of adjacent molecules. From tight binding, we have argued that the HOMO overlap leads to the broadest BW. Hence, it is not surprising that holes transported near the top of this band experience the highest mobility, as is often the case.

### 4.3 Charge transport

Charge transport over macroscopic distances occurs through a sequence of intermolecular charge transfer steps. Mechanisms of charge transport, therefore, determine the macroscopic electronic properties of charge mobility, diffusion and conductivity. We now relate the quantum mechanical couplings in Section 4.2 to these macroscopic quantities.

In Fig. 4.11a we illustrate the process of band transport that develops when  $J_{nm} > g_m^2$  and  $g_{nm}^2$ , that is, when  $H_e^r > H_{e-ph}^{loc}$  and  $H_{e-ph}^{non}$  (see Eq. 4.40). This situation arises when the BW is greater than the polaron

**Figure 4.11** Modes of charge conduction in semiconductors. (a) Band transport where the mean free path ( $\lambda$ ) of an electron is large and the transport is coherent (i.e. the path of the electron is correlated between collisions).  $E_C$  is the energy of the conduction band minimum, and  $E_{VAC}$  is the vacuum energy. (b) Hopping transport from molecule to molecule. The orbitals of each molecule are shown. The LUMO energy ( $E_{LUMO}$ ) is indicated by the topmost level containing an unpaired spin. (c) Tunneling occurs between states of equal energy in adjacent molecules.  $\Delta E_B$  is energy barrier to hopping or tunneling, and  $a$  is the molecular spacing. The energy scales and energy references for (a) are independent of (b) and (c).

energy in Eq. 4.55, such that the distance between scattering events is much larger than  $a$ . The charge motion is then limited by acoustic phonon scattering at the lattice sites. To determine the temperature dependence of the band-like mobility, the root mean square thermal velocity of charges that follow Boltzmann statistics is given by

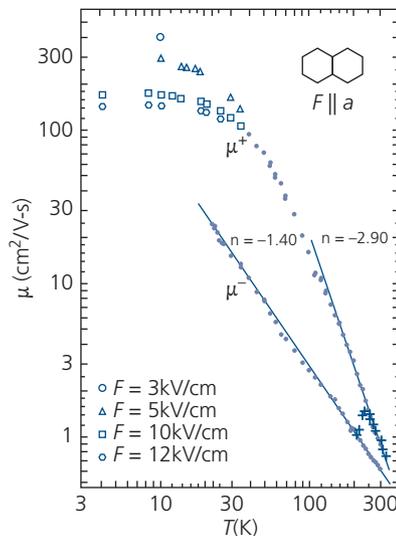

$$\langle v \rangle = \sqrt{\frac{3k_B T}{m^*}}. \quad (4.62)$$

Now the scattering time for an electron or hole is  $\tau^{-1} \sim \rho \sigma_X \langle v \rangle$ , where  $\sigma_X$  is the scattering cross section and  $\rho$  is the molecular number density in the medium. The temperature dependence of  $\sigma_X$  due to phonon scattering is  $\sigma_X \sim T$ , resulting in  $\tau \sim T^{-3/2}$ . It then follows from Eq. 4.32 that temperature dependence of the mobility for band-like conduction is  $\mu \sim T^{-3/2}$ . More generally, the temperature dependence of band-like mobility is

$$\mu \sim T^{-n}, \quad (4.63)$$

where for most common semiconductors such as Si, Ge, and GaAs,  $n$  is in the range from  $\frac{3}{2}$  to  $\frac{5}{2}$  for both electrons and holes.

Intrinsic band-like behavior has been observed in ultrapurified naphthalene and perylene single crystals (Warta et al., 1985, see Chapter 5.3), where great care was taken to remove impurities and their associated scattering processes that can introduce significant deviations from Eq. 4.63. For example, charged defects can lead to  $\sigma_X \sim \langle v \rangle^{-4} \sim T^{-2}$ , from which we infer  $\mu \sim T^{3/2}$ . In Fig. 4.12 we show the dependence of the time of flight (TOF) mobility on  $T$  for both

**Figure 4.12** Dependence of the electron ( $\mu^-$ ) and hole ( $\mu^+$ ) mobilities on temperature along the  $a$ -axis of an ultrapurified naphthalene crystal. Also shown is the electric field dependence of the hole mobility at  $T < 40$  K. The (+) data between  $T = 200$  K and 300 K are for naphthalene, that has not undergone ultrapurification (Warta et al., 1985).

electrons and holes for such highly pure naphthalene. The mobility shows a  $T^{-n}$  dependence down to  $T = 20$  K in Fig. 4.12. This is a clear indication of band-like conduction extending to room temperature. As in the case of perylene, however,  $n$  is somewhat larger than commonly observed in inorganic materials, ranging from 2.19 (electrons in perylene) to 2.90 (holes in naphthalene) suggestive of strong interactions with high energy acoustic phonons (Warta et al., 1985). Notably, the electron mobility is 5–10 times less than the hole mobility. Since the single crystals studied in Fig. 4.12 have been thoroughly refined, it is unlikely that this rather significant difference between hole and electron mobilities can simply be ascribed to the presence of impurities. As noted in the previous section, differences in HOMO vs. LUMO overlaps between molecules in a crystal can lead to intrinsically different mobilities due to different magnitudes of the transfer integral,  $J_{nm}$ , in Eq. 4.47.

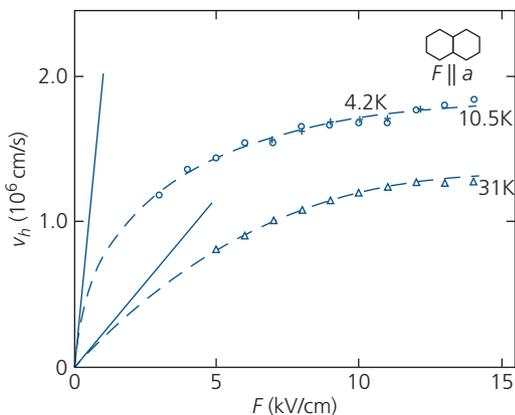

Even though highly pure, the room temperature mobility does not exceed  $\sim 1$  cm<sup>2</sup>/V s, and indeed is comparable to values for less purified materials. The low mobility arises from strong electron–phonon interactions (i.e. small polarons) due to dynamic lattice disorder. This is an intrinsic property of even the highest quality organic materials. Hence, reports of exceptionally high mobilities, often obtained from interface conduction in transistors at room temperature, should be taken with healthy skepticism (cf. Section 4.4.3). Nevertheless, phonon scattering is

reduced with temperature, leading to the power-law dependence in Fig. 4.12, with naphthalene achieving hole mobilities of  $>200 \text{ cm}^2/\text{V s}$ . This is similar to data for ultrapure perylene in Fig. 5.6 with an electron mobility of  $80 \text{ cm}^2/\text{V s}$  at 30 K.

Another phenomenon observed for ultrapurified naphthalene is the dependence of the hole drift velocity on applied electric field,  $F$ , shown in Fig. 4.13. The differential mobility,

$$\mu_{\text{diff}} = \frac{\partial v}{\partial F}, \quad (4.64)$$

is given by the slope of the data. At all temperatures,  $\mu_{\text{diff}} \rightarrow 0$  as  $F \rightarrow$  large, characteristic of velocity saturation due to increased acoustic phonon scattering in the bands. The data in Fig. 4.12 are taken from the

**Figure 4.13** Hole drift velocity ( $v_h$ ) vs. electric field ( $F$ ) in an ultrapurified naphthalene crystal at two different temperatures. The slope of the lines as  $F \rightarrow 0$  gives the mobilities (Warta et al., 1985).

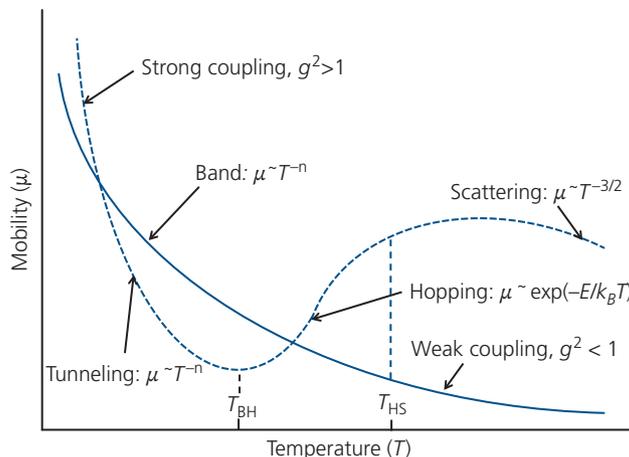

linear interpolation of the drift velocities to  $F = 0$ . Extremely high mobilities ( $400 \text{ cm}^2/\text{V s}$  at  $F = 3 \text{ kV/cm}$ ) are attained at  $T = 4.2 \text{ K}$  where scattering is minimal.

Polaron-limited transport is important when  $BW < \hbar\omega_0, k_B T$ . In this case dynamic disorder leads to  $H_{e-ph}^{\text{loc}}, H_{e-ph}^{\text{non}} > H_e^{\text{tr}}$ . The polaron is scattered at each molecular site, leading to transport dominated by thermally-assisted hopping at high temperature. As temperature is decreased, tunneling between sites dominates. These two processes are illustrated in Fig. 4.11b and 4.11c, respectively. Tunneling is isoenergetic, that is, it involves the transfer between equal energies. Therefore, it is only weakly temperature dependent arising from thermal phonon broadening of the electron DOS. Like band transport, tunneling leads to *coherent transport* where the mean free path of the carrier is  $\lambda \gg a$ . In thermally assisted hopping, however, the polaron requires energy to hop over the barriers between adjacent molecules. Since scattering and relaxation occur on time scales less than the hopping rate, the transfer is *incoherent*. That is, there is no “memory” of past events that determines the direction and time of subsequent hops.

The total mobility is given by

$$\mu_T = \mu_{\text{hop}} + \mu_{\text{tun}}. \quad (4.65)$$

The various mobility regimes vs. temperature have the functional forms illustrated in Fig. 4.14. The dominance of either band or polaron transport is a determined by the strength of the electron–phonon coupling constants, for on-diagonal dynamic disorder, and for

**Figure 4.14** Mobility vs. temperature for both strongly and weakly electron–phonon coupled systems showing the various transport regimes. The transitions between the band and hopping, and hopping and scattering regimes approximately occur at temperatures  $T_{\text{BH}}$  and  $T_{\text{HS}}$ , respectively. The electron–phonon coupling constant is  $g^2$ .

off-diagonal disorder. These couplings exceed the electron transfer integral,  $J_{nm}$  when hopping dominates. Since hopping is thermally assisted, the mobility follows:  $\mu_{hop} \sim \exp(-\Delta E/k_B T)$  with an activation energy,  $\Delta E$ . As temperature is increased, hopping over barriers no longer is the rate-limiting step in the transport process, and residual acoustic phonon scattering dominates, leading to  $\mu \sim T^{-3/2}$ .

### 4.3.1 Hopping in the presence of dynamic disorder

Having calculated the transfer energies and integrals in Section 4.2, we now determine the polaron mobilities in the presence of both dynamic and static disorder. First, we will consider the effects of on-diagonal and off-diagonal dynamic disorder where  $H_{e-ph}^{loc}$ ,  $H_{e-ph}^{loc} \gg H_e^{tr}, H_e^{stat}$ . This is the small polaron, or polaron transport regime first described by Holstein (1959b). Second, we will consider disorder effects, where  $H_e^{stat} \gg H_{e-ph}^{loc}, H_{e-ph}^{loc}, H_e^{tr}$ .

Since only nearest neighbor interactions need to be considered, we can describe electron transfer from initial site,  $p$ , to the neighboring site,  $p \pm 1$ . Then for a three dimensional, cubic lattice with lattice constant  $a$ , the diffusion constant is given by (Holstein, 1959b)

$$D = \frac{1}{6} k_{ET} (p \rightarrow p \pm 1) a^2. \quad (4.66)$$

The factor of  $1/6$  arises from the choice of hop in any of 6 directions. We assume that molecules at all sites  $p$  are identical, and hence positive and negative hops occur with equal probability. For diagonal transitions, the vibrational quantum numbers remain unaltered during transfer, whereas for off-diagonal transitions, the quantum numbers change by  $\pm 1$ . Then, from Eq. 4.36 and 4.66, we can relate the transfer rate  $k_{ET}$  to the hopping mobility:

$$\mu = \frac{q}{6k_B T} k_{ET} (p \rightarrow p \pm 1) a^2. \quad (4.67)$$

The calculation of  $k_{ET}$  follows from the Schrödinger equation employing the Hamiltonian in Eq. 4.40, but excluding disorder,  $H_e^{stat}$ . Thus (Holstein, 1959b),

$$\begin{aligned} i\hbar \frac{\partial \phi_n(Q)}{\partial t} = & \left[ \sum_m^N \left( -\frac{\hbar^2}{2M} \nabla_m^2 + \frac{1}{2} M \omega_0^2 Q_m^2 \right. \right. \\ & \left. \left. + \frac{1}{2} M \omega_0^2 Q_m Q_{m+1} \right) + V_Q(m) Q_n \right] \phi_n(Q) \\ & - J_{n,n \pm 1} (\phi_{n-1}(Q) + \phi_{n+1}(Q)), \end{aligned} \quad (4.68)$$

where  $\phi_n$  is the wavefunction at site  $p$  whose vibrational coordinates are  $Q_m$ , and  $V_Q(m)$  is the electron-lattice interaction with the  $m$ th phonon mode. Also  $J$

are the orbital overlap integrals as previously. Here,  $V_Q$  is taken to be a small perturbation (Holstein, 1959a), and results in a linear displacement in relative coordinates,  $Q_m$ . Solutions to Eq. 4.68 have been derived by Holstein (1959b) for the transfer rate based on time-dependent perturbation theory to yield

$$k_{ET} = \frac{J^2}{\hbar^2 \omega_0} \left( \frac{\pi}{g^2 \text{csch}\left(\frac{\hbar \omega_0}{2k_B T}\right)} \right)^{1/2} \exp\left(-2g^2 \tanh\left(\frac{\hbar \omega_0}{4k_B T}\right)\right), \quad (4.69)$$

taking  $g = g_m = g_{nm}$ . Here  $\omega_0$  is the optical phonon frequency. Thus, using  $E_{pol} = \hbar \omega_0 g_m^2$  from Eq. 4.53 in the high temperature limit of  $k_B T \gg \hbar \omega_0$  this simplifies to

$$k_{ET} = \frac{J^2}{\hbar} \left[ \frac{\pi}{2E_{pol} k_B T} \right]^{1/2} \exp\left(-\frac{E_{pol}}{2k_B T}\right), \quad (4.70)$$

which, from Eq. 4.67, leads to the following thermally activated mobility:

$$\mu_{hop} = \frac{qJ^2 a^2}{6k_B T \hbar} \left[ \frac{\pi}{2E_{pol} k_B T} \right]^{1/2} \exp\left(-\frac{E_{pol}}{2k_B T}\right). \quad (4.71)$$

At large  $T$  where the thermal energy is higher than the polaron energy, the value of the exponential term is 1, leading to  $\mu \sim T^{-3/2}$ , characteristic of band transport. Below that temperature, the transport is primarily by diffusion due to hopping to nearest neighbor sites over a potential barrier equal to the polarization energy.

Comparing Eq. 4.68 with the energy expansion in Eq. 4.54, we see that  $V_Q(m) = \frac{\partial E_m}{\partial Q_m} |_{Q=0}$ . Then, in the special case of the symmetric transfer illustrated in Fig. 4.10 along with Eq. 4.55, we obtain for the polaron binding energy:

$$E_{pol}^{loc} = \lambda_{rel} = \frac{1}{2} \sum_m^N M_m \omega_m^2 \Delta Q_m^2(j) = \sum_m^N V_Q^2(m) / 2M_m \omega_m^2. \quad (4.72)$$

As noted above,  $J$  is the orbital overlap integral related to the electronic bandwidth via  $BW = 4J$  in a simple cubic lattice (Holstein, 1959a). Hence, it follows that a small polaron exists when

$$BW = 4J \ll \lambda_{rel} \approx V_Q^2 / 2M\omega_0^2, \quad (4.73)$$

and large polarons dominate when the inequality is reversed. This implies that small polarons dominate at low temperatures and for narrow BWs less than the reorganization energy during charge transfer.

An important prediction of the small polaron model is that the BW narrows with increasing temperature. This is an outcome of the temperature dependence of the overlap integral (Holstein, 1959b, Coropceanu et al., 2007):

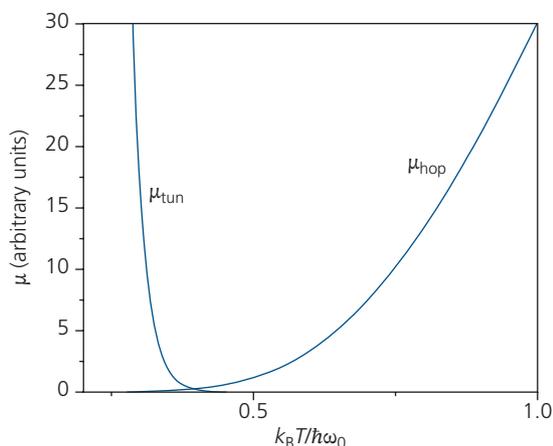

$$J(T) = J \exp(-g^2 \coth(\hbar\omega_0/2k_B T)) \approx J \exp\left(-g^4 \frac{2k_B T}{E_{pol}}\right), \quad (4.74)$$

where, to first order, the approximation on the right is valid for  $E_{pol} < k_B T$ . For  $T \rightarrow 0$ , then  $J(T) = J$ . From tight binding theory (Section 4.1.1), the effective mass is  $m^* = \hbar^2/2Ja^2$  (c.f. Eq. 4.29). But if the bands are sufficiently narrow in weakly coupled molecular systems, all states are equally populated. Furthermore, since the electron can hop forward or backward in all three dimensions, the relaxation time is given by  $\tau = 1/3k_{ET}$ . Then the tunneling mobility at low temperature is

$$\mu_{tun} = \frac{qa^2}{3k_B T \hbar^2 k_{ET}} J^2(T) \quad (4.75)$$

(cf. Eq. 4.71). The temperature dependence of the mobility separates the hopping from the tunneling regimes at  $T_{BH}$  in Fig. 4.14. This transition is shown in detail in Fig. 4.15 for a coupling,  $g^2 = 10$  and a BW equal to twice the optical phonon frequency, corresponding to  $J = \hbar\omega_0$ .

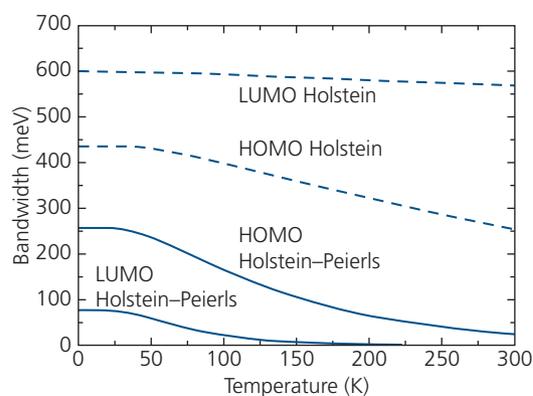

Finally, we note that the hopping mobility is only accurately determined when both on-diagonal and off-diagonal (corresponding to local and non-local) couplings are considered. The Holstein model treats only on-diagonal terms ( $g_{nm} = 0$ ) whereas the Peierls

**Figure 4.15** Mobility transition between tunneling and hopping as determined from small polaron theory. The bandwidth,  $2J$ , decreases with increasing temperature, resulting in a decrease in tunneling probability and hence  $\mu_{tun}$ , along with an increase in thermally activated hopping. For this calculation,  $g^2 = 10$  and  $J = \hbar\omega_0$  (Coropceanu et al., 2007).

model considers systems where  $g_m = 0$ , that is, only non-local terms are present. Both of these effects have been incorporated to provide explicit expressions combining both local and non-local couplings while also accounting for crystalline anisotropy (Munn and Silbey, 1985, Hannewald et al., 2004). It is found that the polaron transport BW due solely to local coupling is  $\sim 100$  meV, but both the shape and the width of the transport bands are significantly impacted by off-diagonal disorder. These couplings add  $\sim 10 - 30$  meV to the polaron binding energy arising from intermolecular phonon interactions, and hence cannot be ignored. Their inclusion in our analysis, however, does not qualitatively change the conclusions although they impact the magnitude of the observed effects.

In Fig. 4.16 we compare the HOMO and LUMO BWs as functions of temperature for naphthalene using only on-site local (Holstein) interactions, with a combination of local and non-local (Holstein–Peierls) couplings that indicates the influence of intermolecular vibronic interactions (Hannewald et al., 2004). There are several features to note in this comparison. The first is that the BWs are considerably overestimated, and the decrease in BW with  $T$  is reduced if off-diagonal disorder is ignored. That is, the LUMO BW from the Holstein model ( $g_{nm} = 0$ ) is 600 meV at  $T = 0$  K, decreasing by only  $\sim 30$  meV as  $T$  is increased to 300 K. This compares to  $BW = 75$  meV at  $T = 0$  K and a decrease of approximately that same magnitude between 0 K and 200 K when incorporating both on- and off-diagonal couplings. It is also striking that the BW of the LUMO level for the Holstein approximation

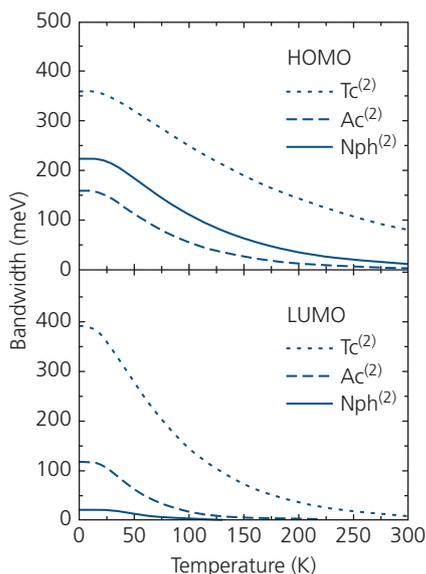

**Figure 4.16** Calculations of the LUMO and HOMO bandwidths of naphthalene assuming only local (on-diagonal) couplings corresponding to the Holstein model, along with local plus non-local (off-diagonal) couplings of a combine Holstein–Peierls model (Hannewald et al., 2004).

Reprinted figure with permission from Hannewald, K., Stojanovic, W. M., Schellekens, J. M. T., Bobbert, P. A., Kresse, G. & Hafner, J., *Physical Review B*, 69, 075211, 2004. Copyright 2004 by the American Physical Society.

is larger than for the HOMO, whereas the opposite obtains in the case of the Holstein–Peierls solution. Indeed, it has been experimentally determined that the hole mobility in naphthalene is larger than its electron mobility (see Fig. 4.12), suggesting that intermolecular polaronic interactions giving rise to the larger HOMO BW ( $\sim 250$  meV at  $T = 0$  K) in the Holstein–Peierls model are an essential part of an accurate calculation of the molecular transport properties. When considering both on- and off-diagonal couplings, the LUMO and HOMO BWs are smaller and their dependence on temperature is larger than for cases where only intramolecular couplings are included.

In Fig. 4.17 we show the dependence of BW on temperature for several linear polyacenes. Most noticeable is that the LUMO BW at  $T = 0$  K increases monotonically with the number of fused benzene rings, from naphthalene (with 2 rings) where  $BW = 20$  meV, to tetracene (4 rings) with  $BW = 400$  meV. A similar monotonic dependence is not seen for the HOMO levels, although the ordering is approximately consistent with this “rule.” The trend with molecular size follows from the more extended  $\pi$ -system that permits a larger orbital overlap (and hence intermolecular interactions), which results in the increased BW. However, crystal symmetry and anisotropy, molecular shape and lattice structure play important roles in determining the couplings,  $g$  and  $J$ , and hence these factors can affect the observed trends in unexpected ways, as apparent in Fig. 4.17.

**Figure 4.17** Bandwidth of the HOMO and LUMO levels as functions of temperature of three linear polyacenes: Nph = naphthalene, Ac = anthracene, and Tc = tetracene (Hannewald et al., 2004).

An interesting observation is that the high temperature BWs for electrons are considerably smaller than for holes, leading to a concomitant reduction in the mobility of the former. These calculations do not include all effects (particularly disorder) and hence are only approximations to the physical properties of the systems themselves. The asymmetry in BWs may be due to intermolecular interactions of the filled HOMO orbitals that stabilize the orbital overlap (and hence crystal structure) even as temperature is increased. In contrast, the empty LUMO bands are not similarly stabilized, and hence their BW decreases more rapidly as temperature is increased. This leads to the higher mobilities for holes than electrons observed for polyacenes and associated molecules such as PTCDA (Forrest et al., 1984b).

Note that small BW narrowing from 240 meV at  $T = 120$  K, to 190 meV at room temperature has been observed in pentacene nanocrystals using ARUPS (Koch et al., 2006). This is within a factor of 2-3 of calculations for the HOMO levels in similar linear polyacenes in Fig. 4.17.

### 4.3.2 Hopping in the presence of static disorder

Since organic crystals are particularly prone to defects, the effects of static disorder cannot be ignored. Referring to Eq. 4.40, static disorder is important when  $H_e^{stat} \gg H_{e-ph}^{loc}, H_{e-ph}^{loc}, H_e^{tr}$ . Unlike dynamic disorder, the potential environment of nearest neighbors is not identical, and hence the probabilities for a forward *vs.* a reverse hop are not always equal. There are two models used for site hopping in the presence of disorder; one due to Miller and Abrahams, and the other to Marcus.

#### 4.3.2.1 Miller–Abrahams electron transfer

Miller and Abrahams developed a theory for impurity band conduction in semiconductors that was later successfully adapted to molecular materials. Impurity band conduction occurs by hopping from one dopant atom to the next in a heavily doped (degenerate) semiconductor. Hence, the process is analogous to that which occurs in organics, where hopping between individual molecules leads to scattering at each hopping site. In this formulation, the rate of hopping from site  $i$  to site  $j$  is given by (Miller and Abrahams, 1960, Ambegaokar et al., 1971, Fishchuk et al., 2002)

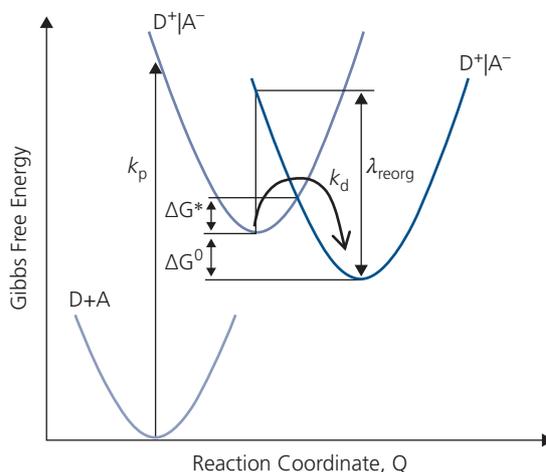

$$k_{ET,ij} = v_0 \exp(-2\gamma_{ij}R_{ij}) \begin{cases} \exp\left(-\frac{E_j - E_i}{k_B T}\right) & E_j > E_i \\ 1 & E_j < E_i \end{cases} \quad (4.76)$$

where  $E_i$  and  $E_j$  are the energies of the initial and final sites, respectively, separated by distance,  $R_{ij}$ ,  $\gamma_{ij}$  is the orbital overlap factor, and  $\nu_0$  is the “attempt frequency,” that is, the rate at which a charge attempts to overcome the energy barrier between nearest neighbor molecules. To reasonable approximation,  $\nu_0$  is equal to the highest energy (optical phonon) frequency. The overlap factor is the degree to which the wavefunction on site  $i$  ( $\phi_i(\mathbf{r}_i)$ ) overlaps that on site  $j$ , that is,  $\gamma_{ij} \sim \langle \phi_i(\mathbf{r}_i) | \phi_j(\mathbf{r}_i - \mathbf{R}_j) \rangle$  (cf. Eq. 4.15). The exponential prefactor in Eq. 4.76 thus gives the spatial decay of the wavefunction with distance from the original molecular site, similar to the dependence of exchange transfer for excitons (Section 3.8.2). This points to an important aspect of charge transfer: the probability for transfer decays rapidly with distance since it entails tunneling between adjacent molecules. This results in more rapid transfer, and hence higher charge mobility, for tightly  $\pi$ -stacked molecular crystals where the disorder is minimal. As disorder increases, due for example to the formation of boundaries at the edge of nanocrystalline domains, we expect the mobility to decrease accordingly, similar to observations in a decrease in exciton diffusion length with structural disorder (Lunt et al., 2010 and Chapter 3.9).

Another feature of Miller–Abrahams theory is that the rate from  $E_i$  to  $E_j$  is thermally activated when  $E_j > E_i$ , that is, endothermic processes require the absorption of a phonon whose probability is expressed by a Boltzmann factor. On the other hand, exothermic transfer occurs when  $E_i > E_j$  with unity probability. In both cases, the rate is modified by the magnitude of orbital overlap between the initial and final electronic states.

#### 4.3.2.2 Marcus electron transfer

An alternative and more physically consistent model for CT reactions in solutions was introduced by Marcus; an accomplishment that earned him the Nobel Prize in 1992 (Marcus, 1956, 1993). This theory is equally applied to charge transfer in solids, and predicts phenomena that are absent from the Miller–Abrahams formulation. In the Marcus picture, electron transfer occurs between the outer sphere (i.e. orbital) of a donor molecule to that of an acceptor illustrated in the free energy ( $G$ ) vs. reaction coordinate ( $Q$ ) diagram of Fig. 4.18. It is convenient to express the total system energy in terms of the *Gibbs free energy* which avoids multidimensional considerations of the many hundreds, if not thousands, of electronic, vibronic, and spin coordinates of the reactant and product involved in the transfer.

**Figure 4.18** Electronic manifolds involved in a charge transfer reaction according to Marcus theory. The diagram shows the initial ( $D+A$ ), precursor ( $D^+|A^-$ ), and final ( $D^+|A^-$ ) dissociated states.

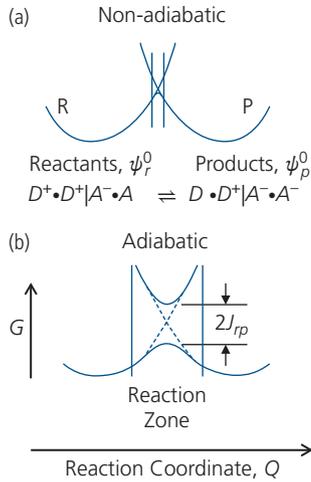

Indeed, it is this insight of Marcus that allows conversion to an  $N$ -dimensional space of molecular coordinates for the initial, precursor and dissociated systems to a single energetic representation that makes the problem of charge transfer tractable. A further assumption is that the Franck–Condon principle is operative; that is electron transfer occurs before the molecular nuclei can adjust.

Charge transfer occurs by a process that starts with the *precursor*  $D|A$ , moving through an intermediate *successor*  $D^+|A^-$ , finally resulting in *dissociation* via the following steps:

The rates of each process are indicated, including their reverse, or back-transfer rates. Thus,  $k_p$  is the forward precursor formation rate,  $k_{ET}$  is the rate of electron transfer to form the successor (or reactant) state, and  $k_d$  is the dissociation rate into a charge pair (or product state) that completes the transfer. In Fig. 4.19 we show the case where  $k_{ET} \gg k_p, k_d$ , and hence  $D|A \rightarrow D^+|A^-$  is not the rate-limiting step. The changes in free energy,  $\Delta G^0$  between the  $D^+|A^-$  and the dissociated state, and the barrier between them,  $\Delta G^*$ , are shown. As previously, molecular reorganization that occurs during transfer results in a reduction of the total energy by  $\lambda_{reorg}$ , see Eqs. 4.55 and 4.59.

There are two possibilities for electron transfer: the first is *non-adiabatic transfer* where the reactant–product (i.e. donor–acceptor) coupling integral,  $J_{RP}$ , is small, and the second is *adiabatic electron transfer*

**Figure 4.19** (a) Non-adiabatic and (b) adiabatic electron transfer. Reaction zones are delineated by vertical lines. After Newton (1991).

where  $J_{RP}$  is large. In analogy to Eq. 4.47, we can express the coupling as

$$J_{RP} = \langle \psi_R^0(\mathbf{r} - \mathbf{R}_R) | H_e | \psi_P^0(\mathbf{r} - \mathbf{R}_P) \rangle, \quad (4.78)$$

where  $\psi_{R,P}^0$  are the initial wavefunctions of the reactants and products, respectively, and  $H_e$  is the Born–Oppenheimer electronic Hamiltonian for the system. The rate of transfer for weak, or non-adiabatic coupling is limited by the energy barrier height,  $\Delta G^*$ , that can be surmounted by thermal or optical excitation, or by tunneling following the path  $R \Rightarrow P$  in Fig. 4.19a. The rate of transfer in this case can be calculated using Fermi’s Golden Rule. For strong coupling, the upper and lower branches are split at their intersection by energy  $2J_{RP}$ , and adiabatic transfer between the reactant and product states occurs as in Fig. 4.19b. Note that the *reaction zone*, corresponding to the region over which the coordinate changes to move from the reactant to the product state, is larger, and the transition more gradual for strongly coupled adiabatic vs. non-adiabatic systems.

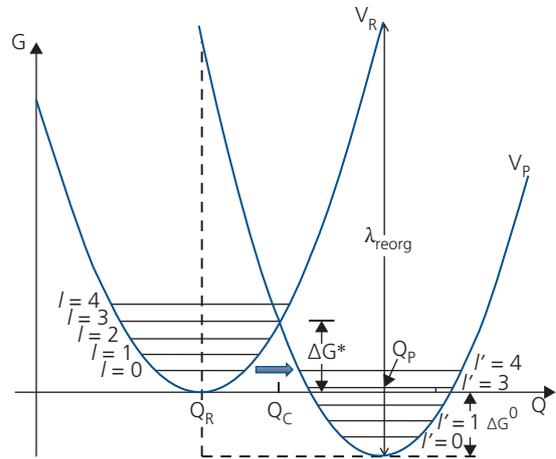

To determine the Gibbs free energy barrier,  $\Delta G^*$ , we refer to Fig. 4.20. Assuming that the potential surfaces for the approximately parabolic reactant and product states are undistorted by the transfer, then at the point of crossing:

$$V_R(Q_C) = V_P(Q_C). \quad (4.79)$$

If the curvature (i.e. the force constant) of these states is  $\kappa$ , then from the crossing point,  $Q_C$ :

$$\frac{1}{2}\kappa(Q_C - Q_R)^2 = \Delta G^0 + \frac{1}{2}\kappa(Q_C - Q_P)^2. \quad (4.80)$$

Furthermore, the reorganization energy is given by

**Figure 4.20** Representation of the reactant and product states with potentials  $V_R(Q)$  and  $V_P(Q)$ , respectively. Tunneling (block arrow) from the  $l = 0$  to the  $l' = 4$  vibronic mode and thermal activation over barrier  $\Delta G^*$  are two processes leading to charge transfer.

$$\lambda_{reorg} = \frac{1}{2}\kappa(Q_P - Q_R)^2 \quad (4.81)$$

and the energy barrier is

$$\Delta G^* = \frac{1}{2}\kappa(Q_C - Q_R)^2. \quad (4.82)$$

Combining the results of Eqs. 4.80–4.82 we arrive at:

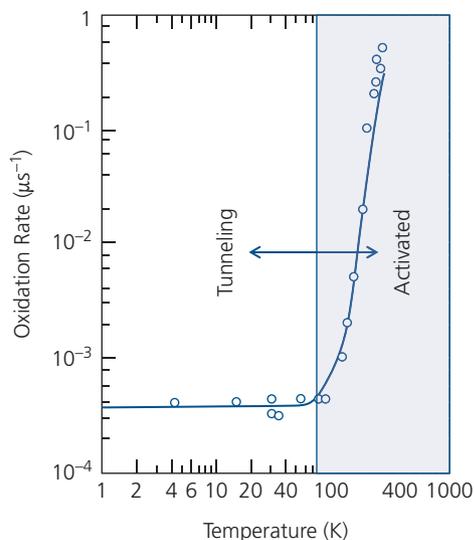

$$\Delta G^* = \frac{1}{4\lambda_{reorg}}(\lambda_{reorg} + \Delta G^0)^2. \quad (4.83)$$

In classical Marcus theory, the transfer across this energy barrier is thermally activated, in which case the rate of transfer is given by:

$$k_{ET} = A \exp\left[-\frac{\Delta G^*}{k_B T}\right] = A \exp\left[-\frac{(\lambda_{reorg} + \Delta G^0)^2}{4\lambda_{reorg} k_B T}\right]. \quad (4.84)$$

A striking difference between this expression and Eq. 4.76 for the Miller–Abrahams model is that there is no separate treatment for downward or upward steps; the electron transfer rate is simply due to the change in free energy of the entire system,  $\Delta G^*$ .

One prediction of Eq. 4.84 is that the transfer rate vanishes in the limit of  $T \rightarrow 0$ . However, this is not found to be the case; the transfer rate is indeed thermally activated at high temperature but achieves a non-zero asymptotic value at low temperature. The lack of complete quenching of the rate of oxidation in *Chromatium* is evident from the data in Fig. 4.21. The persistence of electron transfer at low temperature is due to quantum mechanical tunneling through the

**Figure 4.21** Rate of electron transfer from cytochrome to chlorophyll in *Chromatium* molecules as determined by changes in optical density vs. temperature. The rate decreases to a steady state, tunneling-limited value of  $\sim 4 \times 10^{-4} \mu\text{s}^{-1}$  at  $T < 80$  K. At higher temperatures the rate is thermally activated (Jortner, 1976)

barrier separating the reactant and product states. This process occurs between the vibronic states of the  $R$  and  $P$  electronic manifolds (Fig. 4.20), and hence the full wavefunction including electronic and nuclear coordinates,  $\Phi(\mathbf{r}, Q) = \phi_e(\mathbf{r}, Q)\phi_N(Q)$ , must be employed to calculate the transition rate.

We can estimate the boundary between the quantum and classical regimes based on the phonon (i.e. vibronic) modes in the initial and final states that are coupled via tunneling transfer. That is, the process is adequately described by the classical picture if the thermal energy is greater than the energy of the  $l$ th vibronic with energy  $\hbar\omega_l$  in  $V_P$  into which the electron transfers. At  $k_B T < \hbar\omega_l$ , the treatment fails and quantum mechanical tunneling dominates the transfer reaction.

From Fermi's Golden Rule in the Franck–Condon approximation, the transfer rate is

$$k_{ET} = \frac{2\pi}{\hbar} |\langle \phi_{eR} | H | \phi_{eP} \rangle|^2 |\langle \phi_{NR} | \phi_{NP} \rangle|^2 \rho(E_P), \quad (4.85)$$

where  $\rho(E_P) = \delta(E_R - E_P)$  is the density of product states around  $E_P = E_R$ . The first term is due to electronic states, and the second is the nuclear Franck–Condon factor weighted by the DOS, that is,

$$FC_p = |\langle \phi_{NR} | \phi_{NP} \rangle|^2 \rho(E_P). \quad (4.86)$$

Writing the energy expended in mixing the initial and final electronic states as the familiar transfer integral

$J_{RP} = \langle \phi_{eR} | H_e | \phi_{eP} \rangle$  that involves only the electronic part of the Hamiltonian,  $H_e$ , Eq. 4.85 becomes

$$k_{ET} = \frac{2\pi}{\hbar} J_{RP}^2 FC_p. \quad (4.87)$$

The remaining challenge is to evaluate the matrix elements. For this treatment we consider only non-adiabatic (i.e. weakly coupled) transfer. Then the total Hamiltonian of the system is given by (Barbara et al., 1996)

$$\begin{aligned} H = & |\phi_{eR}\rangle \langle \phi_{eR}| \left( E_R^0 + \frac{1}{2} \sum_l \kappa_l (Q_l - Q_{R,l})^2 \right) \\ & + |\phi_{eP}\rangle \langle \phi_{eP}| \left( E_P^0 + \frac{1}{2} \sum_l \kappa_l (Q_l - Q_{P,l})^2 \right) \\ & + (|\phi_{eR}\rangle \langle \phi_{eP}| + |\phi_{eP}\rangle \langle \phi_{eR}|) J_{RP} \end{aligned} \quad (4.88)$$

Here,  $E_R^0$  and  $E_P^0$  are the unperturbed initial reactant and product energies, and  $\kappa_l$  is the force constant of the  $l$ th mode. This generalization of the parabolic potential approximation requires only a single value of  $\kappa$ . The summations in Eq. 4.88 are over all vibronic modes. The first term corresponds to the unperturbed reactant state, the second to the product state, and the last term is the interaction that leads to electron transfer due to overlap of the electronic orbitals,  $\phi_{eR}$  and  $\phi_{eP}$ . Indeed, due to the orthogonality of  $|\phi_{eR}\rangle$  and  $|\phi_{eP}\rangle$ , it is clear from Eq. 4.85 that only the term in  $J_{RP}$  affects the transfer rate.

The rate has been calculated for non-adiabatic transfer in the low temperature limit for a single coupled mode between two electronic states to yield (Jortner, 1976)

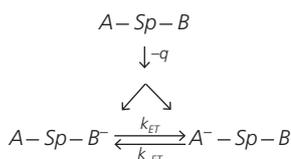

$$\begin{aligned} k_{ET} = & \frac{J_{RP}^2}{\hbar} \left( \frac{\pi}{\lambda_{reorg} k_B T} \right)^{1/2} \sum_l \frac{S^l}{l!} \exp(-S) \\ & \times \exp \left[ \frac{-(\lambda_{reorg} + l\hbar\omega + \Delta G^0)^2}{4\lambda_{reorg} k_B T} \right]. \end{aligned} \quad (4.89)$$

In this expression, it is assumed that the transition occurs from the lowest ( $l = 0$ ) vibronic with frequency  $\omega$  in  $R$ , to  $l'$  in  $P$ . The sum takes into account the transfer from the initial mode into a distribution of final modes whose probability is determined by Boltzmann statistics. Here,  $S^l$  is the *Huang–Rhys parameter* (Huang and Rhys, 1950, Jortner, 1976) that gives the electron–phonon coupling strength in the localized molecular states, see Eq. 3.110. The energy released in electron transfer is thus modified such that  $\Delta G^0 \rightarrow \Delta G^0 + l'\hbar\omega$  in the transfer from  $0 \rightarrow l'$ . Furthermore, the maximum term in the sum is at  $-|\Delta G^0| \sim \lambda_{reorg} + l'\hbar\omega$  where there is the closest energy match between initial and final

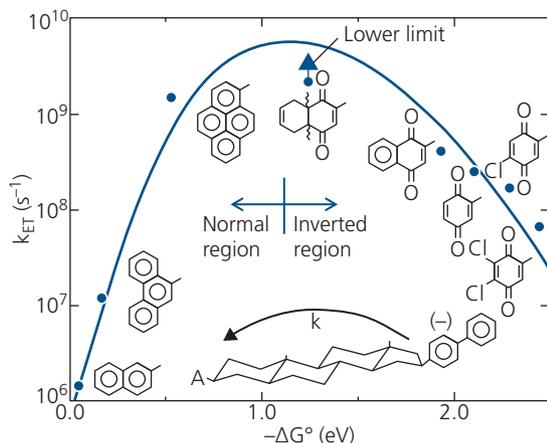

charge transfer for a series of compounds with an A-Sp-B structure, where A is one of eight  $\pi$ -conjugated molecules ranging from 4-biphenyl to 5,6-dichlorobenzoquinon-2-yl, Sp is a rigid 5 $\alpha$ -androstande skeleton spacer, and B is 4-biphenyl. The molecules were dissolved in MeTHF. Transient optical absorption probed the time for the compound to equilibrate following the CT reaction in Fig. 4.23. The charge transfer rate between B and A across the molecular bridge vs. free energy was determined for each compound, with results in Fig. 4.24. The solid line is a fit to Marcus theory, assuming that the reorganization is equal to the sum of the contributions from solvent reorganization (0.75 eV) and the change in internal vibrational modes during transfer (0.45 eV) (Miller et al., 1984). Since a large fraction of  $\lambda_{reorg}$  is due to the solvent, data were also taken by dissolving the molecules in isoctane, where it was found that the peak of the curve shifts according to predictions of Marcus theory.

An example of *intermolecular* Marcus inversion has been observed between contacting molecules across a series of heterojunctions (HJs) comprising

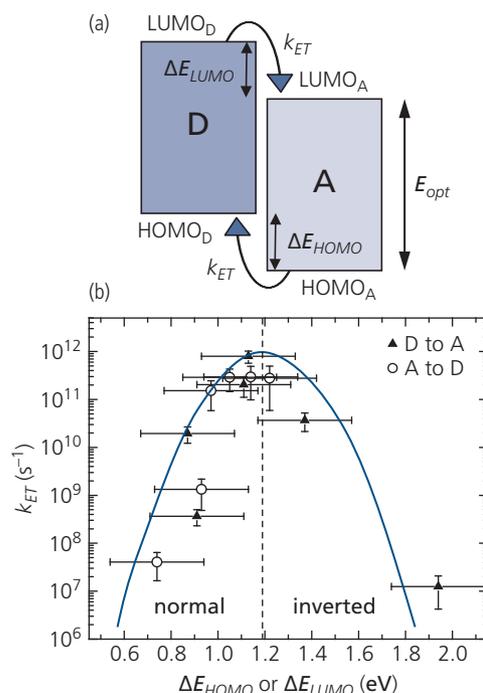

**Figure 4.23** Charge transfer route in A-Sp-B compounds. The neutral compound (top) undergoes reduction, and then reversibly transfers between A-Sp-B<sup>-</sup> and A<sup>-</sup>-Sp-B.

**Figure 4.24** Intramolecular electron transfer rate,  $k_{ET}$ , for a series of A-Sp-B compounds. The solid line is a fit to Marcus theory with a peak in electron transfer rate defining the point  $\Delta G^0 = \lambda_{reorg} = -1.23$  V. To the right of that point is the inverted region (Miller et al., 1984).

neat films of the donor and acceptor molecules, with results shown in Fig. 4.25 (Rand et al., 2007). The electron transfer rate parameters,  $\lambda_{reorg}$  and  $J_{RP}^2$ , and consequently  $k_{ET}$  in Eq. 4.91 were determined from the dark current of each donor-acceptor pair listed in Table 4.1. The dark current is measured by sandwiching the HJ between metal electrodes, and then applying a small voltage. The current is due to the difference in the probability of forward transitions from a filled initial state with occupation probability  $f_i$  as determined by Fermi-Dirac statistics, to an empty final state with occupation probability  $(1 - f_f)$ , and reverse transitions from an occupied final to an empty initial state. The rates of forward and reverse transfer are equal, at  $k_{ET,if}$ . Since  $f \rightarrow i$  must overcome a barrier due to relaxation after transfer, its rate is weighted by a Boltzmann factor,  $\exp(-\Delta E_{if}/k_B T)$ . Then, the current density is given by (Nelson et al., 2004)

$$j = q\rho dk_{ET,if} (f_i(1 - f_f) - \exp(-\Delta E_{if}/k_B T)f_f(1 - f_i)). \quad (4.93)$$

**Figure 4.25** (a) Energy level diagram for a heterojunction between a donor (D) and acceptor (A) layer. Charge transfer is indicated by curved arrows. Energy offsets at the HOMO are  $\Delta E_{HOMO}$ , and at the LUMO are  $\Delta E_{LUMO}$ . (b) Electron transfer rate for several donor and acceptor junctions, showing the normal and inverted regions. Donor-to-acceptor transfer (D→A, filled triangles) versus  $\Delta E_{LUMO}$  and acceptor-to-donor transfer (A→D, open circles) vs.  $\Delta E_{HOMO}$  are shown (Rand et al., 2007).

**Table 4.1** Parameters obtained from fitting the current vs. voltage characteristics for the various donor/acceptor interfaces in Fig. 4.26 (Rand et al., 2007)

Donor/acceptor interface	Donor to acceptor		Acceptor to donor		$\lambda_{cv}$ (eV) <sup>c</sup>
	$k_{ccD}$ (s <sup>-1</sup> ) <sup>a</sup>	$\lambda_{ccD}$ (eV) <sup>b</sup>	$k_{ccA}$ (s <sup>-1</sup> ) <sup>a</sup>	$\lambda_{ccA}$ (eV) <sup>a</sup>	
Pentacene/C <sub>60</sub>	$8 \times 10^{11}$	0.9	$3 \times 10^{11}$	1.1	0.8

Pentacene/C <sub>70</sub>	$4 \times 10^{10}$	0.9	$3 \times 10^{11}$	0.7	0.5

<sup>a</sup>  $k_{ccD}$  is the charge transfer rate from  $D \rightarrow A$ ,  $k_{ccA}$  is for  $A \rightarrow D$ .

<sup>b</sup>  $\lambda_{ccD}$  and  $\lambda_{ccA}$  are the reorganization energies for  $D$  and  $A$ , respectively.

<sup>c</sup>  $\lambda_{cv}$  is the reorganization energy for transitions from HOMO to LUMO, that is assumed are equal for  $D$  and  $A$ .

Here  $d$  is the layer thickness and  $\rho$  is the volume density of molecules. Also, the activation energy,  $\Delta E_{if}$ , is equal to either the difference in HOMO energies between donor and acceptor ( $\Delta E_{HOMO}$ ) for transitions  $A \rightarrow D$ , or the difference in LUMO energies ( $\Delta E_{LUMO}$ ) for transitions  $D \rightarrow A$ . It is assumed that the change in system free energy is induced by transfer across the HJ, such that  $E_{if} = \Delta G^0$ , which can be directly measured from the open circuit voltage of the HJ diode under simulated solar illumination (see Section 4.7.2). We will show in Chapter 7 that Marcus transfer in both the inverted and normal regions significantly contributes to voltage losses in organic solar cells.

#### 4.3.2.3 Charge mobility in organic semiconductors with static disorder: the effective medium approximation

Mobilities in almost all small molecule and polymer systems have activation energies of  $\Delta E_a = 0.3$ – $0.6$  eV. Since  $\Delta E_a = E_{pol}/2$  in the non-adiabatic limit (Eq. 4.71), polarization energies of 0.6–1.2 eV are too large to be due solely to reduced coupling arising from purely dynamic disorder. Furthermore, there is often a transition from dispersive to non-dispersive transport as temperature is decreased. Here, *dispersive transport* refers to mobilities that cannot be defined by a single value (see Section 4.4.3). This is inconsistent with dynamic disorder, where transport is governed by small polarons, and hence is temperature independent. Thus, the effects of static disorder must be included to provide a complete description of most organic systems.

As in the case of dynamic disorder, the coupling between molecules is short range, requiring consideration of only nearest neighbor interactions. The master equation for the change in occupancy of site  $i$  during hopping is

$$\frac{\partial f_i(t)}{\partial t} = \sum_{j \neq i}^N \{ -k_{ij} f_i(t) [1 - f_j(t)] + k_{ji}(t) [1 - f_i(t)] \} - k_{rec} f_i(t), \quad (4.94)$$

where  $k_{ij}$  is the hopping rate from  $i \rightarrow j$  as determined by either Miller–Abrahams or Marcus theory, and  $f_i(t) = \{1 + \exp[(E_j - E_F)/k_B T]\}^{-1}$  from Fermi–Dirac statistics. It is the probability for site  $j$  to be occupied at time  $t$ ,  $E_F$  is the Fermi energy, and  $k_{rec}$  is the rate of charge recombination, leading to its loss.

This expression is complicated, and hence we make the following simplifications: (i) only low charge densities are considered, in which case terms in  $f^2$  can be ignored, and (ii) recombination is much slower than charge transfer, allowing us to neglect the last term. Thus, the master equation simplifies to

$$\frac{\partial f_i(t)}{\partial t} = \sum_{j \neq i}^N \{ -k_{ij} f_i(t) + k_{ij} f_j(t) \}. \quad (4.95)$$

From this we can write the current density generated in a layer of thickness,  $d$ :

$$j(\mathbf{r}, t) = q \int g(E) dE \sum_i^N \left[ \frac{\partial f_i(\mathbf{r}_i, E_i, t)}{\partial t} - \frac{\partial f_j(\mathbf{r}_j, E_j, t)}{\partial t} \right]. \quad (4.96)$$

The first term in brackets corresponds to transfers,  $i \rightarrow j$ , whereas the second term accounts for back transfer,  $i \leftarrow j$ . Furthermore,  $g(E)$  is the DOS, such that  $Ng(E)f(E)$  is the total number of occupied states at energy,  $E$ .

The challenge for determining the mobility, therefore, is to calculate the *net* hopping rate  $i \rightarrow j$ , and  $g(E)$ . It is convenient to assume that the states are distributed over an energy space defined by a Gaussian distribution centered around energy  $E_0$  and with width,  $\sigma_{GDM}$ . (Bässler, 1993) This physically intuitive and mathematically manageable assumption is

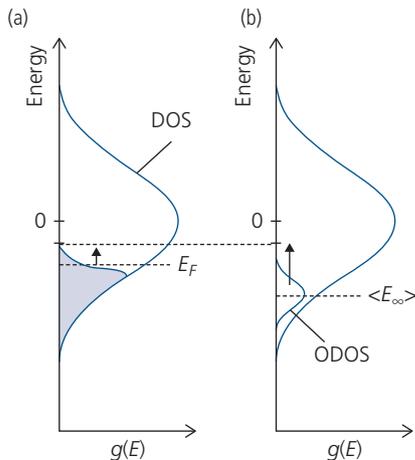

known as the *Gaussian disorder model* (GDM). The GDM distribution is illustrated in Fig. 4.26, and can be expressed by

$$g(E_i) = \frac{N}{\sqrt{2\pi\sigma_{GDM}^2}} \exp\left(-\frac{(E_i - E_0)^2}{2\sigma_{GDM}^2}\right), \quad (4.97)$$

where  $N$  is the density of hopping sites. Since the mean energy can be arbitrarily referenced, it is convenient to set  $E_0 = 0$ , in which case Eq. 4.97 is referred to as the *occupational density of states* (ODOS). This is the equivalent of the actual DOS reduced to a Gaussian centered about the average energy,  $E_\infty$ , given by:

$$\langle E_\infty \rangle = \frac{\int_{-\infty}^{\infty} E g(E) \exp(-E/k_B T) dE}{\int_{-\infty}^{\infty} g(E) \exp(-E/k_B T) dE} = -\frac{\sigma_{GDM}^2}{k_B T}. \quad (4.98)$$

The assumption in this analysis is that the level of injection is low (i.e. the fraction of free charge,  $n$  to the number of available sites,  $N$  is  $\zeta = n/N \ll 1$ ). Thus, the system is non-degenerate, allowing for a replacement of the Fermi-Dirac distribution with the Boltzmann approximation. Further, the organic medium is only weakly disordered and homogeneous. This implies that a single probability function can be used throughout the film volume. The

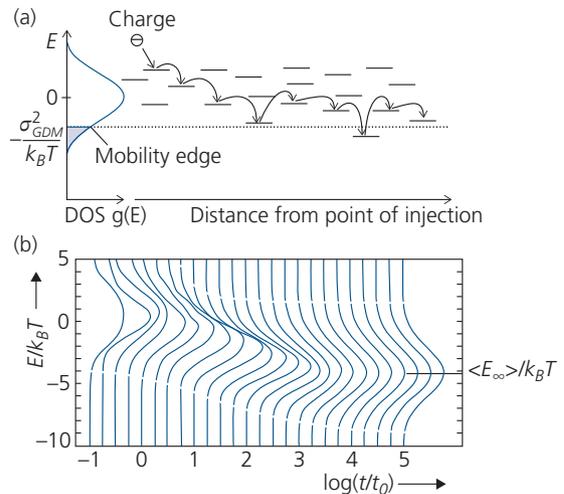

**Figure 4.26** Transport density of states (DOS) due to static disorder. (a) The filled states are shown by the shaded area with a tail extending from the Fermi energy,  $E_F$ , to the transport level (dotted line). (b) The same as in (a) except at very low current injection. The mean energy of the occupational DOS (ODOS) is  $\langle E_\infty \rangle$ . After Köhler and Bässler (2015).

probability for a hopping site to be available is determined by the Gaussian DOS along with Fermi-Dirac statistics. This is known as the *effective medium approximation* (EMA).

In Fig. 4.26a we show the case of moderate charge injection, where the filled states have a tail of width  $\sim 2k_B T$  centered around the Fermi energy,  $E_F$ . Free polarons hop to the empty states into the transport level, which defines the *mobility edge*. Only charges occupying states near  $E_F$  can acquire sufficient energy to hop to unoccupied states, and hence contribute to conduction. For low charge densities, the hopping energy required to reach the mobility edge must be correspondingly larger (Fig. 4.26b), and consequently, the conductivity is reduced.

Figure 4.27a shows the mobility edge for the transport DOS. Monte Carlo calculations have been employed to determine the rate at which equilibrium is reached following the injection of a hot (i.e. at  $E \gg E_F$ ) charge into the transport band. Results in Fig. 4.27b are shown for a distribution of width  $\sigma_{GDM} = 2k_B T$ . The dwell time between each step is given by  $1/t_0 = 6v_0 \exp(-2\gamma a)$  (see Eq. 4.76), where a simple cubic lattice with edge length,  $a$ , is assumed, and the factor of 6 accounts for all possible nearest neighbor hops. Since the

**Figure 4.27** (a) Equilibration of a hot charge in both space and energy via a series of intermolecular hops from disordered states whose energy distribution is described by the Gaussian disorder model. The mobility edge, that is, the equilibrium energy of the filled states is shown. (b) Monte Carlo calculation of the relaxation to the equilibrium energy,  $\langle E_\infty \rangle$ , of a distribution of charges injected at reference energy  $E = 0$  into a density of states of width  $\sigma_{GDM} = 2k_B T$ . The dwell time between steps is  $t_0$ . After Bässler (1993).

time follows a logarithmic scale, it is apparent that it takes many hops and a considerable distance before the charge distribution fully equilibrates.

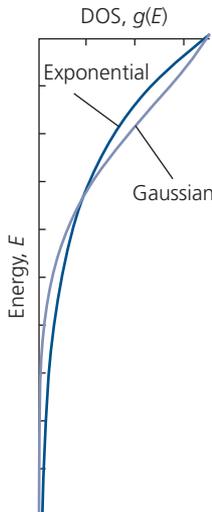

Note that the GDM represents only one of several possible functions that can be used to represent the transport DOS,  $g(E)$  (Tessler et al., 2009). A uniform DOS with  $g(E) = \text{constant}$  can be employed for its calculational simplicity, although it does not accurately represent the situation in disordered media. Alternatively, the tail in a Gaussian distribution can be approximated by an exponential DOS given by

$$g(E) = \frac{N}{k_B T_T} \exp\left(-\frac{E}{k_B T_T}\right), \quad (4.99)$$

where  $T_T$  is the *characteristic trap temperature*. A comparison between a Gaussian and exponential DOS is provided in Fig. 4.28. The exponential function has a longer, more gentle roll-off than the Gaussian. Given that the exponential distribution is readily adaptable to analytical solutions of the master transport equation, it is often used to model trap-limited transport and injection from contacts, as discussed in greater detail in Section 4.4.

With the assumption of a Gaussian density distribution, we can proceed to calculate the mobility in a one-dimensional electric field  $\mathbf{F} = \{F, 0, 0\}$ . Once more assuming molecules are arranged on a cubic lattice with side,  $a$ , then the mobility is given by the difference in the rate of jumps from  $i \rightarrow j$  vs.  $i \leftarrow j$  (Fishchuk et al., 2003):

$$\mu = a \frac{k_{ij} - k_{ji}}{F}. \quad (4.100)$$

**Figure 4.28** Comparison between a Gaussian and exponential DOS.

The rates are given by Miller–Abrahams theory (Eq. 4.76) where the energy difference now includes the driving force provided by the electric field, viz.

$$k_{ij} = v_0 \exp(-2\gamma_{ij}a) \times \exp\left[-\frac{|E_j - E_i| + E_j - E_i + q(\mathbf{r}_j - \mathbf{r}_i) \cdot \mathbf{F}}{2k_B T}\right]. \quad (4.101)$$

This must be weighted by the Gaussian DOS in Eq. 4.97 to account for hops from states at or near the mobility edge. Alternatively, the hopping rate can be calculated using Marcus theory (Eq. 4.89):

$$k_{ij} = \frac{J_{RP}^2}{\hbar} \left(\frac{\pi}{\lambda_{reorg} k_B T}\right)^{1/2} \sum_l \frac{S^l}{l!} \exp(-S) \times \exp\left[\frac{-(\lambda_{reorg} + l'\hbar\omega + \Delta G^0 + q(\mathbf{r}_i - \mathbf{r}_j) \cdot \mathbf{F})^2}{4\lambda_{reorg} k_B T}\right] \quad (4.102)$$

with  $\Delta G^0 = E_j - E_i$ . We must similarly weight this expression by the DOS.

Solving Eq. 4.100, we arrive at two analytical expressions for the mobility depending on the hopping rate employed. For Miller–Abrahams hopping at “small” electric fields in the range:  $k_B T \ll qaF \ll \langle E_\infty \rangle$ , that is, where the field-induced hopping is larger than thermally activated hops, yet it is smaller than the mean energy of the DOS, then (Fishchuk et al., 2003)

$$\mu = \frac{\sigma_{GDM} v_0}{\sqrt{2\pi} q F^2} \exp(-2\gamma a) \cdot \exp\left[-\frac{1}{2} \left(\frac{\sigma_{GDM}}{k_B T}\right)^2\right] + \frac{1}{\sqrt{2}} \left[ \left(\frac{\sigma_{GDM}}{k_B T}\right)^{3/2} - \left(\frac{\sigma_{GDM}}{k_B T}\right)^{1/2} \right] \sqrt{\frac{qaF}{\sigma_{GDM}}}. \quad (4.103)$$

Similarly, for Marcus theory in the low temperature-low field limit, and assuming that transfer only occurs from  $l = 0$  to the lowest vibronic state in the product,  $l' = 0$ , then

$$\mu = \frac{\sigma_{GDM} \xi}{\sqrt{2\pi} q F^2} \left[ \frac{J_{RP}^2}{\hbar} \sqrt{\frac{\pi}{4E_A k_B T}} \right] \cdot \exp\left[-\frac{E_A}{k_B T} - \frac{1}{8\xi^2} \left(\frac{\sigma_{GDM}}{k_B T}\right)^2\right] + \frac{1}{2\sqrt{2}\xi^2} \left[ \left(\frac{\sigma_{GDM}}{k_B T}\right)^{3/2} - \left(\frac{\sigma_{GDM}}{k_B T}\right)^{1/2} \right] \sqrt{\frac{qaF}{\sigma_{GDM}}} \quad (4.104)$$

where  $\xi = [1 - \langle E_\infty \rangle / (8E_A)]^{1/2}$  and we have replaced the reorganization energy with the mobility activation energy, that is,  $\lambda_{reorg} = E_A$ . This allows for a direct comparison with experiment.

There are clear similarities, and some notable differences between the expressions in Eqs. 4.103 and 4.104:

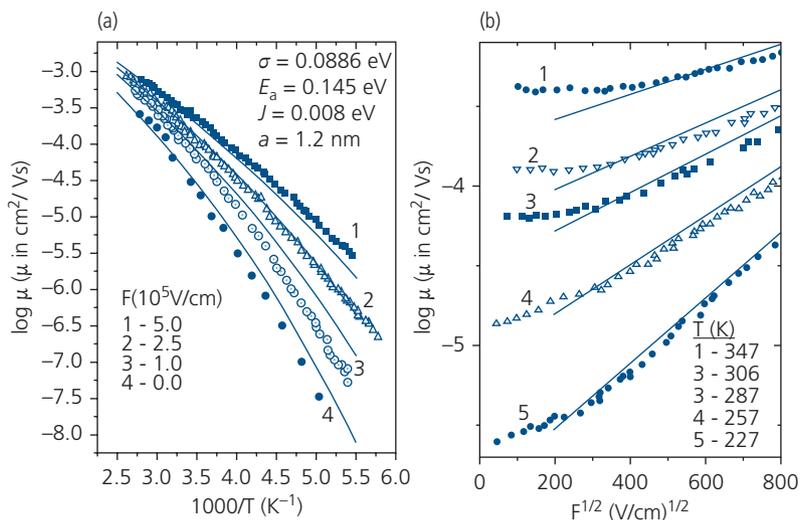

- (i) Both Miller–Abrahams and Marcus theories predict a dependence on electric field that follows  $\mu \sim \exp(-A\sqrt{F})$ . This is a characteristic of the *Frenkel–Poole effect* (Sze, 1981) where the barrier to electron emission from a molecule to its neighbor is lowered by the applied electric field.
- (ii) The mobility in both cases decreases exponentially with molecular separation (see Eq. 4.92). Again, this is consistent with charge tunneling between orbitals on nearest neighbors, which increases rapidly as molecular separation,  $a$ , decreases.
- (iii) Both expressions predict that  $\mu \sim \exp[-B/(k_B T)^2]$  at high temperature, which is strikingly different from conventional thermal activation that follows  $\mu \sim \exp[-E_A/k_B T]$ . However, at low temperatures there is a deviation from the  $1/T^2$  behavior, with notable differences between predictions by Miller–Abrahams vs. Marcus theories, although distinguishing these differences from mobility data may not be possible unless the transport is clearly non-dispersive (see Section 4.4.3).
- (iv) The expressions primarily differ by the reorganization energy in the exponential term,  $E_A$ , and the transfer integral,  $J_{RP}$  that appear in the Marcus formula, Eq. 4.104.
- (v) Both expressions are consistent with Monte Carlo calculations of the mobility that result in the

following empirical temperature- and electric field-dependent mobility (Bässler, 1993):

$$\mu = \mu_0 \exp\left(-\left(\frac{2\sigma_{GDM}}{3k_B T}\right)^2\right) \times \begin{cases} \exp\left[C\left(\left(\frac{\sigma_{GDM}}{k_B T}\right)^2 - \Sigma^2\right)\sqrt{F}\right] & \Sigma \geq 1.5 \\ \exp\left[C\left(\left(\frac{\sigma_{GDM}}{k_B T}\right)^2 - 2.25\right)\sqrt{F}\right] & \Sigma < 1.5 \end{cases} \quad (4.105)$$

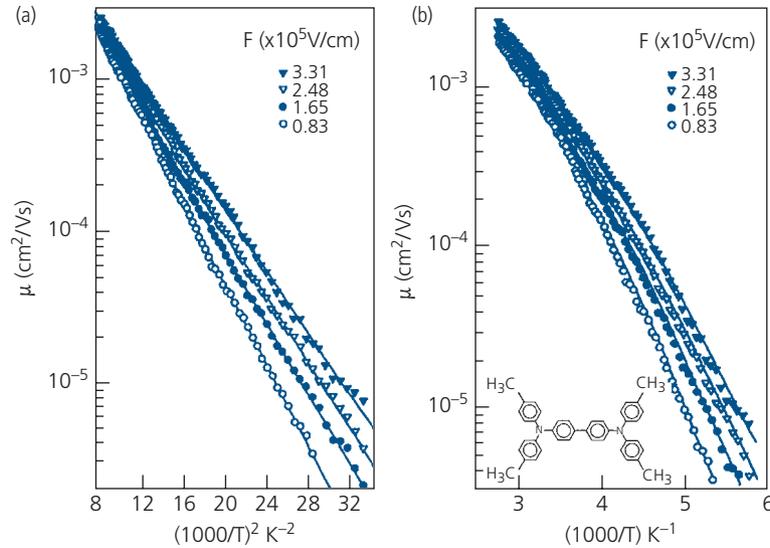

For these expressions, it is assumed that the overlap parameter,  $2\gamma a$ , also has a Gaussian form. This results from application of the *central limit theorem* to account for the varying separation and orientation of molecules in a disordered solid. The variance is given by  $\Sigma$ , and determined by the magnitude of the off-diagonal disorder. Then the ensemble average of the mobility is  $\langle \mu \rangle = \mu(\Sigma = 0) \exp(\Sigma^2/2)$ .

The mobility dependence on  $F$  and  $T$  for the polymer, PMPSi measured using the time of flight method (Bässler et al., 1994) has been fit to Eq. 4.104, with results shown in Fig. 4.29. The temperature dependence is reasonably well fit by an activation that follows  $\mu \sim \exp[-B/(k_B T)^2]$ , although it is often difficult to distinguish between this functional dependence and that due to simple thermal activation of  $\mu \sim \exp[-E_A/k_B T]$  (Fishchuk et al., 2003). The high field dependence is consistent with Frenkel–Poole emission. Note, however, that the mobility is not expected to increase indefinitely since scattering

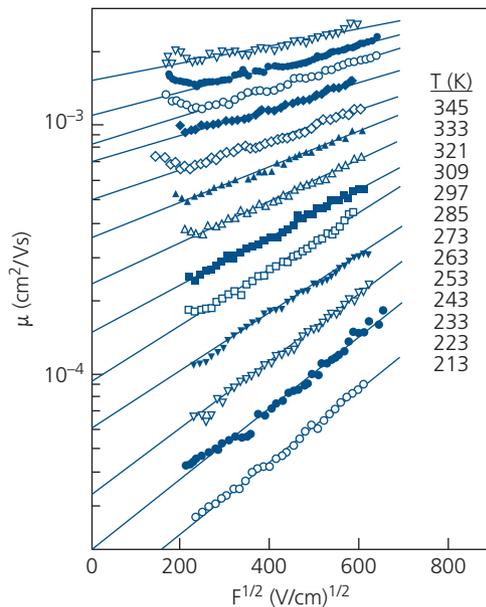

**Figure 4.29** Mobility (data points) vs. (a) temperature and (b) electric field for PMPSi along with fits (lines) assuming Marcus electron transfer in the presence of static disorder. Parameters used in the fits are shown in the legends (Fishchuk et al., 2003).

**Figure 4.30** Mobility vs. temperature with electric field as parameter for the molecule, TTB. (a)  $\mu \sim \exp[-B/(k_B T)^2]$  characteristic of the static disorder model. (b)  $\mu \sim \exp[-E_A/k_B T]$  expected for transport limited by small polaron hopping in dynamically disordered systems. Inset: Molecular structural formula of TTB. The lack of curvature in (a) indicates that static disorder limits the measured mobility. Lines in both cases are fits assuming a  $1/T^2$  behavior (Heun and Borsenberger, 1995).

**Figure 4.31** Mobility vs. electric field with temperature as parameter for TTB (Heun and Borsenberger, 1995).

becomes important at high electric fields, at which point the mobility saturates, as in Fig. 4.13 for ultrapure naphthalene crystals.

Results from similar TOF measurements on amorphous films of the small molecule, TTB, are shown in Figs. 4.30 and 4.31. The TTB molecular structural formula is provided in the inset of

Fig. 4.30b. The single bond between the two triarylamine end groups allows for torsional modes that lead to dynamic disorder that adds to the temperature dependence of the static disorder in the amorphous solid. Plots of  $\mu$  vs. an exponential with either a  $1/T^2$  (Fig. 4.30a) or a  $1/T$  dependence (Fig. 4.30b) assuming Miller–Abrahams electron transfer show fits that are easily distinguished, favoring the  $1/T^2$  behavior characteristic of static disorder (Heun and Borsenberger, 1995). In Fig. 4.37, we show the field dependence (with temperature as a parameter), exhibiting the  $\mu \sim \exp(-A\sqrt{F})$  dependence anticipated for Frenkel–Poole dominated electron transfer.

#### 4.3.2.4 Beyond the Einstein relation and the EMA

In the previous section, we derived the mobility from the diffusion constant that are proportional, using the Einstein relation in Eq. 4.36. Strictly speaking, this relationship is only valid at or very near equilibrium in an undoped semiconductor where the ratio of the free charges to hopping sites,  $\zeta \ll 1$ . That is, we assume that the system is non-degenerate, thereby allowing for the replacement of the Fermi–Dirac distribution with the Boltzmann approximation. However, this condition is rarely met in disordered organic semiconductors where the Fermi ODOS overlaps the transport level ( $E'$ ) due to the extended width of the distribution,  $\sigma_{GDM} > E' - E_F$ . This condition is also violated in high current devices such as OLEDs and thin film transistors. A more general relationship

between  $\mu$  and  $D$  is found from the formal expressions for electrons and holes, viz.

$$\mu_n = qD_n \frac{\partial \ln(n)}{\partial E_F} \quad (4.106a)$$

and

$$\mu_p = qD_p \frac{\partial \ln(p)}{\partial E_F}, \quad (4.106b)$$

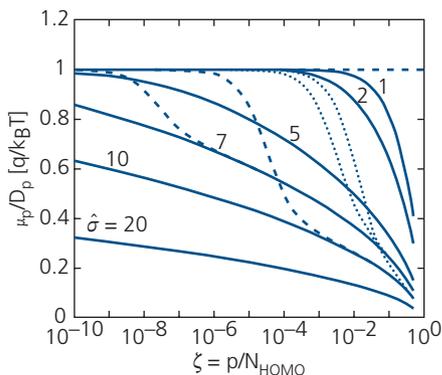

where the electron (hole) density is  $n$  ( $p$ ) and the Fermi energy,  $E_F$  is the chemical potential. Now the hole concentration is given by

$$p(E_F) = \int g(E)f(E, E_F)dE \quad (4.107)$$

with an analogous expression for electrons. Substituting the Fermi–Dirac distribution and the Gaussian DOS into Eqs. 4.107 and 4.106a gives a hole mobility of

$$\mu_p = \frac{qD_p}{k_B T} \frac{\int \exp\left(-\frac{(E-E_0)^2}{2\sigma_{GDM}^2}\right) \frac{\exp((E-E_F)/k_B T)}{[1 + \exp((E-E_F)/k_B T)]^2} dE}{\int \exp\left(-\frac{(E-E_0)^2}{2\sigma_{GDM}^2}\right) \frac{1}{[1 + \exp((E-E_F)/k_B T)]} dE} \quad (4.108)$$

A plot of the ratio  $\mu_p/D_p$  in units of  $q/k_B T$  is shown vs.  $\zeta = p/N_{HOMO}$  for several different values of the normalized distribution width,  $\hat{\sigma} = \sigma_{GDM}/k_B T$  in Fig. 4.32. Here, we assume that the density of hopping sites,  $N$ , is equal to the DOS at the HOMO, i.e.  $N_{HOMO}$ . For  $\hat{\sigma} = 7$  and 10, the distribution has been cut off at  $-19 k_B T$  (dotted lines) and  $-40 k_B T$  (dashed lines) to prevent overlapping into the HOMO states. The deviation from the Einstein relation is quite significant as the Gaussian width increases. This is evidence for the degeneracy that arises from the wide ODOS that can overlap well into the frontier orbitals, causing a significant deviation

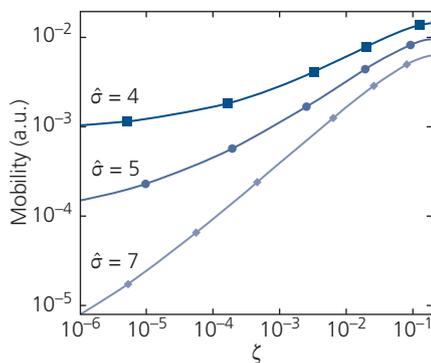

**Figure 4.32** Normalized hole mobility vs. the normalized charge density for various Gaussian DOS widths (solid lines). Dashed lines correspond to a cutoff in the DOS of  $-40 k_B T$ , and the dotted lines at  $-19 k_B T$  for widths of  $\hat{\sigma} = 7$  and 10. Here,  $\mu_p/D_p = 1$  corresponds to the Einstein relation. After Roichman and Tessler (2002).

from the mobilities predicted by Eq. 4.36. Furthermore, a narrow DOS leads to adherence to the classical Einstein relationship even at charge densities approaching that of the total density of hopping sites.

The conclusion is that the *rate* of mobility increase with charge density depends on the Gaussian width. That is, as the width is increased, there are higher energy states available for transport as the Fermi energy moves towards the conduction level. In contrast, the states in the tails of a narrow distribution are rapidly filled, resulting in a decrease in the change in mobility. This is illustrated in Fig. 4.33 where we plot the low field mobility vs.  $\zeta$  for different values of  $\hat{\sigma}$ .

From the foregoing, we see that the mobility is a function of the charge density, and hence the position of the Fermi energy relative to the conduction levels. Furthermore, the assumption of an effective medium where all charges have the same probability of hopping into a nearby site fails to capture the details of the physics of disordered media, since the available final hopping sites are not evenly distributed about the initial site. Given the very short range nature of the electron wavefunction captured by the exponential,  $v_0 \exp(-2\gamma a)$  in the Miller–Abrahams formalism, or the overlap integral,  $J_{RP}$ , in Marcus theory, the distance from charge to hopping site is critically important, yet is ignored in the effective medium approach. Ultimately, the hopping process is one of percolation; there are favored continuous pathways that lead to lower resistance conduction channels than others. These pathways are ultimately governed by the random details of the local disorder. Conduction is limited by those steps within the favored paths that are most difficult to overcome. That is, the average hop is replaced by the “most difficult but still relevant” hop within a percolating path (Coehoorn et al., 2005). These are the unavoidable steps that,

**Figure 4.33** Mobility vs. normalized charge density for various Gaussian widths of the DOS. After Roichman et al. (2004).

statistically must be accounted for in determining the macroscopic, measurable quantities of mobility, diffusion constant, and conductivity. And, as noted above, these quantities not only have a complex temperature dependence, but also depend on the details of the distribution assumed for the DOS (e.g. uniform, Gaussian, or exponential), and on the morphology and the steric nature of the molecules comprising the solid. To complicate matters even more, dipolar materials can result in locally organized domains, as well as polaron-dipole interactions that influence the percolation paths available. This so-called *spatially correlated disorder* can create significant departures in the field and temperature dependences of the mobility predicted by the simplified randomness assumed in the GDM (Gartstein and Conwell, 1995; Dunlap et al., 1996; Van Mensfoort et al., 2010).

Several models have been developed to describe the complexities of transport within organic media. These models have been reviewed in the literature (Coehoorn et al., 2005; Tessler et al., 2009); here we will describe and compare several of the most prominent such approaches with the caveat that the results of such models are sensitive to the materials systems considered, the film morphologies, the temperature and injection conditions extant, and the DOS distribution function that is assumed. Furthermore, as in the previous section, most models are developed in the limit of  $\zeta \rightarrow 0$ , and thus must be modified when used to model systems (e.g. thin film transistors) at high current densities.

For most semi-analytical, semi-empirical models, the mobility in the zero charge density limit follows the general form of (Coehoorn et al., 2005)

$$\mu(\zeta \rightarrow 0) = \mu_0 \exp\left(-a - \beta\hat{\sigma} - \chi\hat{\sigma}^2\right). \quad (4.109)$$

With the exception of some additional but perhaps minor deviations in the powers of  $\hat{\sigma}$  in the argument of the exponent, this is similar to that predicted by the effective medium approach (Eqs. 4.103–4.105). A tabulation of  $\mu_0$  and  $a$  for several important examples is provided in Table 4.2. In these models, it is assumed that hopping is governed by a Miller-Abrahams process, and that the DOS is defined by Gaussian disorder.

In each of the models with the exception of RT, we provide a factor,  $B$ , that depends on the statistics governing the onset of percolation. Also,  $\xi^{1/3} = \gamma/N^{1/3}$  is the ratio of the decay length of the wavefunction to the average distance between hopping sites. The basic elements of the models are as follows:

- (i) MS is the Movaghar–Schirmacher model based on hopping controlled by the average distance between sites,  $\bar{R}\alpha 1/N^{1/3}$ . This is effectively the EMA, but is corrected by the inclusion of  $B = \exp(1)$  to discount the importance of hops to states that are far removed from  $E_F$ .
- (ii) VM is the model of Vissenberg and Matters. It assumes that the medium is equivalent to a random network of resistors, whose resistance is determined by Miller-Abrahams hopping energetics. Thus, the conductance between sites,  $i$ ,  $j$  is  $G_{ij} = (q^2 v_0 / k_B T) \exp(-\hat{\epsilon}_{ij})$ , where  $\hat{\epsilon}_{ij}$  is the reduced energy given by the exponential terms in the expression in Eq. 4.101. The path taken by the hopping charge is determined from percolation theory, whereby there is a critical energy value,  $\hat{\epsilon}_C$  above which the conductance drops to

**Table 4.2** Terms used in defining the generalized low-charge-density mobility of Eq. 4.109 for several models assuming Gaussian disorder. Adapted from Coehoorn et al. (2005)

Model	$\mu_0$	$a$	$B$	Ref.
MS	$\frac{q v_0 \bar{R}^2}{k_B T} B$	$\left(\frac{6B}{\pi} \xi\right)^{1/3}$	2.7	(Movaghar and Schirmacher, 1981)
VM	$\frac{\sigma_0}{qN}$	$\left(\frac{6B}{\pi} \xi\right)^{1/3}$	2.7	(Vissenberg and Matters, 1998)
Arkhipov <sup>a</sup>	$\frac{q v_0 \bar{R}^2}{k_B T}$	$\Gamma\left(\frac{4}{3}\right) \left(\frac{6B}{\pi} \xi\right)^{1/3}$	3.933	(Arkhipov et al., 2002)
Martens	$\frac{\sigma_0}{qN}$	$\left(\frac{6B}{\pi} \xi\right)^{1/3}$	1.969	(Martens et al., 2003)
Baranovskii	$\frac{q v_0 R(E_t)^2}{k_B T} \Psi$	$\left(\frac{6B}{\pi} \xi\right)^{1/3}$	1.969	(Baranovskii et al., 2000)
RT	$\frac{q v_0}{N^{2/3} k_B T}$	$\ln\left(\frac{1}{\pi} \xi^{5/3}\right)$	1	(Roichman et al., 2004)

<sup>a</sup>  $\Gamma(\frac{4}{3}) = 0.893$  is the Euler gamma function.

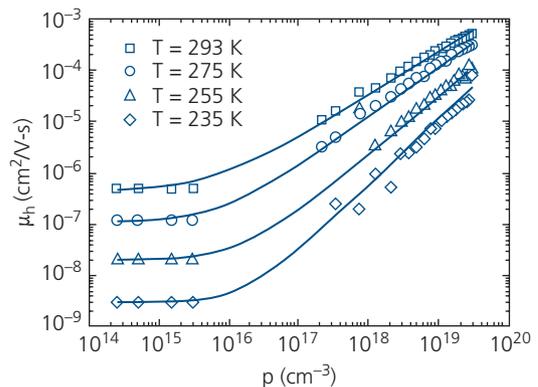

zero. This is the point whereby the “most difficult but still relevant” path is broken, and percolation paths form only isolated clusters. The percolation factor is identical to that of the MS approach.

- (iii) Arkhipov invoked a “favored first hop” formulation that asserts that hops occur between neighboring sites where the Miller–Abrahams rate is largest. The available site energies are determined by applying a step function in the Miller–Abrahams hopping energy argument. Then, only those available sites whose average density is less than  $B$  participate in the percolation process. As in the EMA, the mobility is assumed to be proportional to  $D$  according to the Einstein relation. Unlike VM, the Arkhipov model does not take Fermi–Dirac statistics into consideration, and hence a charge may hop into an already occupied site. For this reason, it is only valid at very low charge concentrations.
- (iv) Martens specifically requires that hopping occurs from a site at energy  $E_F$  to a neighboring site at distance  $R^*$ , whose energy is  $E^*$ . Hence, the conductivity is given by  $\sigma = \sigma_0 \exp(-2\gamma R^* - (E^* - E_F)/k_B T)$ , where  $\sigma_0$  is the conductivity for  $R^* = 0$ , and  $E^* = E_F$ . The primary assumption of this model that is absent in VM and MS is that each site is connected to only one other favored site, similar to the model of Arkhipov.
- (v) Baranovskii and co-workers developed a model very similar to Martens, but assume the most favored transfer occurs within a sphere whose radius lies in a *range*,  $R(E_t)$ . The charge can access sites whose energies lie below  $E_t$  and the transport level. The parameter  $\Psi$  is a function of  $E_t$  and the Gaussian width, and is on the order of unity. The Baranovskii model also faithfully reproduces the temperature dependence of Eq. 4.109, containing both the linear and quadratic dependences by setting  $E_t = \langle E_\infty \rangle = \beta \hat{\sigma}$  where  $\beta = \sigma_{\text{GDM}}$  and  $\xi = \frac{1}{2}$ .
- (vi) RT denotes the Roichman–Tessler model which is distinct from the other five models in Table 4.2. Indeed, this is another EMA theory, where percolation does not play a role (i.e.  $B = 1$ ). Thus, the material is considered to be homogeneous, with each carrier randomly selected from the Gaussian DOS. Starting with the conventional definition for the current density,  $j = ne\bar{v}$ , an average velocity,  $\bar{v}$  is calculated for each carrier which is the product of the displacement,  $dx$ , parallel to the applied electric field,  $F(x)$ , and  $k_{ij}$  in Eq. 4.101. This has the advantage of including the effects of electric field, and thus  $\mu$  can be obtained at all fields as in the GDM. It also accounts for site

occupancy as determined by Fermi–Dirac statistics, which avoids disallowed hops into occupied final states. The fundamentally different nature of the RT model thus predicts temperature and concentration dependences that are not found in the other, percolation-based analyses that are based on the principle of carriers hopping along “lucky,” continuous but largely independent pathways.

One further model is that of Pasveer that is based on solving the master occupancy-based Eq. 4.94 (Pasveer et al., 2005). We will show in the following section that this can lead to satisfactory fits to the mobility as a function of both electric field and charge density over a moderate temperature range in PPV-based polymers. However, it is a largely parametric computational approach and is not based on Eq. 4.109 as are the other percolation models.

In the foregoing, we have not explicitly included the concentration dependence of the mobility. Increased charge concentration results in a change in the Fermi energy, as implied in Figs. 4.32 and 4.33. In effect, the states closer to the center of the DOS have a higher probability of occupancy, resulting in the preferential selection of conduction states in the high energy tails of the DOS. The outcome of state filling is an abrupt increase in mobility with charge density, shown in Fig. 4.34. The onset of the high mobility region is independent of temperature, which is consistent with percolation being linked to a physical property of the material (i.e. the density of sites). The lines are fits to the data using the VM model. Interestingly, it has been found through numerical comparisons that for  $\hat{\sigma} > 2$ , all the models predict that, at charge densities corresponding to the condition  $E_F = \langle E_\infty \rangle$  (Eq. 4.98), the mobility is twice that of its value at  $p = 0$  (Coehoorn et al., 2005). That is,

**Figure 4.34** Hole mobility vs. hole concentration in a OC1C10-PPV thin film transistor as a function of temperature. Lines are fits to the VM percolation model (Tanase et al., 2004).

$$\frac{\mu(p(E_F = \langle E_\infty \rangle))}{\mu(p=0)} \simeq 2. \quad (4.110)$$

Furthermore, the carrier concentration at this “cross-over” point is:

$$\zeta(E_F = \langle E_\infty \rangle) = \frac{1}{2} \exp(-\hat{\sigma}/2) \quad (4.111)$$

By measuring the mobility vs. charge concentration, these two expressions combined can yield the width of the DOS. Indeed, for the data in Fig. 4.34 we obtain  $\sigma_{GDM} = 23k_B T$ , which at 300 K corresponds to 600 meV. This is a significant fraction of the energy gap, justifying our skepticism in using the Einstein relation to deduce the mobility from the diffusion constant.

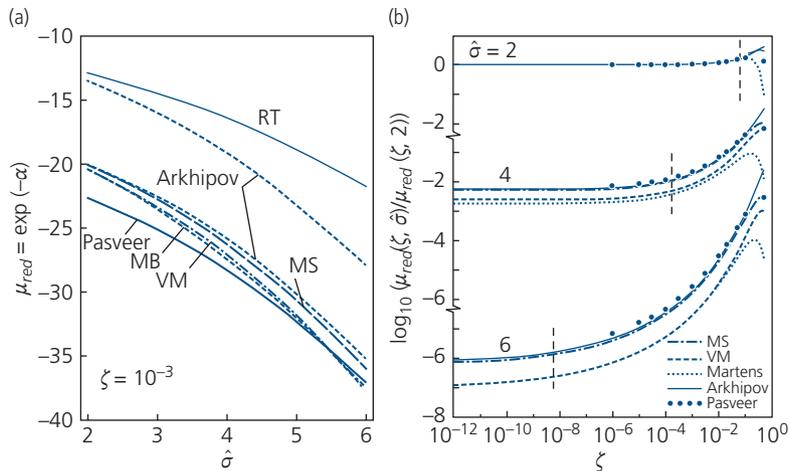

The several models in Table 4.2 are compared in the mobilities vs.  $\hat{\sigma}$  and  $\zeta$  in Figs. 4.35a and b, respectively. The reduced mobility is given by Eq. 4.109, that is:  $\mu_{red} = \exp(-a)$ , where  $a$  is provided in Table 4.2 for all except the model of Pasveer (Pasveer et al., 2005). The width dependence of the several percolation models is approximately equivalent. The two outliers are the Arkhipov model (upper curve) and that of RT. The higher Arkhipov curve corresponds to the situation where  $B = 1$ . This result obtains when hops can occur between neighboring sites whether they are within continuous or discontinuous percolating paths. When only continuous paths are included,  $B = 3.933$ , yielding the lower curve that conforms to results of the other percolation models. Since the RT model assumes the EMA, it generates a considerably larger mobility.

Figure 4.35b compares the predicted dependences of the reduced mobilities vs. charge concentration for several different Gaussian widths normalized to their values at  $\hat{\sigma} = 2$ . The vertical lines show that the cross-over into the high concentration conduction regime occurs at approximately twice the mobility value at  $\zeta \rightarrow 0$  for all models. Note that results from RT are not provided since they show a much higher mobility and concentration dependence than the models in the plot. The percolation models predict an increase in  $\mu$  with charge concentration, with the largest changes occurring for the broadest distributions. However, as the charge density approaches that of the hopping sites (i.e. as  $\zeta \rightarrow 1$ ), the available sites become saturated. Fermi–Dirac statistics prohibit hopping into filled sites, thus resulting in a decrease in mobility, as shown for all models except Arkhipov. We noted above that this latter picture does not account for the occupancy of the final states, and hence it continues to increase with  $\zeta$ .

An empirical relationship that accounts for the features of the several percolation-based models is as follows (Coehoorn et al., 2005):

$$\mu = \frac{q\nu_0}{N^{2/3}k_B T} \Phi \exp[-a - \ln\zeta - \beta'\hat{\sigma} - \chi'\hat{\sigma}^2], \quad (4.112)$$

where  $\beta' = a - E_F/\sigma_{GDM}$  and  $\chi' = -d/a$ . Here,  $\Phi$  and  $d$  are dimensionless fitting parameters on the order of unity. We note, once again, that such a semi-analytical expression is dependent on many factors that are possibly unique to a given materials system. These include the shape of the DOS function, the sterics of

**Figure 4.35** (a) Reduced mobility vs. normalized Gaussian DOS width in the low ( $\zeta$ ) concentration limit calculated using the various models in Table 4.2 including results by Pasveer. (b) Normalized reduced mobility vs.  $\zeta$  for different DOS widths calculated using various models with the exception of the RT model. The vertical lines correspond to the concentration at which  $\mu_{red}(\zeta)$  is twice its value at  $\zeta = 0$  (Coehoorn et al., 2005).

individual molecules that control the hopping process, morphology of the solid, and so on. However, given the calculational intensity and the uncertainties that accompany the analysis of transport in disordered systems, empirical expressions such as Eq. 4.105 and 4.112 are helpful in analyzing the results of mobility measurements in bulk and thin film organic semiconductors. These measurements and other factors that impact conductivity such as doping are the subjects of the next two sections.

#### 4.4 Conduction in organic thin films

A distinctive feature of semiconductors in device applications is the ability to change their conductivities over several orders of magnitude by doping. Organic electronic materials typically have large energy gaps (1–4 eV), and consequently have very low background intrinsic carrier concentrations. Furthermore, as we have seen in previous sections, the room temperature charge mobility is often  $<1 \text{ cm}^2/\text{V s}$ , and the narrow energy BWs of organic semiconductors (typically with a maximum at  $\sim 500 \text{ meV}$ ) are considerably smaller than for inorganics (with  $BW = 1\text{--}4 \text{ eV}$ ). This implies an effective mass  $m^* > m_0$ . Taking all of these properties together, organic semiconductors have exceptionally low conductivities in their native state. Of course, there are examples of ultrapurified and highly ordered molecular materials that have higher mobilities and large BWs. Nevertheless, these represent exceptions rather than the norm for this materials class.

Our discussion up to this point has concentrated on understanding the mobility of both ordered and disordered organics. However, conductivity—the primary property of an electronic material—is a result of both mobility *and* charge concentration. Both quantities can be complicated functions of temperature, electric field, defect and dopant concentrations, and film morphology. In Sections 4.4.1 and 4.4.2, we describe the conductive properties of both pure and doped organic materials, their dependence on film morphology (i.e. crystalline vs. amorphous), and on defects. Closely associated with dark conductivity is the photoconductivity of organic semiconductors. Indeed, photoconductivity is a signature property of all semiconductors, and it governs the performance of photodetectors and solar cells. However, we will leave the discussion of the photoconductive properties to the chapter on photodetectors, Chapter 7. In Section 4.4.3, we discuss commonly used measurement methods of conductivity and mobility. We have already

introduced this topic in our discussions of band structure and hopping, where we reported the results of time of flight measurements of mobility in single crystals and polymers. However, time of flight represents only one of several methods of determining these properties. It is important to fully understand the limitations and the range of validity of the principal methods employed to quantify the electronic properties of organic semiconductors, which is the topic of Section 4.4.3.

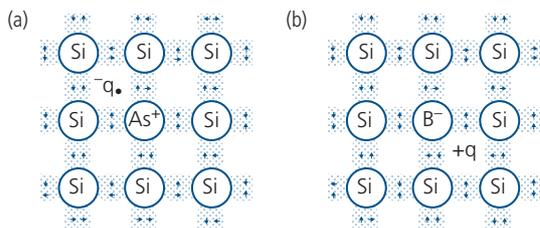

##### 4.4.1 Ohmic conduction and doping

Ohm's law predicts a linear relationship between current and voltage, that is,  $\mathbf{j} = \vec{\sigma}\mathbf{F}$ , where the conductivity tensor is  $\vec{\sigma} = q(n\vec{\mu}_e + p\vec{\mu}_h)$  (see Eq. 4.35). A measurement of the conductivity yields the *product* of mobility and the background charge concentration,  $n\mu_e + p\mu_h$ . For an undoped semiconductor in equilibrium,  $n = p = n_i$ , where  $n_i$  is the intrinsic carrier concentration:

$$n_i^2 = N_{HOMO}N_{LUMO} \exp\left[-\frac{E_G}{k_B T}\right]. \quad (4.113)$$

Here,  $E_G$  is the energy gap, and  $N_{HOMO}$  and  $N_{LUMO}$  are the densities of states at the frontier HOMO and LUMO energies, respectively. In many cases, the mobility of one charge carrier is much larger than its counter charge, allowing us to neglect the smaller charge-mobility products. Due to the large energy gaps of most organic electronic semiconductors, the background carrier concentration is much larger than  $n_i$  due to either intentional or adventitious doping.

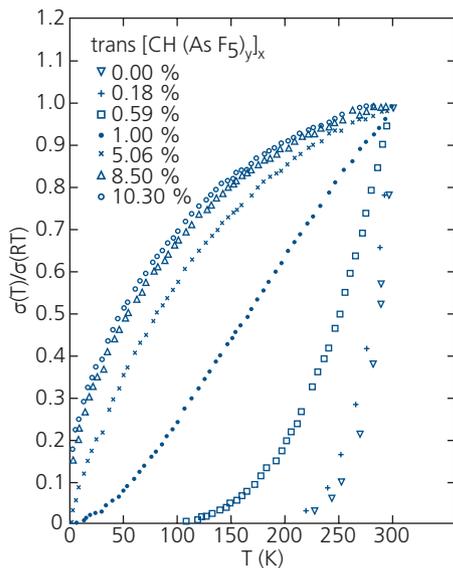

Intentional doping of inorganic semiconductors is the means by which the conductivity of the material is controlled. This is accomplished by introducing atomic species that have either one more valence electrons than the host lattice (for electron donors), or one less (for acceptors). The *substitutional doping* of As into a Si lattice for n-type doping via the excess and loosely bound valence electron (As has a valence of 5 compared to 4 for Si) and B for p-type doping due to its lack of a fourth valence electron is

**Figure 4.36** Doping by substitutional impurities in a Si lattice: (a) n-type doping via introduction of As atoms, (b) p-type doping via B atoms.

illustrated in Fig. 4.36. Alternatively, dopants can be introduced as interstitial impurities between lattice atoms, although due to the lack of shared bonds with the lattice molecules, the doping efficiency is reduced as there may not be one electron, or hole, released per dopant atom, as there is with substitutional impurities.

The lack of chemical bonds between organic molecules implies that only *interstitial doping* is possible, that is, the dopant atom or molecule is placed between molecules in either crystalline or amorphous solids. Doping to control conductivity in organic semiconductors is, therefore, inefficient, although it can be effective in increasing the conductivity of otherwise insulating solids. While interstitials can introduce additional charge carriers, they can also disrupt the lattice order. This additional static disorder, in turn, reduces the charge mobility, as discussed in Section 4.3. This partially counteracts the effects of increased charge density, and hence may decrease the anticipated gains in conductivity. *Unintentional doping* of organics by oxygen and other contaminants has been observed since the earliest work on organic semiconductors (Eley, 1948, Kearns et al., 1960, Martin et al., 1983), whereas intentional doping has been only recently been effectively used to control the conductivity of organic electronic devices (Chiang et al., 1977, Maitrot et al., 1986, Kido and Matsumoto, 1998, Pfeiffer et al., 1998, Parthasarathy et al., 2001, Lüssem et al., 2013).

**Figure 4.37** Normalized (to room temperature) conductivity of a polyacetylene film vs. temperature doped with different molar ratios of  $\text{AsF}_5$  (Chiang et al., 1977).

The first report of doping of an organic semiconductor was the addition of  $\text{AsF}_5$  into a 0.1–0.5 mm thick film of *trans*- $\text{CH}_x$  (Chiang et al., 1977). The room temperature conductivity of the film changed by >7 orders of magnitude as the *p*-type  $\text{AsF}_5$  concentration was varied from 0% (with  $\sigma_0 = 10^{-5}$  mS/cm) to 10.3% (with  $\sigma = 220$  mS/cm). The dependence of conductivity on temperature for films of several different  $\text{AsF}_5$  concentrations is shown in Fig. 4.37. The temperature dependence can be understood in terms of the Fermi–Dirac functions for the occupancy of the dopant levels. That is, for an acceptor energy at  $E_A$ , the hole concentration is

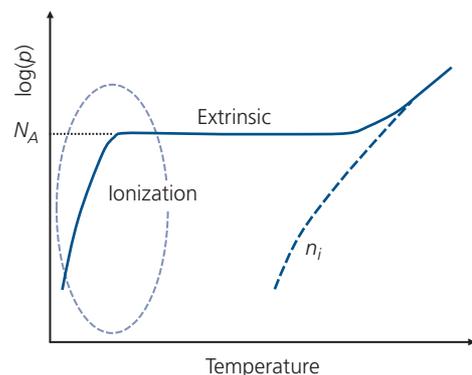

$$p(T) = N_A \int g(E) f(E_A, T) dE, \quad (4.114)$$

where the acceptor level occupancy is

$$f(E_A, T) = \frac{1}{1 + \exp((E_A - E_F)/k_B T)}. \quad (4.115)$$

Similar expressions are obtained for electrons and donor levels.

The temperature dependence of the charge concentration is shown in Fig. 4.38. At low temperatures, the exponential function is large, implying that not all acceptor molecules are ionized, that is,  $N_A^-/N_A < 1$ . This corresponds to the ionization regime where the charge concentration follows a Boltzmann distribution, viz.  $p(T) \sim \exp((E_F - E_A)/k_B T)$ . Once all the acceptors are ionized, the semiconductor enters the extrinsic region where its conductivity is determined by the free holes. Finally, at high temperature,  $n_i = p_i > N_A$ , where the intrinsic properties of the semiconductor dominate (corresponding to the *intrinsic regime*). Returning to Fig. 4.37 doped polyacetylene

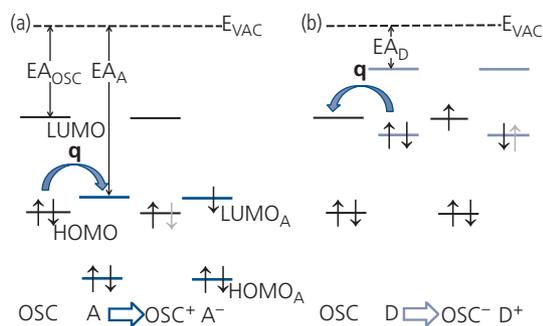

**Figure 4.38** Carrier concentration vs. temperature for an *p*-type semiconductor showing the various charge concentration regimes. Here,  $N_A$  = total acceptor concentration,  $n_i$  = intrinsic charge density, and the dashed oval corresponds to the data for doped polyacetylene in Fig. 4.37.

moves from the ionization to the intrinsic regime as the dopant concentration is increased.

Atomic dopants can be introduced that either release or capture an electron at an incomplete valence. For example, Li has the valence of  $1s^2 2s^1$ , and therefore can contribute an excess electron from its 2s shell, thereby serving as a donor in the following reaction:  $Li \rightarrow Li^+ + q^-$  (Kido and Matsumoto, 1998, Parthasarathy et al., 2001). Calcium has also been identified as an atomic donor in  $Alq_3$  (Choong et al., 1998) and Cs in Bphen (Reineke et al., 2009). A shortcoming of using metallic dopants, however, is that they are small compared to the molecular host, and therefore they can diffuse away from their initial location, and dope unintended regions of a device. Larger atoms (e.g. Cs vs. Li) have a smaller diffusion constant, and hence are preferred.

Molecular dopants can contribute electrons or holes while being less susceptible to diffusion within the solid due to their larger size. Doping is effectively achieved by choosing molecules with suitable frontier orbital energies relative to the host organic semiconductor, as illustrated in Fig. 4.39. For example, a molecular acceptor molecule should have a very deep LUMO energy relative to vacuum such that it is positioned close to the HOMO of the host (Fig. 4.39a). Subsequently, an electron is transferred from the host HOMO to the acceptor LUMO, leaving behind a semiconductor cation while adding that electron to the acceptor, forming a counter anion. Alternatively, a molecule with a very small electron affinity is easily oxidized via transfer of an electron to the LUMO of the host (Fig. 4.39b). The donor cation is then left with an excess hole, and the host acquires an excess electron.

Several candidate molecular dopants are shown in Fig. 4.40. An example donor, Li quinolate (Liq), releases an electron into the host as an n-type dopant

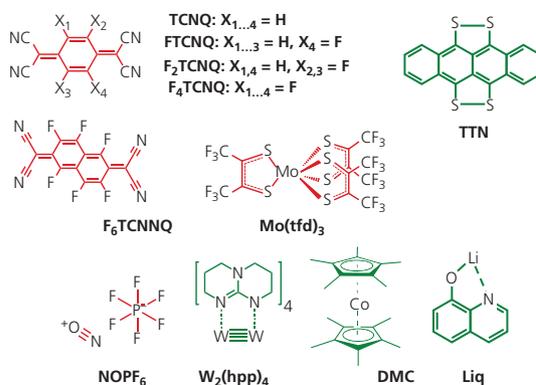

**Figure 4.39** Doping of an organic semiconductor (OSC) by (a) an acceptor (A), leaving behind a hole in the  $OSC^+$  cation (grey arrow) and an excess electron (black arrows in the LUMO) on the acceptor ( $A^-$ ). (b) A donor (D) resulting in an  $OSC^-$  anion.  $EA$  is the electron affinity and  $E_{VAC}$  is the vacuum level energy.

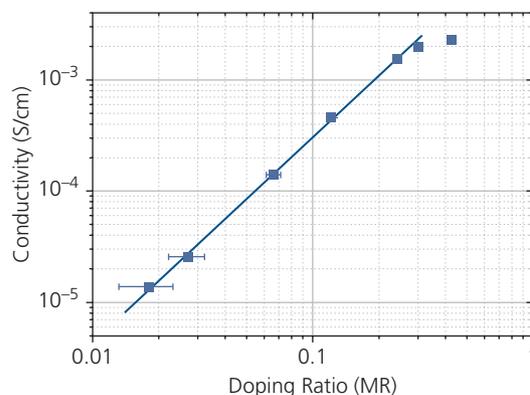

(Liua et al., 2002). Fluorinated tetracyanoquinodimethanes have been identified as effective p-type dopants due to their exceptionally large electron affinities ( $EA$ ) that increase with the degree of fluorination, making this a highly reductive species.

Figure 4.41 shows the relationship between the conductivity of MeO-TPD with concentration of the p-type dopant,  $F_4$ -TCNQ. Interestingly, the conductivity is superlinear with molar dopant ratio, that is,  $\sigma \sim p^{1.85}$  up to  $MR = 0.24$ . Above this concentration, the conductivity saturates at  $\sigma \sim 2 \times 10^{-3}$  S/cm; a value that is approximately  $10^4$  times higher than the neat host semiconductor. Taking a mobility of  $\sim 10^{-6}$   $cm^2/Vs$ , a conductivity of  $10^{-3}$  S/cm at a  $MR \sim 0.1$  suggests that  $p \sim 10^{22}$   $cm^{-3}$ . This implies that a maximum of 10% of the dopant molecules provide free holes to the host. This contrasts with inorganic semiconductors where the efficiency of substitutional doping approaches 100%.

The superlinear dependence of conductivity on dopant concentration is due to electric field screening in the low dielectric constant organic semiconductor. That is,

**Figure 4.40** Representative molecular dopants. Red = acceptors, green = donors.

**Figure 4.41** Conductivity vs. molar doping ratio ( $MR$ ) of MeO-TPD with  $F_4$ -TCNQ (Olthof et al., 2009).

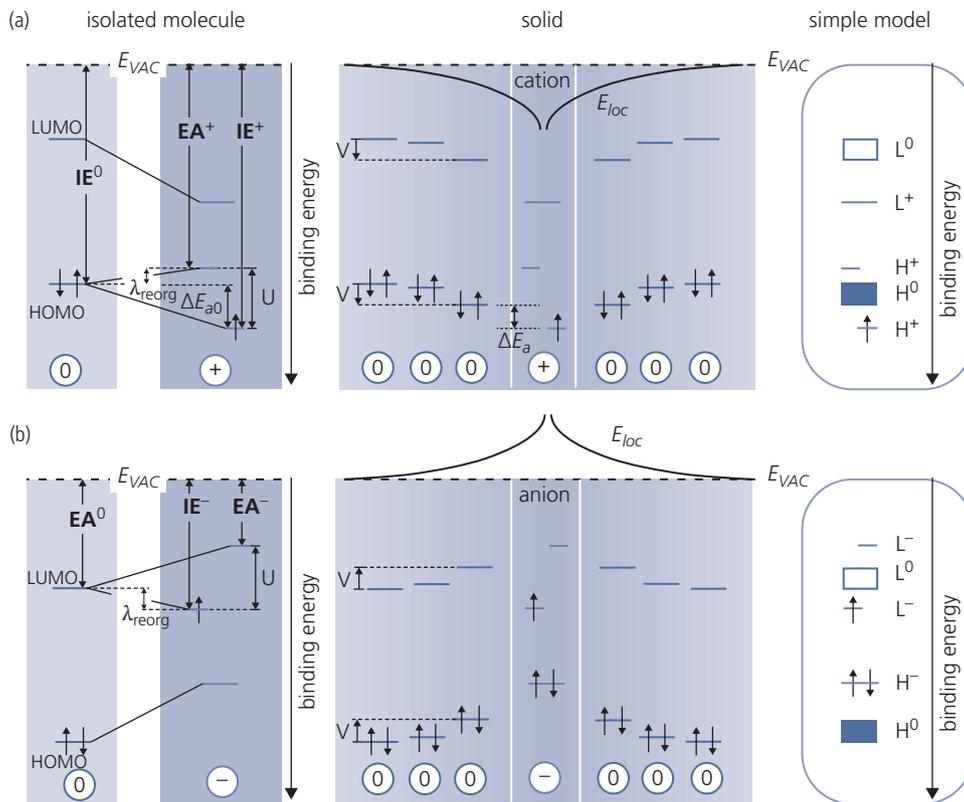

the film polarizability is increased by electrons bound to the acceptor molecules. The screening field increases with the number of trapped charges given that the free charge density is  $p = p_0 + N_A^-$ . In the limit where the background carrier concentration,  $p_0$ , is much less than the number of charges provided by the dopant, then  $p = N_A^- \exp(-\Delta E_a/k_B T)$ , where the activation energy,  $\Delta E_a$ , of the charge is equal to the difference between the electron affinity of the acceptor and the Fermi energy of the host semiconductor. The superlinearity in Fig. 4.41 suggests that  $\Delta E_a$  is a function of  $N_A^-$ , that is, it is not a constant as expected in an inorganic semiconductor. The power law dependence,  $\sigma \sim p^{1.85}$  implies that the change in activation energy arises from a decrease in binding energy of the charge to the dopant. The energy thus scales roughly linearly with the inverse distance between dopant molecules, that is,  $\Delta E_a = \Delta E_{a0} - \beta(N_A^-)^{1/3}$ . Here,  $\Delta E_{a0}$  is the activation energy of the undoped solid and  $\beta$  is a constant (Gregg et al., 2004).

The effect of dopant polarization is understood using the energy level diagram in Fig. 4.42 (Winkler

et al., 2015). We focus our attention on the addition of a cationic molecule (with an excess hole) illustrated in Fig. 4.42a, with identical, symmetrical arguments applying to anions in Fig. 4.42b. When an excess electron is added to a molecule, its HOMO is split into two levels. One is the singly ionized electron affinity,  $EA^+$  which is increased above the HOMO by the reorganization energy,  $\lambda_{reorg}$ . The second is the ionization energy,  $IE^+$ , which is increased by the on-site repulsive energy,  $U$  (left panel, Fig. 4.42a). The on-site energy is due to Coulomb repulsion of electrons experienced by a doubly ionized molecule, and is calculated using the *Hubbard Hamiltonian*:

$$H = - \sum_{\langle i,j \rangle, \sigma} t_{ji} c_{j\sigma}^\dagger c_{i\sigma} + U \sum_j \left( N_{j\uparrow} - \frac{1}{2} \right) \left( N_{j\downarrow} - \frac{1}{2} \right) - \sum_j \mu_j (N_{j\uparrow} + N_{j\downarrow}). \quad (4.116)$$

The first term is the kinetic energy resulting in transfer of an electron from site  $i, \sigma$  to site  $j, \sigma$ , and  $t_{ji}$  is the overlap of wavefunctions on these two sites. Here,

**Figure 4.42** Effect on the energy levels of an isolated molecule and a solid in the presence of a (a) cationic dopant and a (b) anionic dopant. Here,  $E_{VAC}$  is the vacuum level,  $E_{loc}$  is the distorted local potential in the presence of a charged molecule,  $\Delta E_a$  is the conductivity activation energy,  $\Delta E_{a0}$  is the activation energy without taking into account polarization of the surrounding medium,  $\lambda_{reorg}$  is the reorganization energy,  $V$  is the total energy shift due to the ionized impurity, and  $U$  is the on-site repulsive energy for a doubly ionized dopant.  $EA$  and  $IE$  are the electron affinity and ionization energy, respectively. The diagram at the far right is a simplified representation of the solid where  $L =$  LUMO and  $H =$  HOMO. The superscripts signify "0" = neutral, "-" = anion, and "+" = cation molecules (Winkler et al., 2015).

$c_{j\sigma}^\dagger$  ( $c_{j\sigma}$ ) is the creation (annihilation) operator at lattice site  $\mathbf{j}$  with spin  $\sigma$ , and the sum is over all sites,  $\mathbf{j}, \mathbf{i}, \sigma$ , where the brackets  $(\mathbf{j}, \mathbf{i})$  in the summation indicates that only nearest neighbor hops are included due to the short range interaction between molecules. As previously,  $N_{j\uparrow}$  is the number operator for site  $\mathbf{j}$ , and in this case for a spin-up electron (subscript  $\uparrow$ ). The second term is the on-site repulsive energy for two electrons with strength  $U$ , known as the *Hubbard*  $U$ . Following the Pauli Exclusion Principle, the electrons have opposite spins. The final term is the chemical potential ( $\mu_j$ ) of site  $\mathbf{j}$ , which determines the state occupancy.

The unperturbed activation energy is obtained from the isolated molecule. From Fig. 4.42a, this is approximately  $\Delta E_{a0} = U - \lambda_{reorg}$ . PES measurements indicate that  $U \approx 1.4$  eV for the acceptor C<sub>60</sub>, and as in the previous section,  $\lambda_{reorg} \sim 0.5$ – $1$  eV for most molecules. When placed in a solid, the long range Coulomb potential of the ionized impurity polarizes the local molecules, resulting in a total HOMO shift by  $V \approx 0.5$  eV (Winkler et al., 2015). Then, the activation energy decreases to  $\Delta E_a = \Delta E_{a0} - V$ . The amount of energy needed to remove a charge from the dopant is thus reduced to that of the first (largest) step required to overcome the local potential ( $E_{loc}$ ) surrounding the cation.

For an electron polaron (i.e. an anionic state), the energy levels are shifted upward by approximately the same energy as for hole polarons. Thus, the same arguments leading to estimates of  $\Delta E_a$  and  $\Delta E_{a0}$  apply. The microscopic diagrams in the middle panels of Fig. 4.42 can be simplified by assuming that the HOMO and LUMO energies are broadened as shown on the right hand panels, with the ionized hole and electron dopant levels residing either above or below their corresponding frontier orbitals.

We can put this discussion in the context of the GDM by assigning a second, Gaussian distribution to the polarization induced splittings in Fig. 4.42. That is, the introduction of dopants releases free carriers that increase the mobility by filling the high energy tail of the Gaussian DOS. The increased mobility, along with the higher density of free charge both conspire to increase the conductivity. However, the ionized dopants introduce an electrostatic retardation of the mobile charges, thereby decreasing the mobility via energetic disorder. Also, increased static disorder due to lattice disruption by the high density of dopants ultimately limits the maximum mobility to less than if disorder were absent. The Coulomb traps formed by the dopants can be visualized by the one-dimensional energy level diagram in Fig. 4.43 for an

organic with ionized dopants separated by distance,  $d = N_d^{-1/3}$ , where  $N_d$  is the dopant density (i.e. either the donor or acceptor concentration). The electrostatic attraction of the dopant creates a potential minimum of depth  $\Delta$  from the maximum at a distance  $r_m - r_0$  from the dopant itself. Then it follows that

$$U(r) = -qFr + \frac{q^2}{4\pi\epsilon_0\epsilon_r r} + \frac{q^2}{4\pi\epsilon_0\epsilon_r |r-d|}, \quad (4.117)$$

where  $\epsilon_r$  is the relative dielectric constant of the material. The energy barrier is at the maximum of  $U(r)$ , yielding

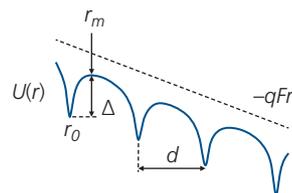

$$\Delta = \frac{q^2}{4\pi\epsilon_0\epsilon_r a} + U(r_m), \quad (4.118)$$

where  $a$  is the distance between the dopant and the nearest hopping site. Then, assuming a Gaussian distribution for both hopping and dopant sites, the total DOS is (Arkhipov et al., 2005a, 2005b)

$$g(E) = \frac{N - N_A^-}{N} g(E) + \frac{N_A^-}{N} g\left(E + \frac{q^2}{4\pi\epsilon_0\epsilon_r a} + U(r_m)\right). \quad (4.119)$$

As previously,  $N$  is the density of hopping sites, and for convenience we have assumed a  $p$ -type dopant is used such that  $p \approx N_A^-$ .

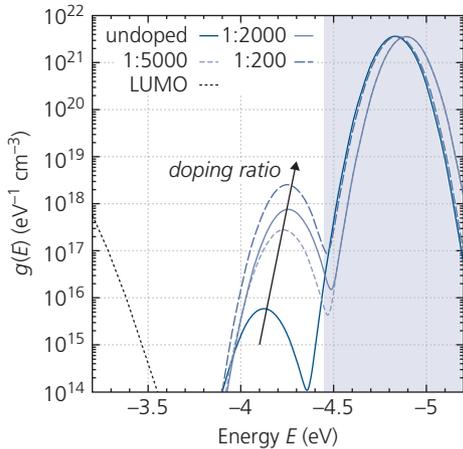

A calculation of the HOMO DOS for a P3HT film  $p$ -doped with different ratios of F<sub>4</sub>TCNQ is shown in Fig. 4.44. The doping ratio is the number of F<sub>4</sub>TCNQ molecules per thiophene unit in the P3HT chains. The calculations assume that the undoped Gaussian is centered at  $E_{HOMO}$  determined from the surface Kelvin probe potential (see Chapter 8). It is found that  $E_{HOMO}$  increases from  $-4.83$  eV for the undoped sample to  $-4.94$  eV for the 1:200 sample. Furthermore,  $N = 7 \times 10^{20}$  cm<sup>-3</sup>,  $N_d$  is taken from the doping ratio,  $\sigma_{HOMO} = 78$  meV, and  $a = 0.57$  nm. Importantly, the doping states have a DOS that is a function of the doping ratio. The HOMO distribution is also a Gaussian that shifts toward  $E_{HOMO}$  with doping ratio. The

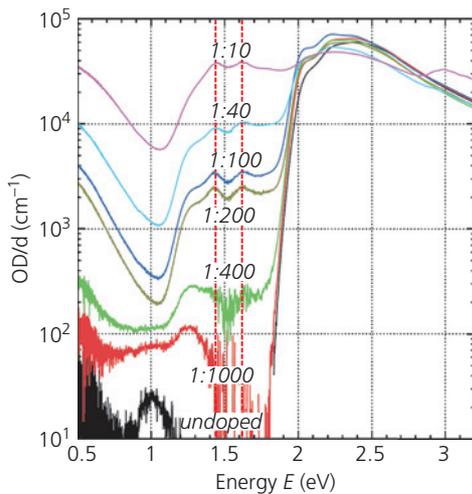

**Figure 4.43** Electrostatic potential,  $U(r)$ , along one dimension for a series of Coulomb traps spaced at distance  $d$ . The trap depth is  $\Delta$  measured from the bottom (at  $r_0$ ) to the top of the potential (at  $r_m$ ). The applied electric field is  $F$ .

small DOS for the undoped sample is attributed to Al diffusion from the back contact. The width of this distribution is the Hubbard  $U$ , ultimately determined by the splitting of the HOMO level due to polarization described in Fig. 4.42a.

Direct evidence for charge transfer from the dopant to the host is obtained using absorption spectroscopy, shown for the  $F_4TCNQ:P3HT$  films in Fig. 4.45. The singly ionized (anionic)  $F_4TCNQ$  features at 1.43 eV and 1.62 eV are identified from optical measurements

**Figure 4.44** Density of HOMO states as a function of  $F_4TCNQ$  in P3HT, where the doping ratio (1: $x$ ) is equal to the number of dopant molecules per  $x$  thiophene units. The LUMO is shown by the dashed line. The shaded region encompasses the states in the undoped P3HT (Pingel and Neher, 2013).

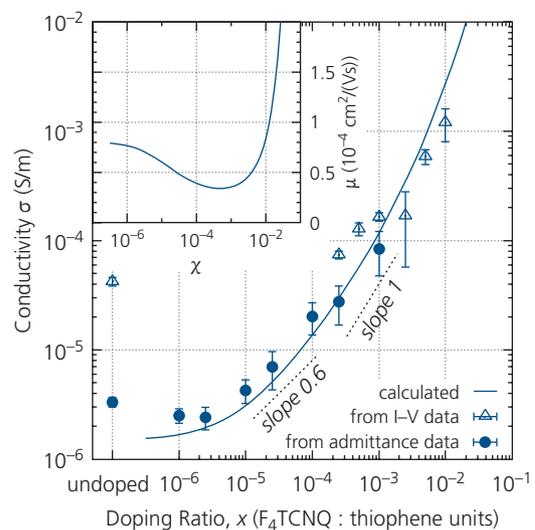

**Figure 4.45** Optical density normalized to the film thickness of  $F_4TCNQ$ :P3HT (1: $x$ ) at various doping ratios. The vertical red dashed lines indicate the positions of singly negatively ionized  $F_4TCNQ$  molecules (Pingel and Neher, 2013).

on the neat species themselves. The rectangular background between 2 eV and 1 eV lying below the neutral P3HT energy gap at 2 eV is attributed to P3HT hole polarons, as is the rising absorption at  $<1$  eV. The free polaron concentration is then extracted from the correspondence between OD and doping ratio,  $x$ .

The measured conductivity vs.  $x$  is provided in Fig. 4.46, with a fit to the data (solid line) employing the mobility model extracted using the DOS in Eq. 4.119 (Arkhipov et al., 2005b) and the hole concentration from Fig. 4.45. The slope of the conductivity is sublinear at low doping ratios, becoming linear at moderate ratios, and then superlinear as in Fig. 4.41 at high doping ratios. At low ratios, the dopants compensate the native traps in the P3HT. As doping is increased, the Gaussian tail states are filled, resulting in an increased number of free holes, leading to a rapid rise in hole concentration. Note the decrease in calculated mobility at low to moderate doping concentrations, as shown in the inset of Fig. 4.46. The drop in mobility that leads to the sublinear dependence of the conductivity with  $x$  is due to Coulomb traps from the cationic molecular dopants, discussed above. At the highest doping levels, both the mobility and the charge concentration increase, leading to the superlinear dependence of  $\sigma$  on  $x$ .

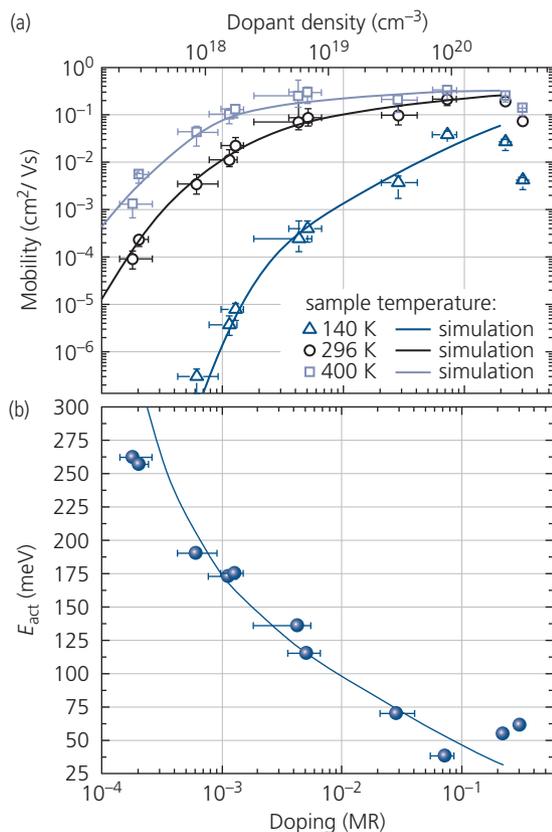

The low doping regime and the facility for dopant charge to compensate native traps induced by structural disorder was studied in the n-type semiconductor system comprising  $C_{60}$  doped at very low levels using the donor,  $[RuCP^*(mes)]^+$  (Olthof et al., 2012).

**Figure 4.46** Conductivity vs. doping ratio. The solid line fit is to Arkhipov's Gaussian disorder model. Inset: Plot of mobility using the disorder model at low doping ratios (Pingel and Neher, 2013).

The samples were grown in ultrahigh vacuum, and the molar ratio of the dopant was controlled by its relative deposition rate with  $C_{60}$ . The free charge concentration ( $n$ ) was obtained from UPS and IPES measurements of the Fermi energies and frontier orbitals. From this, the mobility was deduced from conductivity measurements, viz.  $\mu_n = \sigma/qn$ .

The electron mobility vs. dopant  $MR$  is shown for three different temperatures in Fig. 4.47a. There is a striking change from a region of high slope at  $MR < 2 \times 10^{-3}$ , to a much lower slope at higher  $MR$ . This inflection appears to be relatively temperature independent. The transition also corresponds to an abrupt transition from a large dependence of the work function and HOMO energy on  $MR$  to a much slower dependence as  $MR$  is increased beyond this apparent threshold value. The explanation for this transition is the compensation of native traps in the disordered  $C_{60}$

**Figure 4.47** (a) Electron mobility in  $C_{60}$  as a function of  $n$ -type doping concentration ( $MR =$  molar ratio) by the cation  $[RuCp^*(mes)]^+$ . Data points are measurements, lines are fits based on kinetic Monte Carlo modelling using the GDM effective medium approximation. The data are taken from conductivity vs. temperature along with photoelectron spectroscopy measurements of the Fermi energy to obtain  $n$ . (b) Conductivity activation energy vs.  $MR$ . The line is a fit to the theory in (a) (Olthof et al., 2012).

film at low  $MR$ . The Fermi energy moves toward the conduction level with doping until those traps are filled. This has the combined effects of neutralizing charged traps while increasing the mean energy of conducting charges. Once compensated, additional dopants simply contribute more electrons. These fill the tail states in the Gaussian DOS, thereby resulting in hopping from higher energy, and hence higher mobility states. This is also supported by the slower approach of the Fermi energy toward the LUMO at the rate of  $\sim 60$  meV/decade in  $MR$ , consistent with the theoretical behavior of conventional inorganic semiconductors. However, at these higher doping levels, the mobility no longer shows a significant increase in mobility with doping; indeed it begins to decrease at  $MR > 0.05$  due to increased disorder from impurities disrupting the  $C_{60}$  lattice.

These conclusions are supported by fits to the data shown by the solid lines in the figure using the GDM in the effective medium approximation (Fishchuk et al., 2007). Here, a Gaussian DOS is assumed for the conduction level states, and an exponential for the band tail state. The Gaussian and exponential distributions fit the data assuming widths of 64 meV and 128 meV, respectively, and the ratio of the total number of exponential to Gaussian states is 0.007 (Olthof et al., 2012). Note that the low temperature mobility does not saturate, even at high  $MR$ . This results since traps near to the conduction level are not thermalized as temperature is reduced.

A plot of the conductivity activation energy,  $\Delta E_a$ , is shown in Fig. 4.47b. The line follows  $\sigma = \sigma_0 \exp(-\Delta E_a/k_B T)$ , where  $\sigma_0$  is a constant. Since the activation energy is a function of the donor energy relative to  $E_F$ , it moves rapidly toward the LUMO energy at low doping, until it saturates at approximately 39 meV at  $MR \sim 0.07$ . The fit to the EMA model used in Fig. 4.47a is shown by the line in Fig. 4.47b.

In the very high doping regime, the host material can no longer be simply considered to be doped, but rather it is a blend of two organics (host and dopant). Thus, conductivity can occur on either species. In some cases the introduction of a dopant can form an intermediate neutral CT complex rather than releasing a free polaron into the host. Often, an ion pair is never formed, and doping does not result in free charge. In cases when free charge is released, the CT state levels are split above and below the transport energy level. For p-type doping for example, the  $EA$  of the CT state lies above, and its IP lies below that of the host (Salzmann et al., 2016).

Finally, note that thermally activated diffusion of small dopant molecules can lead to their migration

from their intended location (e.g. in a highly doped charge transport layer or in the emission zone of an OLED) over time; a process whose rate is increased at high temperature. While atomic dopants such as Li and Cs are particularly prone to rapid diffusion along the interstices between molecules, even small molecular dopant species can rapidly migrate at even modest temperatures. Similarly, the spatial distribution of binary mixtures of molecules can change over time, and junctions between layers of different compositions can also intermix, changing the electronic properties of the original structure.

Simple, single species diffusion as a function of time,  $t$ , in three dimensions is described by *Fick's second law*:

$$\frac{\partial c(r, t)}{\partial t} = D_c \nabla^2 c(r, t), \quad (4.120)$$

where we have assumed that the diffusion constant,  $D_c$ , is independent of concentration,  $c(r, t)$  of the diffusing species. Furthermore, this expression assumes that  $D_c$  is a scalar, independent of direction within the sample. This is not the case for molecular crystals where there is usually substantial anisotropy along the various crystal axes.

Lateral diffusion of  $F_4TCNQ$  doped into P3HT has been followed as a function of both time and temperature using fluorescence microscopy to determine the diffusion constant and the mechanisms leading to dopant migration. The sample preparation steps are illustrated in Fig. 4.48a. The 50 nm thick P3HT host film is spun onto the surface of a glass substrate, followed by deposition of a 2.2 nm thick layer of the dopant through a fine Cu shadow mask with square holes,  $38 \mu\text{m}$  on a side on a  $66 \mu\text{m}$  pitch. The dopant is prevented from escaping from its location by depositing an encapsulating layer of 50 nm  $\text{MoO}_3$ /100 nm Ag. The  $\text{MoO}_3$  prevents the Ag layer from diffusing into the sample. Then the entire unit is encapsulated using a glass lid epoxied around its periphery to form a moisture and oxygen-proof seal. The thin  $F_4TCNQ$  provides a finite amount of dopant, thus establishing well-defined boundary conditions that simplify diffusion analysis.

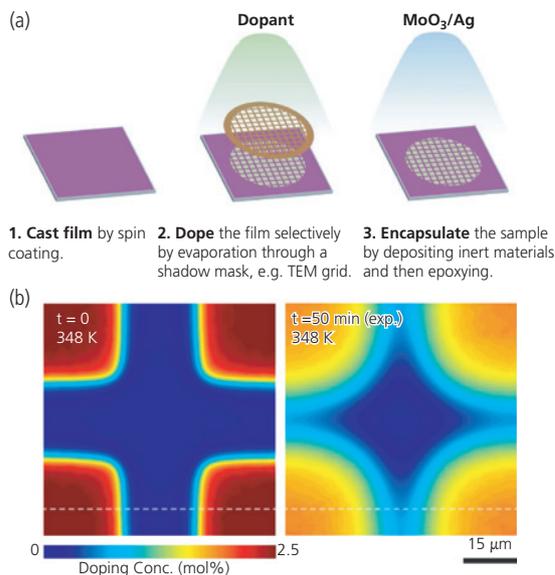

Since the dopant quenches the luminescence of the P3HT film, the spatial distribution of  $F_4TCNQ$  is monitored over time using fluorescence microscopy. The sample was excited at 488 nm wavelength and imaged through a microscope objective focused onto the P3HT film via the glass substrate. The fluorescence intensity around the periphery of the original  $F_4TCNQ$  deposit provides a relative measurement of the amount of dopant that is within that region, providing a spatial-temporal map of the diffusion front. The image on the left shows the initial conditions (at

$t = 0$ ) with the dopant confined to the regions where it was deposited. After 50 min at 348 K, the dopant molecules have diffused far from their point of origin, almost contacting in the  $26 \mu\text{m}$  wide regions that were masked during deposition.

The diffusion profile is found to deviate from predictions made using Eq. 4.120. To provide an improved fit, it was assumed that both the neutral  $F_4TCNQ$  and the anionic  $F_4TCNQ^-$  acceptor molecule compete in the diffusion process. Since only one molecule can occupy a site at a given time, the neutral  $F_4TCNQ$  has to “jump” over the anions, thus resulting in an increased diffusion constant of the neutral compared to the ionic species. At room temperature, fits to the diffusion profiles yield the anion diffusion constant for  $F_4TCNQ^-$  of  $D_{F_4TCNQ^-} = 1.5 \times 10^{-11} \text{ cm}^2/\text{s}$ , and for the neutral species,  $D_{F_4TCNQ} = 3 \times 10^{-10} \text{ cm}^2/\text{s}$ . Measurement of the diffusion constants at several different temperatures yields activation energies via

$$D_c = D_{c0} \exp(-\Delta E_{ac}/k_B T). \quad (4.121)$$

Measurements of  $F_4TCNQ$  in P3HT yield  $\Delta E_{ac} = 74.2 \text{ kJ/mol}$  and  $55.9 \text{ kJ/mol}$  for the neutral and anionic

**Figure 4.48** (a) Fabrication sequence for creating grid patterns useful in visualizing diffusion in an organic film by a dopant. (b) Relative  $F_4TCNQ$  density distribution in P3HT before (left image) and after (right) 50 min diffusion at 348 K. The distribution maps are obtained from analysis of P3HT fluorescence. $F_4$ TCNQ species, respectively. We note that the activation energies and diffusion constants are not separately measured, but are taken from fits to the diffusion front using a two species, two dimensional diffusion analysis of the concentration profiles (i.e. the fluorescence intensity maps) as functions of time and temperature.

The diffusion constants and activation energies found for  $F_4$ TCNQ are similar to those of PC<sub>61</sub>BM in P3HT which can be fit using only a single species, one-dimensional model as Eq. 4.120 (Treat et al., 2013). The diffusion constants in both cases are sufficiently large that dopants can lead to significant, temperature dependent changes in morphology, and ultimately the optical and electronic properties of materials over time.

We will show in Chapters 6 and 7 that molecular doping can lead to very small internal resistances in OLEDs and OPVs. However, from the foregoing discussion it should be clear that interstitial doping of organics leads to complex and as yet not fully understood dependencies of the number of free charges (and hence conductivity) on such factors as temperature, dopant and host molecular species, dopant concentration, and film morphology. We will find that the stability of organic electronic devices is thermally activated, that is, their operational lifetime is reduced as temperature is increased. Diffusion of species across interfaces, and within the layers themselves is one of the primary mechanisms for device failure, as implied from the foregoing discussion.

#### 4.4.2 Space charge limited conduction

At relatively low currents, the doping and the background free charge concentration in organics allow for Ohmic conduction. However, as the current density is increased, a deficiency in bulk charge leads to injection from the contacts, leading to the *space charge limited (SCL) transport* regime. Two situations are considered in this section: SCL current in the absence or presence of traps. While space charge conduction can be supported by injection of a single carrier type (i.e. an electron or hole), double carrier injection is also possible. For simplicity we consider only single carrier injection. The analysis of the current density *vs.* voltage ( $j$ - $V$ ) characteristics of a semiconductor in the presence of bipolar conduction is quite complex since it requires consideration of charge recombination in the material bulk (Lampert, 1962, Kao and Hwang, 1981). Interested readers can find references that treat this topic in *Further reading* at the end of the chapter.

**Figure 4.49** (a) Distribution of charge and field lines for a semiconductor dominated by space charge injection from a contact. (b) Charge distribution for Ohmic and SCL currents.

##### 4.4.2.1 Trap-free SCL conduction

The origins of SCL current can be understood from the illustration in Fig. 4.49. The applied voltage is sufficiently high to inject electrons from the cathode. Since field lines terminate on individual charges, the electric field near the cathode is higher than elsewhere in the bulk. In Fig. 4.49b, we illustrate the differences in the field distribution for Ohmic and SCL currents in a sample of thickness,  $d$ . Ohmic conduction is characterized by a uniform field, whereas SCL conduction results in a high field near the injecting contact, falling rapidly into the bulk.

In the following derivation, we make several simplifying assumptions, each of which can be removed to consider more general circumstances. (i) Only a single carrier type (holes) is injected, (ii) the hole mobility ( $\mu_p$ ) is independent of field,  $F$ , (iii) the free carrier distribution is governed by Boltzmann statistics, (iv)  $F$  is sufficiently small that there is no field emission from the contacts, (v) carrier diffusion from contacts is small and therefore ignored, and (vi) only one-dimensional transport along the  $\hat{x}$ -direction is considered. Then from Gauss' law:

$$\frac{dF(x)}{dx} = \frac{qp(x)}{\epsilon_r \epsilon_0} = \frac{q(p_{inj}(x) + p_0)}{\epsilon_r \epsilon_0} \approx \frac{qp_{inj}(x)}{\epsilon_r \epsilon_0}, \quad (4.122)$$

where the total free hole polaron density,  $p$ , consists of the sum of injected hole density,  $p_{inj}$ , and the background charge density,  $p_0$ . In the SCL regime,  $p_{inj} \gg p_0$ . Now, the current is given by

$$j(x) = q\mu_p p_{inj}(x)F(x). \quad (4.123)$$

Using Eq. 4.123, we can rewrite Eq. 4.122 as follows:

$$\frac{dF^2(x)}{dx} = 2F(x) \frac{dF(x)}{dx} = \frac{2qp_{inj}(x)F(x)}{\epsilon_0 \epsilon_r} = \frac{2j(x)}{\epsilon_0 \epsilon_r \mu_p}. \quad (4.124)$$

Then,

$$F^2(x) = \frac{2j_{SCL}x}{\epsilon_0\epsilon_r\mu_p}. \quad (4.125)$$

Current continuity requires that  $j(x) = j_{SCL}$ , a constant that is independent of position. In this regime, the field is no longer constant across the sample, but according to Eq. 4.125 increases quadratically. Thus  $F^2(x) \sim x$  until it reaches a peak value at  $x = d$ . Also, Eqs. 4.123 and 4.125 give:

$$p_{inj}(x) = \left(\frac{\epsilon_r\epsilon_0j_{SCL}}{2q^2\mu_p}\right)^{1/2} \frac{1}{\sqrt{x}}. \quad (4.126)$$

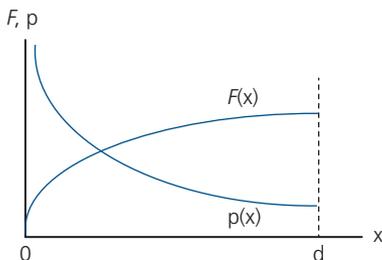

The charge density is, therefore, also quadratic in current (vs. linear for Ohmic conduction) and is inversely proportional to  $\sqrt{x}$ . These various relationships are illustrated in Fig. 4.50.

Now, the potential is simply  $F(x) = -\frac{dV}{dx}$ , and integrating between  $x = 0$  where  $V$  is the applied voltage, and  $x = d$  where  $V = 0$ , we obtain for SCL current in the absence of traps:

$$j_{SCL} = \frac{9}{8}\mu_p\epsilon_0\epsilon_r \frac{V^2}{d^3}. \quad (4.127)$$

This is known as the *Mott–Gurney relationship*, which is analogous to *Child's law* used to describe space charge currents in vacuum tubes. Equation 4.127 is independent of the injected carrier density,  $p_{inj}$ , with the mobility and dielectric constant the only materials-dependent properties. It differs from Ohmic conduction due to its quadratic (versus linear) dependence on voltage and inverse cubic (again versus linear) dependence on sample thickness. Hence, the charge mobility in the space charge region can be extracted directly from the slope of  $j$  vs.  $V^2$ , only requiring knowledge of the film thickness and dielectric constant (the latter can be obtained from the sample capacitance).

Thus, at low voltages, the current is carried by the background charge with density,  $p_0$ , and at higher voltages by injected space charge. The point at

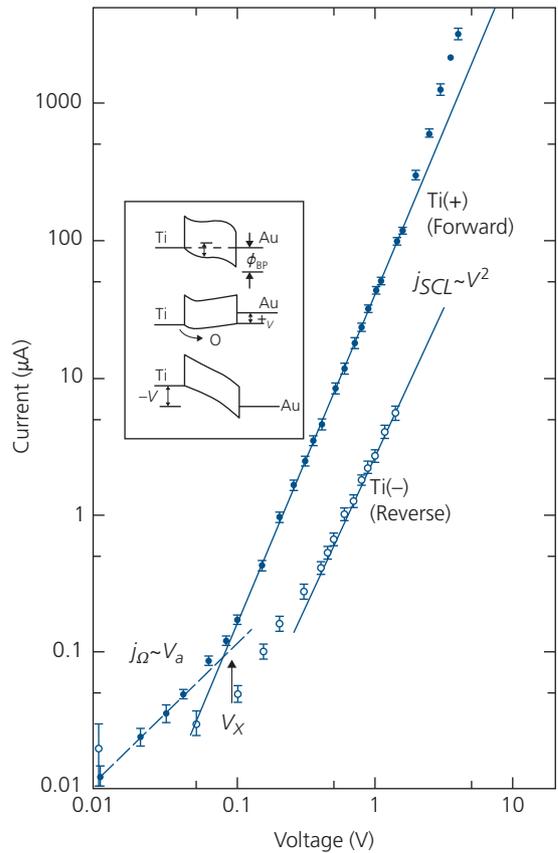

**Figure 4.50** Electric field and charge density vs. distance in the SCL current regime.

which these two current densities are equal is the cross-over current,  $j_x = j_\Omega = j_{SCL}$ . From Eqs. 4.34 and 4.127 we obtain

$$V_X = \frac{8}{9} \frac{qp_0}{\epsilon_0\epsilon_r} d^2, \quad (4.128)$$

where  $V_X$  is the cross-over voltage. These relationships are shown in Fig. 4.51 for a 200 nm thick film of PTCDA sandwiched between a Ti Ohmic contact and a rectifying Au contact (Forrest et al., 1984a). The asymmetry in current depends on whether the Ti contact is positive (corresponding to forward bias) or negative (reverse bias) relative to the Au. The Au/PTCDA contact has an energy barrier of  $(0.61 \pm 0.05)$  eV as determined from the temperature dependence of the current in Au/PTCDA/Au devices. Accurate analysis of the  $j$ - $V$  characteristics requires that the built-in voltage ( $V_{bi}$ ) of the contacts be subtracted

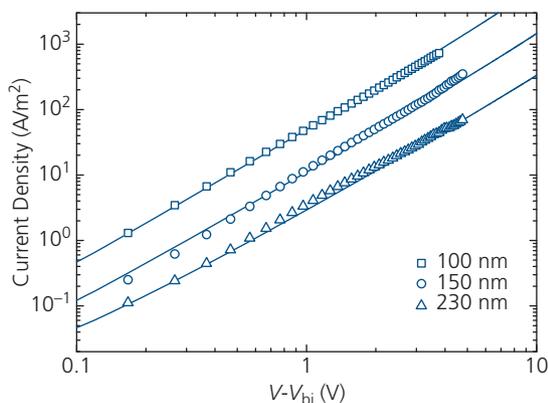

**Figure 4.51** Current regimes of a 200 nm thick PTCDA film sandwiched between Ti and Au contacts. The device area is  $A = 2.5 \times 10^{-4} \text{ cm}^2$ . Films with the Ti electrode positive relative to Au are forward biased, indicating a higher built-in voltage at the Au contact.  $V_X$  is the cross-over voltage, corresponding to a cross over current of  $j_x A = 0.1 \mu\text{A}$ . The dashed line is a fit to Ohm's law, and the solid lines are fits to the Mott-Gurney relationship. Inset: Energy level diagrams at different biases (Forrest et al., 1984a).

from the applied voltage. In Eq. 4.127 we should, therefore, replace  $V$  with  $V - V_{bi}$ .

The cross-over from the Ohmic to the SCL regime is at  $V_X = 0.1$  V. Fits to the data, shown by the lines in Fig. 4.51, yield a mobility of  $\mu_p = 3.5 \times 10^{-3}$  cm<sup>2</sup>/V s and a free hole concentration of  $p_0 = 5 \times 10^{14}$  cm<sup>-3</sup>. The fits extend over four decades, suggesting that the assumption of little or no electric field dependence of the mobility is justified up to fields as high as  $\sim 4$  V/200 nm =  $2 \times 10^5$  V/cm.

SCL conduction has been observed in semiconducting polymers as well as small molecule organics (Blom et al., 1997b, Tanase et al., 2004, Reid et al., 2008, Nicolai et al., 2010). In Fig. 4.52 we show the  $j$ - $V$  characteristics of PFO films of three different thicknesses sandwiched between Ohmic electrodes. The data are consistent with the Mott-Gurney relation, following  $(V - V_{bi})^2/d^3$  over the entire range of voltages and currents measured (Nicolai et al., 2010). The hole mobility is relatively constant at  $\mu_p = 1.3 \times 10^{-5}$  cm<sup>2</sup>/V s, a value that is characteristic of many amorphous semiconducting polymers.

As discussed in Section 4.3.2, static disorder leads to a deviation from a constant mobility with electric field. Indeed, the mobility is generally found to depend not only on  $F$ , but also on charge density due to trap filling. It is difficult to separate the contributions of these two variables, since an increase in field also leads to increased charge injection. The increase in current at high voltage in Fig. 4.51 is an indication of

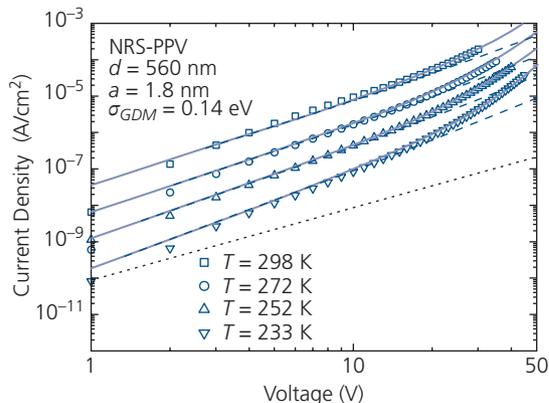

**Figure 4.52** Space charge limited current for three different thicknesses of PFO sandwiched between Ohmic electrodes of PEDOT:PSS and MoO<sub>3</sub>. Lines are fits to the Mott-Gurney relation, Eq. 4.127, after accounting for the contact built-in voltage,  $V_{bi}$  (Nicolai et al., 2010).

changes in mobility at high field. These mobility-dependent effects have been studied for the hole conducting polymer NRS-PPV, sandwiched between ITO and Au contacts (Pasveer et al., 2005). The dotted line in Fig. 4.53 corresponds to the simple  $V^2$  dependence of the Mott-Gurney relationship. The dashed lines are fits to Eq. 4.127 assuming that the mobility depends on hole concentration, and hole transport is via percolation in a Gaussian DOS at the HOMO energy edge. Percolation occurs by charge hopping from conducting polymer cluster to cluster. At a critical density of conducting clusters (which in this case consists of neighboring empty sites into which holes can hop), all clusters are connected and the charge can move from one end of a sample to the other. Within the GDM, the mobility can be approximated by  $\mu_p(T, p) \sim \exp(p^\delta)$  where  $\delta$  is a parameter depending on the width of the site distribution,  $\sigma_{GDM}$  (cf. Table 4.2). The fits are reasonable at the highest temperatures, but the theoretical dependence of  $j$  vs.  $V$  deviates from a simple charge density dependence at lower temperatures. This difference is attributed to the field dependence of the mobility discussed in Section 4.3.2. The solid lines correct for both the field and charge dependence of the mobility (Pasveer et al., 2005).

We caution that while the fits are accurate over a limited range of temperature and voltage, they employ numerous assumptions and fitting parameters. Hence, it is unclear how generally this fitting procedure can be applied to other materials, and what interdependence one variable has on the

**Figure 4.53** Current vs. voltage characteristics for the hole conducting polymer, NRS-PPV, at various temperatures. The solid lines represent fits to the data assuming SCL conduction where mobility is a function of hole concentration and electric field. The dashed lines consider only the contribution of the excess hole concentration. The dotted line is for the constant mobility expression of Eq. 4.127. Here,  $d$  is the film thickness,  $a$  is the distance between molecules, and  $\sigma_{GDM}$  is the Gaussian distribution half width (Pasveer et al., 2005).

others. This ultimately limits the depth of understanding such a parametric model can provide in revealing the origins of the transport processes in organic semiconductors.

#### 4.4.2.2 SCL conduction in the presence of traps

Disorder in organics leads to deep levels or trap states that exist in the energy gap between the HOMO and LUMO. Hence, it is rare indeed when we can apply the Mott–Gurney relation to these materials systems without considering the effects of traps. Inclusion of traps in our analysis, however, is accompanied by assumptions whose validities are often difficult to verify. We must always bear in mind that the measured current is actually the sum over all charge generating mechanisms, making it challenging or impossible to separate out the individual contributions. The strongest leverage for isolating these mechanisms is to determine the dependence of  $j$  on voltage (and hence electric field), and temperature. Even then, ambiguity can arise as we have seen in the analysis of data in Fig. 4.53, necessitating further experiments to access the dependence of current on illumination and frequency to help sort out the origins of the background current. In analyzing the data, therefore, it is useful to use the rule of Occam’s razor whereby “*Among competing hypotheses, the one with the fewest assumptions should be selected.*”

In this section, we expand our understanding of space charge conduction to include the more general case of conduction in an organic semiconductor in the presence of traps, which may be of either intrinsic (i.e. dynamic and static disorder) or extrinsic (e.g. impurities) origin.

We first consider the simplest, albeit somewhat unrealistic case of a single, discrete defect, or trap state located at energy  $E_T$  within the HOMO–LUMO gap. Assuming that the traps are uniformly spatially distributed across the sample, then

$$h_T(E) = H_T \delta(E - E_T) \quad (4.129)$$

is their DOS,  $H_T$  is the total trap density, and the Kronecker delta is  $\delta(E)$ . Then the number of trapped holes (assuming hole-only conduction, with simple substitutions used for electron-only situations) is

$$p_T = \int_{E_{HOMO}}^{E_{LUMO}} h_T(E) f_p(E) dE = \int_{E_{HOMO}}^{E_{LUMO}} \frac{H_T \delta(E - E_T)}{1 + g_p \exp[(E_{Fp} - E)/k_B T]} dE, \quad (4.130)$$

where

$$f_p(E) = \frac{1}{1 + g_p \exp[(E_{Fp} - E)/k_B T]} \quad (4.131)$$

is the Fermi–Dirac distribution for the number of filled hole states,  $E_{Fp}$  is the hole Fermi energy above the HOMO energy  $E_{HOMO}$ , and  $g_p$  is the degeneracy of the state. Typically  $g_p = 2$  due to the two spin states allowed in each level. Evaluating the integral leads to

$$p_T = \frac{H_T}{1 + g_p \frac{N_{HOMO}}{p} \exp[(E_{HOMO} - E_T)/k_B T]} \quad (4.132)$$

where

$$p = N_{HOMO} \exp[-(E_{Fp} - E_{HOMO})/k_B T] \quad (4.133)$$

is the total free hole density which is the sum of the equilibrium ( $p_0$ ) and injected ( $p_{inj}$ ) densities, and  $N_{HOMO}$  is the DOS at the HOMO level. It is convenient to use the free charge factor,  $\theta_f = \frac{g_p N_{HOMO}}{H_T} \cdot \exp[(E_{HOMO} - E_T)/k_B T]$  such that Eq. 4.132 becomes

$$p_T = \frac{H_T}{1 + H_T \theta_f / p}. \quad (4.134)$$

Now, returning to Eq. 4.122 but including trapped charge, we have

$$\frac{dF(x)}{dx} = \frac{q(p_{inj}(x) + p_0 + p_T)}{\epsilon_r \epsilon_0} \approx \frac{q}{\epsilon_r \epsilon_0} \left\{ p_{inj}(x) + \frac{H_T}{1 + H_T \theta_f / p_{inj}(x)} \right\}, \quad (4.135)$$

where the small background carrier density is ignored in the space charge limit. To solve this analytically, we make the further assumption that the trapped charge density is significantly larger than that of free charges, that is,  $H_T \theta_f > p_{inj}(x)$ . Then,

$$\frac{dF(x)}{dx} = \frac{q}{\epsilon_r \epsilon_0 \theta_f} p_{inj}(x) (\theta_f + 1). \quad (4.136)$$

Following the same treatment used to calculate the trap-free SCL current, we arrive at the modified Mott–Gurney relation in the presence of a discrete, high density of traps:

$$j_{SCL} = \frac{9}{8} \left[ \frac{\theta_f}{(\theta_f + 1)} \right] \mu_p \epsilon_0 \epsilon_r \frac{V^2}{d^3}. \quad (4.137)$$

But Eq. 4.135 implies that when  $p_T > p_{inj}$ , then the ratio of free to trapped charge is  $\theta_f \approx p_{inj}/p_T < 1$ , yielding (Rose, 1955)

$$j_{SCL} = \frac{9}{8} \theta_f \mu_p \epsilon_0 \epsilon_r \frac{V^2}{d^3}. \quad (4.138)$$

Thus, the mobility is decreased to  $\mu_{eff} = \theta_f \mu_p < \mu_p$  as the trap density increases. As expected, the reduced mobility also increases the voltage at which Ohmic gives way to SCL conduction. Similar to Eq. 4.128,

$$V_X = \frac{8}{9} \frac{q}{\theta_f \epsilon_r \epsilon_0} p_0 d^2. \quad (4.139)$$

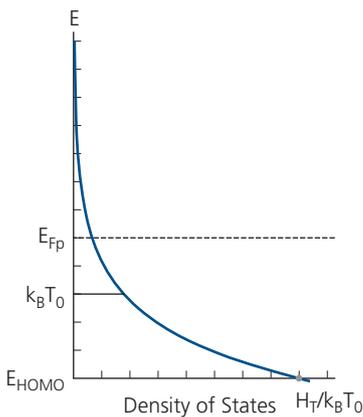

A more physically realistic model assumes that an exponential trap distribution continuously extends from the conduction (frontier) orbital level into the energy gap. We use an exponential DOS in place of a nearly equivalent Gaussian (cf. Fig. 4.28) since the former leads to simple analytical solutions. Then, for the hole trap density (again, assuming a uniform distribution of traps throughout the sample bulk):

$$h_T(E) = \frac{H_T}{k_B T_0} \exp[-(E - E_{HOMO})/k_B T_0] \quad (4.140)$$

where  $T_0$  is the *characteristic trap temperature* that sets the position of the distribution relative to the HOMO energy. This trap distribution is illustrated in Fig. 4.54. States between  $E_{Fp}$  and  $E_{HOMO}$  are filled with holes, and those above  $E_{Fp}$  are empty. The maximum trap state density of  $H_T/k_B T_0$  is found at  $E_{HOMO}$ . An analogous expression can be employed to describe electron traps extending into the energy gap from the LUMO.

For simplicity we take  $f_p \approx 1$  at  $E > E_{Fp}$ , and  $f_p \approx 0$  at  $E < E_{Fp}$ . This gives the number of trapped holes:

$$\begin{aligned} p_T &= \int_{E_{Fp}}^{\infty} h_T(E) dE = \frac{H_T}{k_B T_0} \int_{E_{Fp}}^{\infty} \exp[-(E - E_{HOMO})/k_B T_0] dE \\ &= H_T \exp[-(E_{Fp} - E_{HOMO})/k_B T_0] \end{aligned} \quad (4.141)$$

**Figure 4.54** Density of trap states from the HOMO level ( $E_{HOMO}$ ) extending into the energy gap. The maximum density is  $H_T/k_B T_0$ , and the Fermi level for holes is  $E_{Fp}$ . Also,  $T_0$  is the characteristic trap temperature.

We can now write this in terms of the hole density in Eq. 4.133 to obtain

$$p_T = H_T \left( \frac{p}{N_{HOMO}} \right)^{T/T_0} = H_T \left( \frac{p}{N_{HOMO}} \right)^{1/m}, \quad (4.142)$$

where

$$m = T_0/T = E_T/k_B T, \quad (4.143)$$

with  $E_T = k_B T_0$  equal to the characteristic trap energy.

Multiplying both sides of Gauss' law, Eq. 4.122, by  $[(m+1)/m]F(x)^{1/m}$ , we get

$$\begin{aligned} \left( \frac{m+1}{m} \right) F(x)^{1/m} \frac{dF(x)}{dx} &= \frac{dF(x)^{1/m+1}}{dx} \\ &= \frac{q}{\epsilon_r \epsilon_0} \left( \frac{m+1}{m} \right) (pF(x))^{1/m} (p^{1-1/m} + H_T N_{HOMO}^{-1/m}) \end{aligned} \quad (4.144)$$

or

$$\begin{aligned} F(x)^{1/m+1} &= \frac{q}{\epsilon_r \epsilon_0} \left( \frac{m+1}{m} \right) \left( \frac{j_{SCL}}{q \mu_p} \right)^{1/m} \\ &\quad \times (p^{1-1/m} + H_T N_{HOMO}^{-1/m}) x \\ &= \frac{q H_T}{\epsilon_r \epsilon_0} \left( \frac{m+1}{m} \right) \left( \frac{j_{SCL}}{q \mu_p N_{HOMO}} \right)^{1/m} \\ &\quad \times \left( \frac{p^{1-1/m} N_{HOMO}^{1/m}}{H_T} + 1 \right) x \end{aligned} \quad (4.145)$$

In the high trap density limit:

$$\frac{p^{1-1/m} N_{HOMO}^{1/m}}{H_T} = p \frac{p^{-1/m} N_{HOMO}^{1/m}}{H_T} = \frac{p}{p_T} \approx 0, \quad (4.146)$$

which leaves the simplified expression for the electric field:

$$F(x) = \left( \frac{q H_T}{\epsilon_r \epsilon_0} \frac{m+1}{m} \right)^{\frac{m}{m+1}} \left( \frac{j_{SCL}}{q \mu_p N_{HOMO}} \right)^{\frac{1}{m+1}} x^{m/(m+1)}. \quad (4.147)$$

Integrating this to obtain the voltage, and solving for current, we finally arrive at

$$j_{SCL} = q \mu_p N_{HOMO} \left( \frac{2m+1}{m+1} \right)^{m+1} \left( \frac{m}{m+1} \frac{\epsilon_r \epsilon_0}{q H_T} \right)^m \frac{V^{m+1}}{d^{2m+1}}. \quad (4.148)$$

By equating this to Ohm's law, we can again calculate the cross-over voltage:

$$V_X = \frac{q H_T}{\epsilon_r \epsilon_0} \frac{m+1}{m} \left( \frac{m+1}{2m+1} \right)^{\frac{m+1}{m}} \left( \frac{p_0}{N_{HOMO}} \right)^{\frac{1}{m}} d^2, \quad (4.149)$$

which, as in the case of SCL current, scales as  $d^2$ .

For our treatment of SCL currents, it was assumed that the material is spatially homogeneous (i.e. the traps are uniformly distributed throughout the bulk of the sample), and the mobility is field-independent. In fact, given the several parameters in Eqs. 4.148 and 4.149, it is not possible to unambiguously determine  $\mu_p$  without *a priori* knowledge of  $N_{HOMO}$ ,  $H_T$ , and  $m$ . Thus, mobility should be obtained from an independent time of flight or alternative measurement technique discussed in Section 4.4.3. One further assumption is that there are no injection barriers. This is particularly important since such barriers themselves can also lead to a power-law dependence of  $j_{SCL}$  on  $V$ . Effects of injection can be separated from SCL-like behavior by measuring the dependence of  $j_{SCL}$  on  $d$ : SCL currents have a thickness dependence  $\sim 1/d^{2m+1}$ , whereas injection, in principle, should be layer thickness independent. More often, however, both phenomena exist in the same sample and it is not always possible to distinguish between the limiting sources of the dark current. The topic of injection from contacts is treated in more detail in Section 4.6.

It follows from Eq. 4.148 that the current for the special case of  $m = 1$  reverts to the Mott-Gurney relation in the presence of a discrete trap, with  $\theta_f = p/p_T \rightarrow N_{HOMO}/H_T$ . Also, in the limit of a uniform distribution of traps within the HOMO-LUMO gap,  $T_0 \rightarrow \infty$  in which case  $m \rightarrow 0$ . Then  $p_T = H_T$  (Eq. 4.142) and the cross-over voltage becomes  $V_X = qH_T d^2 / (2\epsilon_r \epsilon_0)$ .

For completeness, we consider the slightly different case of a Gaussian density of trap states with a distribution of width  $\sigma_T$  and a maximum at energy  $E_{Tm}$ . Then we have:

$$h_T(E) = \frac{H_T}{\sqrt{2\pi}\sigma_T} \exp\left[-(E - E_{Tm})^2 / 2\sigma_T^2\right]. \quad (4.150)$$

Following the previous approach for a distribution of traps that lies deeper than the Fermi energy, that is, for  $E_{Tm} > E_{Fp}$ , the density of trapped holes is found by integrating the product  $h_T(E)f_p(E)$  over energy:

$$\begin{aligned} p_T &= \frac{H_T}{\sqrt{2\pi}\sigma_T} \int \frac{\exp\left[-(E - E_{Tm})^2 / 2\sigma_T^2\right]}{1 + g_p \exp\left[(E_{Fp} - E)/k_B T\right]} dE \\ &= H_T^G \left(\frac{p}{N_{HOMO}}\right)^{1/m}, \end{aligned} \quad (4.151)$$

where

$$H_T^G = \left(\frac{H_T}{2g_p}\right) \exp(E_{Tm}/mk_B T) \quad (4.152)$$

and

$$m = \left(1 + 2\pi\sigma_T^2 / 16k_B^2 T^2\right)^{1/2}. \quad (4.153)$$

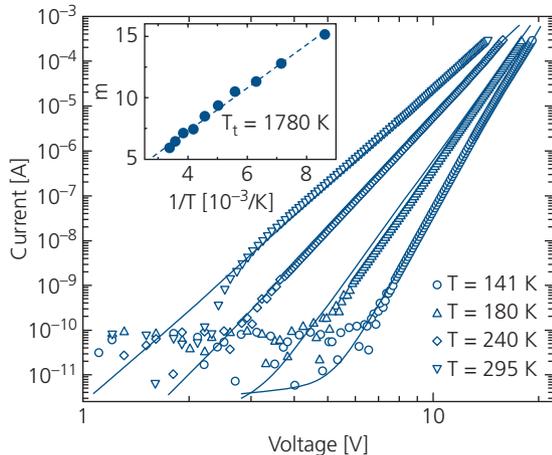

Here,  $g_p$  is the degeneracy of the hole trap state. It is then straightforward to show that the current in the presence of a Gaussian density of trap states is given by Eq. 4.135 using the substitution of  $H_T \rightarrow H_T^G$  (see Prob. 4.6).

Interestingly, if the Gaussian distribution is shallow, then the Fermi-Dirac distribution  $f_p(E)$  can be replaced by the Boltzmann approximation, to yield

$$\begin{aligned} p_T &= \int h_T(E) g_p^{-1} \exp\left[(E - E_{Fp})/k_B T\right] dE \\ &= H_T g_p^{-1} \exp\left[(E_{Tm} - E_{Fp})/k_B T\right] \exp\left[-\left(\sigma_T / \sqrt{2} k_B T\right)^2\right] \\ &= p / \theta_G, \end{aligned} \quad (4.154)$$

which in the limit of a large trap density is an expression similar to Eq. 4.134 for a single, discrete trap level. For a Gaussian distribution of shallow traps, we can use the  $j_{SCL}$  vs.  $V^2$  expression for a discrete trap distribution in Eq. 4.138 by replacing  $\theta_f$  with  $\theta_G$ . Thus, a Gaussian distribution cannot be distinguished from an exponential or discrete trap distribution without further independent determination such as via optical excitation or bleaching of trapped charge.

SCL currents for an exponential distribution of traps within the energy gap have been routinely observed in organic semiconductors such as in *a*-CuPc (Hamann, 1968) and anthracene (Schadt and Williams, 1969). SCL conduction has also been identified in both small molecule and polymer materials that are commonly used in OLEDs. For example, SCL electron transport in the presence of an exponential trap distribution in Mq<sub>3</sub> small molecule materials, where M = Al, Ga or In and q = 8-hydroxyquinoline, has been studied, with the *j*-*V* characteristics for Alq<sub>3</sub> at several temperatures shown in Fig. 4.55 (Burrows et al., 1996). The devices comprise a bilayer of the hole conducting TPD and a 55 nm thick the electron conducting Alq<sub>3</sub> layer sandwiched between an ITO anode and Mg-Ag cathode. The 27 nm thick TPD layer has very low resistance and hence its contribution to the total applied voltage drop is ignored. In the inset, the temperature exponent, *m* is plotted vs. 1/*T* (Eq. 4.143). The slope of the data yields a characteristic trap temperature of  $T_0 = 1780$  K, corresponding to an energy of 0.15 eV below the LUMO of Alq<sub>3</sub>. Several key parameters are obtained from the fit that characterize the amorphous Alq<sub>3</sub> film. Thus,  $H_T = (3.1 \pm 0.1) \times 10^{18} \text{ cm}^{-3}$ , and the DOS in the LUMO

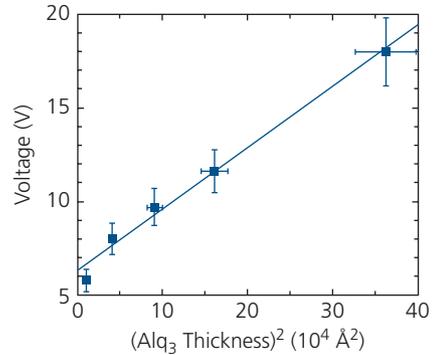

**Figure 4.55** Current–voltage characteristics of a TPD/Alq<sub>3</sub> bilayer OLED at four different temperatures. The solid lines are fits to the data of the form  $j \sim V^{m+1}$  assuming an exponential trap distribution. The inset shows the linear dependence of  $m$  vs.  $1/T$ , consistent with trap-dominated SCL current. A trap temperature of  $T_0 = 1780$  K is obtained from the fit (Burrows et al., 1996).

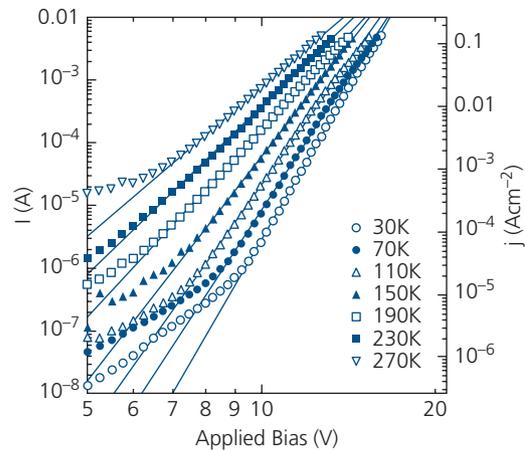

is  $N_{LUMO} = (1.0 \pm 0.5) \times 10^{19} \text{ cm}^{-3}$ , which are determined using the mobility measured from time of flight data of  $\mu_n = (5 \pm 2) \times 10^{-5} \text{ cm}^2/\text{V s}$ . From  $V_X$ , the background free electron concentration is  $n_0 < 10^{11} \text{ cm}^{-3}$ . Since  $H_T$  is near to  $N_{LUMO}$ , it was proposed that  $H_T$  is an intrinsic property of the disordered film, that is,  $H_T$  is the result of static disorder rather than arising from extrinsic sources such as impurities.

An essential test for the existence of SCL current is its dependence on sample thickness. This is shown for a series of Alq<sub>3</sub> samples in Fig. 4.56. In Eq. 4.148 we see that at a constant current,  $V^{m+1} \sim d^{2m+1}$ , which for large  $m$ ,  $V \sim d^2$ . The fit to this behavior is apparent in the data obtained for  $d$  between 10 nm to 60 nm at 20  $\mu\text{A}$ . Due to the pronounced dependence of  $j_{SCL}$  on  $d^{2m+1}$ , small errors in determining film thickness can lead to large errors in measurements of the thickness dependence of  $j$  on  $V$ .

Similar analysis of the electroluminescent polymer, PPV, has also shown SCL conduction limited by an exponential distribution of traps (Campbell et al., 1997). The data in Fig. 4.57 are fit (solid lines) to Eq. 4.148 by varying  $m$  from 6 at 290 K to 17 at 11 K. The fit of  $m$  vs.  $1/T$  follows a linear relationship from 300 K to approximately 120 K, with  $T_0$  nearly the same as for Alq<sub>3</sub>, although at lower temperatures  $T_0$  begins to fall off rapidly. This dependence of trap energy (given by  $E_T = k_B T_0$ ) arises from assuming that the mobility is independent of both temperature and electric field. We have seen that neither of these approximations is valid over large variations in either

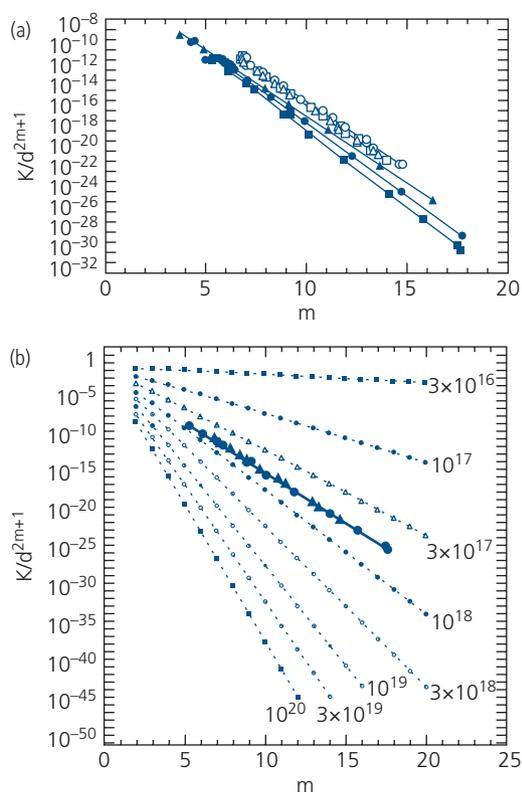

**Figure 4.56** Dependence of voltage on the square of the thickness ( $d$ ) of Alq<sub>3</sub> films at constant current and room temperature (Burrows et al., 1996).

**Figure 4.57** Current–voltage characteristics of a 94 nm thick PPV layer sandwiched between ITO and Al Ohmic contacts. The solid lines are fits based on SCL current in the trap limited regime. For these fits,  $m$  varies from 6 at 290 K to 17 at 11 K (Campbell et al., 1997).

parameter. For example, as temperature is lowered, we expect that mobility changes from hopping-limited, consistent with dynamic disorder, to a tunneling-limited regime. Hence, the decrease in trap energy observed for PPV at low temperature is most likely due to the failure of the constant mobility assumption.

The dependence of current on thickness of the PPV layers is shown in Fig. 4.59a. The data are plots of  $K/d^{2m+1}$  vs.  $m$  obtained from the  $j$ - $V$  characteristics which from Eq. 4.148 is written as  $j_{SCL} = KV^{m+1}/d^{2m+1}$ . The data are for PPV thicknesses of 94 nm and 125 nm, and  $m$  is taken from the high voltage range of the  $j$ - $V$  characteristics in the range  $11 \text{ K} < T < 290 \text{ K}$ . These data conform to the thickness dependence of the trap-limited SCL current in Eq. 4.148. This is supported by replotting these data in Fig. 4.58b after multiplying by  $d^{2m+1}$  to remove the

**Figure 4.58** (a) Dependence of  $K/d^{2m+1}$  obtained from the  $j$ - $V$  characteristics, viz.  $j_{SCL} = KV^{m+1}/d^{2m+1}$  (cf. Eq. 4.148) vs.  $m$  from temperature dependent measurements ranging from 11 K to 290 K. PPV thicknesses are  $d = 94$  nm (open symbols), 125 nm (full symbols). (b) Data from (a) replotted by multiplying by  $d^{2m+1}$  to remove the thickness dependence. Dashed lines are theoretical fits for various  $H_T$  (Campbell et al., 1997).

thickness dependence. All data fit on the same line corresponding to a trap density of approximately  $H_T = 5 \times 10^{17}$  cm $^{-3}$ , inferred from their position among the theoretically calculated lines.

Parametric fits to polymer data similar to those in Fig. 4.57 have used a Gaussian vs. an exponential trap distribution (Nicolai et al., 2011). While those fits are also convincing, as noted above they cannot be clearly distinguished from the exponential model although additional parameters ( $E_{Tm}$  and  $\sigma_T$ ) are required. Unless there are compelling physical reasons for choosing the more complex Gaussian trap model, this may indeed be a case where Ockham's razor can justifiably be applied.

#### 4.4.3 Measuring conductivity and mobility

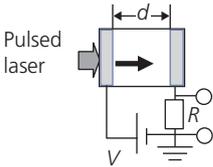

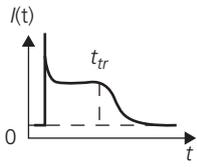

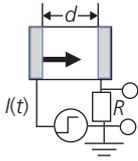

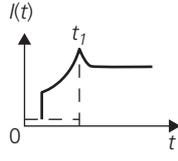

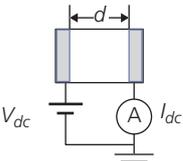

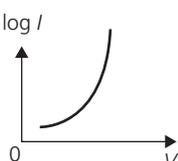

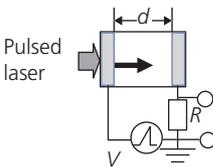

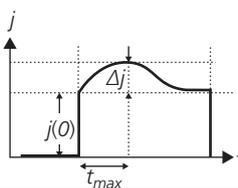

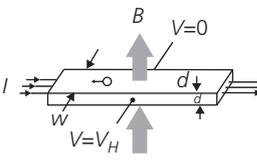

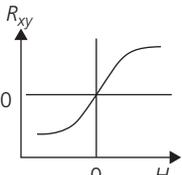

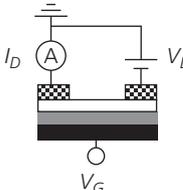

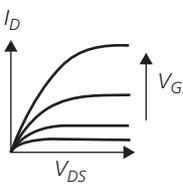

Time of flight of charges in an electric field, and analysis of the  $j$ - $V$  characteristics discussed in the foregoing sections are two of several means used

for measuring charge mobility and conductivity in organic semiconductors. Keep in mind that different techniques go about the measurement of a quantity using different approaches, and hence there can be differences in the values inferred for  $\mu$  and  $\sigma$ . For example, *time of flight* (TOF) measurements are based on analysis of transient currents induced by pulsing the sample either with an external voltage or illumination. On the other hand,  $j$ - $V$  measurements discussed in the previous sections are obtained in the steady state. In the SCL region,  $\mu$  is obtained directly from the slope of the characteristics once the dielectric constant (obtained from capacitance-voltage measurements) and film thickness are known. In the Ohmic regime, only the product,  $n\mu$ , is measured, from which a separate measurement of the charge density is required to obtain  $\mu$ .

Traps that are almost always present in organics can have different occupancies in the steady or transient states, thus altering the internal electric field experienced by a charge as it moves between contacts. Hence, the mobilities obtained from TOF and SCL currents measure mobilities under very different conditions of trap occupancy, and hence these methods will not necessarily return the same value. To complicate matters even more, several methods measure the charge conductivity along a surface or interface where, again, the presence of traps or structural defects can influence conductive properties. Particularly, thin film transistor characteristics measure currents along the organic/insulator interface to yield a *field effect mobility* ( $\mu_{FE}$ ) that should not be confused with a bulk property of the material.

The inherent differences between measurement methods have led to many ambiguities and contradictory values for mobilities (and conductivities) of organics. Indeed, some materials have exhibited mobilities that differ by several orders of magnitude, depending on the measurement technique used. In this section, we discuss several means for measuring bulk mobilities, pointing out, wherever possible, the limitations and advantages of a particular method. In particular, we will discuss TOF mobility, dark injection space charge limited current, charge extraction by linearly increasing voltage (CELIV), and Hall effect mobility. Field effect mobilities, which are applicable to organic thin film transistors but not necessarily for determining an intrinsic materials property, will be discussed in Chapter 8. For reference, the most common methods for measuring bulk charge mobilities are listed in Table 4.3.

**Table 4.3** Methods of mobility measurement

Technique	Sample Geometry	Typical Data
1. TOF (Time-of-flight)		
2. DISLC (Dark-injection space-charge-limited current)		
3. J-V Analysis (current-voltage characteristics)		
4. CELIV (Charge extraction by linearly increasing voltage)		
5. Hall Effect		
6. OTFT (Organic Thin Film Transistor)		

#### 4.4.3.1 Time of flight mobility

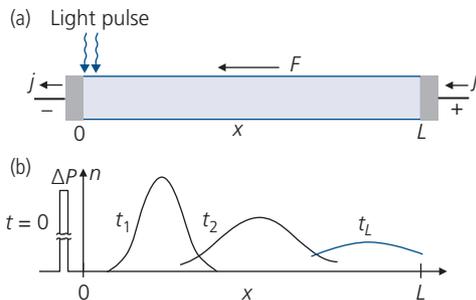

TOF measurements have been extensively used to determine the mobilities of both inorganic and organic semiconductors. The method introduced by Haynes and Shockley is based on application of a voltage between contacts positioned at the opposite ends of a slab of a semiconductor (Haynes and Shockley, 1949, Shockley et al., 1949). A light pulse whose energy  $E = h\nu > E_G$  illuminates the sample of

length,  $L$ , near one of the electrodes. In an inorganic semiconductor, this generates a free electron-hole pair. Charges of the polarity opposite to that of the nearby electrode are rapidly collected, and the counter charges drift under the applied electric field to the opposite electrode (see Fig. 4.59).

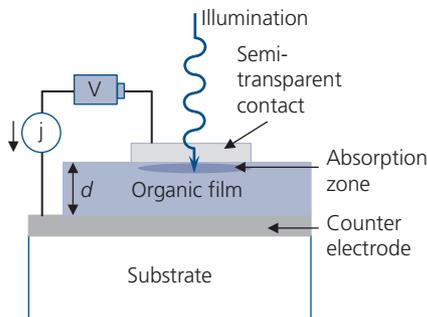

If the field is sufficiently small to avoid space charge injection, the conduction is Ohmic, giving an electron transit time of  $t_{tr} = L/\mu_n F = L^2/\mu_n V$ . Hence,

by measuring the arrival time of the charge pulse at the electrode farthest from the pump location, we extract the electron mobility as a function of the applied voltage,  $V$ . This treatment assumes that there is a single well-defined mobility, and that charge trapping and detrapping (which would affect both the width and the shape of the arriving current pulse) are negligible. It further requires that the illumination area be well-defined and whose extent is small relative to  $L$ . That is, the point of generation must be well separated from the counter electrode such that the charge packet can develop and be allowed to transit the semiconductor without uncertainty about their point of origin.

Organics seldom have sufficient conductivity to use this lateral thin film geometry. Thus, it is common to employ a vertical, or sandwich structure such as that in Fig. 4.60. The sample of thickness,  $d$ , is biased between two electrodes, at least one of which must be Ohmic (i.e. non-blocking). Light is incident on one semi-transparent or transparent (e.g. ITO) electrode, and the current response is measured vs. time. The sample

**Figure 4.59** Haynes–Shockley time of flight measurement of charge mobility. (a) Experimental setup for a sample of length  $L$ , under electric field  $F = V/L$ . The current density induced by the light pulse is  $j$ . (b) *left*: A square light pulse of power,  $\Delta P$ , is incident on the sample at position  $x = 0$  and time  $t = 0$ . *right*: Time evolution of the charge distribution as it traverses the sample from  $x = 0$  to  $L$ .

**Figure 4.60** Device geometry commonly used in measuring mobility in organic thin films of thickness,  $d$ .

must be sufficiently thick to avoid substantial generation far into the film bulk. If this is not the case, then the transit distance will not be the same for all charges, leading to a range of charge arrival times at the opposite electrode. Near-surface generation at the transparent electrode/film interface is accomplished by illumination with a short wavelength pulse that is very strongly absorbed by the organic. To increase exciton dissociation and hence photocurrent, the semi-transparent contact can be photoemitting. Alternatively, an exciton dissociating HJ can be placed immediately beneath the contact (see Section 4.7). In this vertical Haynes–Shockley configuration, the transit time becomes

$$t_{tr} = \frac{d^2}{\mu V}. \quad (4.155)$$

In Fig. 4.59, we show that the charge packet broadens with time due to diffusion. The one-dimensional electron diffusion equation in the absence of recombination is

$$\frac{\partial n(x, t)}{\partial t} = D_n \frac{\partial^2 n(x, t)}{\partial x^2}, \quad (4.156)$$

with a similar equation for holes. Assuming that the Einstein relation obtains, then  $qD_n = \mu_n k_B T$ . The boundary conditions for a sample of width  $w$  are  $n(0, 0) = n_0/w$  and  $n(L, 0) = n(L, \infty) = 0$ . Then Eq. 4.156 has solutions:

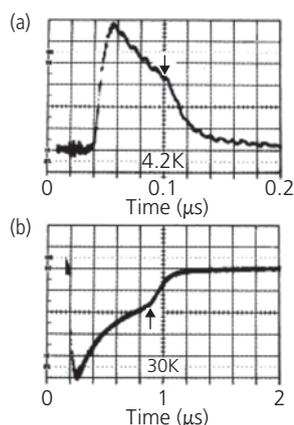

$$n(x, t) = \frac{n_0}{2\sqrt{\pi D_n t}} \exp(-x^2/4D_n t). \quad (4.157)$$

The time of arrival at  $L$  of the full width at  $1/e$  of the maximum current is, from Eq. 4.157:  $\Delta t = 4\sqrt{D_n t_{tr}^3}/L^2$ . The current peak amplitude is proportional to  $n_{peak} = n_0/\sqrt{4\pi D_n t_{tr}}$ . The peak magnitude, its arrival time, and width give the charge diffusion constant, and hence the mobility.

As noted in Chapter 3, illumination of organics does not result in the direct generation of free charge, but rather in excitons that must be separated into electrons and holes. Charge separation can occur at the metal contact/organic interface, albeit with low efficiency. To increase the charge generation efficiency, it is convenient to insert a thin organic zone near the contact that comprises a donor–acceptor HJ. Charge generation at donor–acceptor junctions found in photovoltaic cells or photodetectors can approach 100% efficiency, as will be discussed in Chapter 7.

Figure 4.61 shows the electron and hole current transients due to optical excitation of an ultrapurified naphthalene crystal (Warta and Karl, 1985). The initial

peak is the displacement current due to the capacitance of the organic layer, followed by a plateau due to conduction through the film. Initially the internal field is high, resulting in the injection of a sheet of charge into the sample. The displacement current is then constant as the charge propagates through the sample until it reaches the counter electrode. After this, the charge density decreases, producing the diffusive edge of the transient indicated by the arrows in Fig. 4.61. The mobility is in fact not a scalar, but rather is a tensor that describes the transport properties

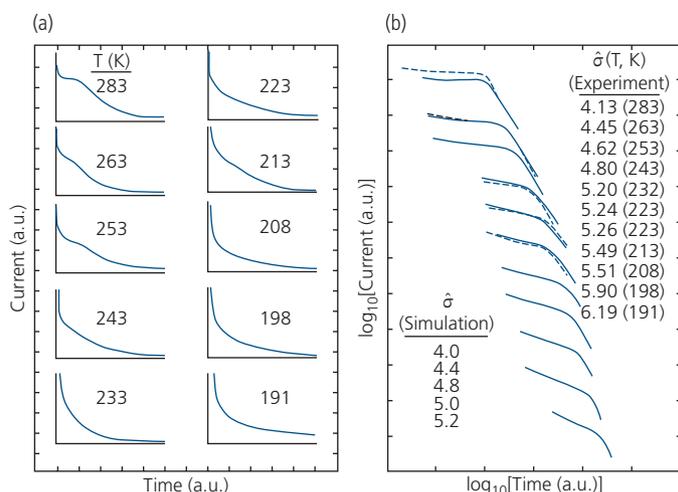

**Figure 4.61** (a) Current transient due to hole transport in an ultrapurified naphthalene crystal of length  $L = 1.01$  mm at  $T = 4.2$  K. (b) Current transient due to electron transport at  $T = 30$  K for the sample in (a) but with the electric field direction reversed. An 8 ns optical pulse at a wavelength of 249 nm generated the charges. The vertical scale divisions are  $40 \mu\text{A}/\text{cm}^2$ . The arrows mark the time of arrival of the peak current, from which  $\mu_n$  and  $\mu_p$  are extracted (Warta and Karl, 1985).

along different crystalline directions. Hence, when measuring  $\mu$  on single-crystalline samples such as in Fig. 4.62, care must be taken to apply the field along a known crystalline axis to obtain an accurate value.

In the presence of energetic disorder with Gaussian width,  $\sigma_{GDM}$ , the arrival times undergo dispersive spreading. That is, the mean charge velocity decreases with time since the initially hot carriers injected into the sample thermalize in a time longer than their transit times. Dispersive transport is due to the arrival of charges with a distribution of mobilities, as opposed to non-dispersive transport where only a single mobility is present. Mobilities measured for dispersive samples depend on the applied voltage, sample length and temperature.

The transition from dispersive to non-dispersive hole transport as a function of temperature has been studied in  $5.6 \mu\text{m}$  long samples of DEH, with results shown in Fig. 4.62 (Borsenberger et al., 1992). The samples were sandwiched between an  $\alpha$ -Se photoemitting anode and an Au cathode, and illuminated by 440 nm wavelength, 3 ns duration pulsed radiation. The transport becomes dispersive at  $T < 243$  K for samples whose Gaussian width is  $\hat{\sigma} = \sigma_{GDM}/k_B T = 4.4$ . Even at higher temperatures, there is some droop in the plateau similar to that seen in Fig. 4.61 due to the presence of on-diagonal energetic disorder. The transition from non-dispersive to dispersive transport is particularly apparent in the double logarithmic plots of the current transients in Fig. 4.62b. The plateau corresponding to non-dispersive transport yields to a continually increasing slope for transients at lower

**Figure 4.62** TOF hole current transients for a  $5.6 \mu\text{m}$  long sample of DEH vs. temperature. (a) Double linear plots and (b) double logarithmic plots along with fits (dashed lines) assuming normalized Gaussian disorder widths ( $\hat{\sigma}$ ) shown in the lower left. Disorder widths in the upper right are extracted from fits to the data. The electric field in these measurements is  $F = 6 \times 10^5$  V/cm, and at room temperature,  $\mu \sim 5 \times 10^{-5}$   $\text{cm}^2/\text{V s}$  (Borsenberger et al., 1992).

temperatures. The long, exponential tail at low temperature is due to slow hopping of holes from the edge of the density of HOMO states that extends deep into the HOMO–LUMO energy gap.

We emphasize that a single value of charge mobility cannot be extracted from samples that exhibit dispersive transport. An important advantage, therefore, is that it can be used to distinguish between non-dispersive and dispersive transport regimes. This differs from measurements based on  $j$ - $V$  analysis, transistor characteristics, or CELIV that only obtain an effective mobility without revealing details of the transport dynamics.

#### 4.4.3.2 Dark injection space charge limited current

The transient response to a voltage pulse is an alternative means to determine mobility. This process is known as *dark injection space charge limited current* (DISCL). The accuracy and applicability of DISCL is essentially the same as for optically induced TOF measurements, and is equally susceptible to errors arising from charge trapping and uncertainties in the field distribution across the sample. Its inherent simplicity, however, makes this an attractive method for measuring mobilities.

In DISCL, charge of one carrier type is injected from an Ohmic contact on one side of the sample using a short voltage pulse. The resulting charge packet transits the semiconductor under a uniform electric field. The collecting electrode should block injection to avoid simultaneous double carrier injection from both contacts. Measurement of the current response, therefore, provides the charge transit time, from which the mobility is extracted.

The time-dependent current due to an applied electric field in a hole-only device in one dimension is given by

$$j(t) = j_c(x, t) + j_d(x, t) = qp(x, t)\mu_p F(x, t) + \epsilon_r \epsilon_0 \frac{\partial F(x, t)}{\partial t}, \quad (4.158)$$

with obvious modifications for electron-only devices. Here,  $j_c(x, t)$  is the conduction current and  $j_d(x, t)$  is the displacement current. From Poisson's equation,

$$\frac{\partial F(x, t)}{\partial x} = \frac{qp(x, t)}{\epsilon_r \epsilon_0} = \frac{Q(x, t)}{\epsilon_r \epsilon_0}. \quad (4.159)$$

Equation. 4.158 thus becomes

$$j(t) = \epsilon_r \epsilon_0 \left( \frac{\mu_p}{2} \frac{\partial F^2(x, t)}{\partial x} + \frac{\partial F(x, t)}{\partial t} \right). \quad (4.160)$$

This can be solved with the boundary condition that the field at the anode,  $F_a(0, t) = 0$ , due to the high density of injected holes in the space charge limit. A constant drop in voltage from cathode to anode at the moment the charge sheet is injected into a sample of thickness,  $d$ , results in a uniform field:  $F(x, 0) = V/d$ . Then, Eq. 4.160 reduces to

$$j(t) = \left( \frac{\epsilon_r \epsilon_0 \mu_p}{2d} \right) F_c^2(t). \quad (4.161)$$

Let  $t_1$  be the time at which the leading edge of charge reaches the cathode. Prior to  $t_1$ , the current is due solely to displacement, whence Eq. 4.158 yields

$$\frac{\partial F_c}{\partial t} = \left( \frac{\mu_p}{2d} \right) F_c^2(t) \quad (4.162)$$

In the absence of traps, the charge per area at the anode is  $Q_a = \epsilon_r \epsilon_0 V/d$ . Then integrating Eq. 4.161, we obtain

$$F_c(t) = \frac{Q_a(t)}{\epsilon_r \epsilon_0 [1 - t/2t_{tr}]}, \quad (4.163)$$

where  $t_{tr}$  is the hole transit time. From Eq. 4.161,

$$j(t) = \frac{\epsilon_r \epsilon_0 \mu_p}{2[1 - t/2t_{tr}]^2} \frac{V^2}{d^3} = j_0/[1 - t/2t_{tr}]^2, \quad (4.164)$$

where  $j_0 = j(0) = \frac{4}{9} j_{SCL}$ . Here,  $j_{SCL}$  is the steady state SCL current given by Eq. 4.127. The final step is to determine the arrival time of charge at the cathode. This is done by calculating the integral of the velocity over the time it takes the charge to transit the length of the sample, yielding

$$L = \mu_p \int_0^{t_1} F_c(t) dt = \frac{2\mu_p t_{tr} V}{d} \ln(1 - t_1/t_{tr})^{-1} \quad (4.165)$$

or

$$t_1 = 2t_{tr}(1 - e^{-1/2}) = 0.786t_{tr}. \quad (4.166)$$

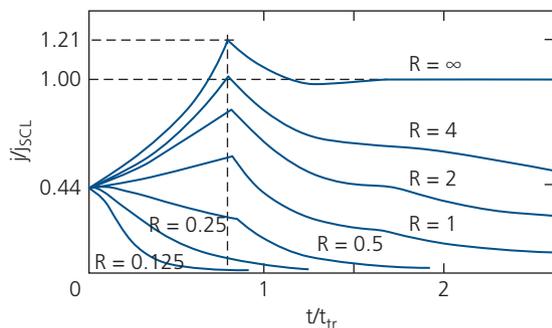

That is, the leading edge of the charge front reaches the cathode approximately 21% earlier than the transit time of the center of the charge distribution.

The current at  $t_1$  relative to its value at  $t = 0$  is  $j(t_1)/j_0 = e = 2.72$ , whereas compared to the current in steady state,  $j(t_1)/j_{SCL} = 4e/9 = 1.21$ . Hence, the current has a peak at  $t_1$ , at which point the sample contains the maximum amount of charge. As time progresses, the charge density decreases by collection at the cathode. The decrease continues until it reaches its steady state value for SCL conduction where the amount injected is equal to that extracted. A measurement of the time,  $t_1$  of the current peak

therefore yields  $t_{tr}$  from Eq. 4.166, from which we calculate the mobility from Eq. 4.155.

The full time dependent solutions to the drift-diffusion equation in the absence or presence of traps is more complex and beyond the scope of our discussion. For a detailed treatment the reader is referred to the work of Many and Rakavy (1962). The current transient solutions for space charge injection from a voltage step function that turns on at  $t = 0$  are shown in Fig. 4.63. The several curves correspond to solutions in the presence or absence of traps, defined by the ratio,  $R = t_p/t_{tr}$ , where  $t_p$  is the mean free time for hole recombination in the presence of traps. That is, as the trap density increases,  $t_p$  decreases accordingly. Here,  $R = \infty$  corresponds to the case of trap-free SCL current. The peak current is at  $t_1$ , and then falls immediately thereafter until steady state is reached. The small dip following the peak arises from the decreased electric field at the anode due to the non-equilibrium oversupply of injected charge. As this excess charge is depleted, the current relaxes to its equilibrium value. A decreased recombination time results in a decrease in the steady state and peak currents. Except for the most extreme cases,  $t_1$  is easily identified at all  $R$ , from which  $\mu$  can be accurately determined.

An example DISCL measurement and fits to the data at several different pulse voltages is shown in Fig. 4.64 for a 300 nm thick film of the first generation hexabutyl triarylamine dendrimer (hexabutyl-MTDATA, Louie et al., 1997) sandwiched between Au contacts. There are several complicating effects that need to be considered to achieve the fits to the data that extend from  $t = 0$  to steady state. The best fits, are obtained for  $\mu = 6.1 \times 10^{-6} \text{ cm}^2/\text{V s}$ , including the small falling transient at low current at the onset of the transient. This feature results

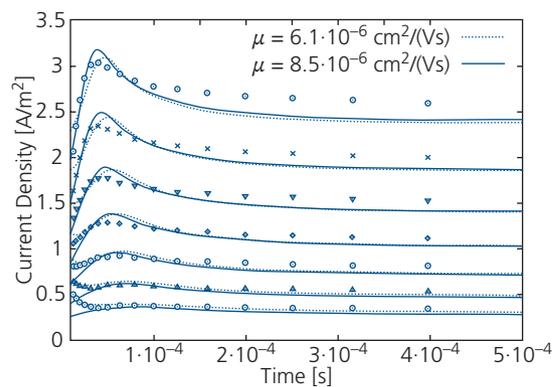

**Figure 4.63** Current transient in units of the steady state trap-free SCL current ( $j_{SCL}$ ) vs. time in units of the charge transit time,  $t_{tr}$ . Here,  $R = t_p/t_{tr}$  is the ratio of the mean free time for recombination of the mobile hole in the presence of traps to the transit time. From Many and Rakavy (1962).

from trap filling. The parameters used in the best fits are a contact barrier height of 0.28 eV, a Gaussian distribution of states at the contact/semiconductor interface of width, 75 meV, a bulk trap density of  $7.37 \times 10^{15} \text{ cm}^{-3}$ , and charge trapping and detrapping times of  $3.39 \times 10^{-12} \text{ cm}^3/\text{s}$  and  $2820 \text{ s}^{-1}$ , respectively. Including a Gaussian DOS within the bulk of the semiconductor does not noticeably improve the fits (Szymanski et al., 2012). While the fits require several independent variables, the mobility extracted from the peak is insensitive to the choice of the other parameters, as inferred from the alternative fit to  $8.5 \times 10^6 \text{ cm}^2/\text{V s}$ .

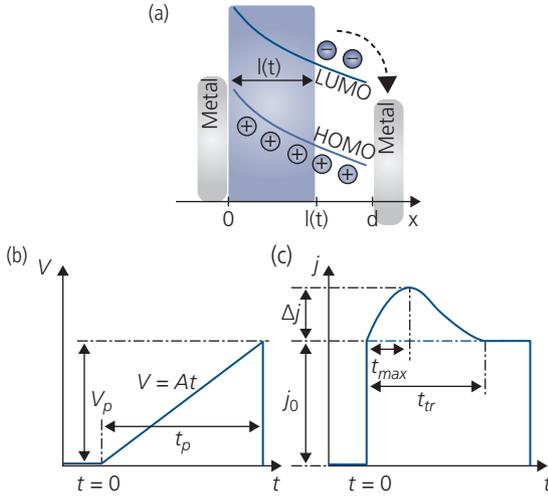

We note that current transient for a Ti/PTCDA/Au device in Fig. 4.52 has been used to obtain an electron mobility of  $\mu_n = 0.018 \text{ cm}^2/\text{V s}$ . This is approximately five times higher than obtained from analysis of the SCL currents (Forrest et al., 1984a). This difference is to be expected, since the transient response is obtained before deep levels can be filled, reducing Coulomb trapping effects, hence resulting in a higher transient than steady state mobility.

#### 4.4.3.3 Charge extraction by linearly increasing voltage

A variation of the DISCL current method that eliminates displacement current transients is the CELIV technique first introduced to measure mobility in microcrystalline Si (Juška et al., 2000). The method was later applied to polymers and other materials employed in organic solar cells (Lorrmann et al., 2010), and extended to include photoexcitation of charges in addition to electrical injection (Bange et al., 2010).

**Figure 4.64** Current transients (points) and theoretical fits (lines) for a 300 nm thick triarylamine dendrimer film at several different pulse voltages from 1.0 – 2.5 V. The pulse is turned on at  $t = 0$ . The fits correspond to two different hole mobilities shown in legend, with the best fit obtained at  $6.1 \times 10^{-6} \text{ cm}^2/\text{V s}$  (Szymanski et al., 2012).

**Figure 4.65** (a) Charge distribution and sample geometry used in CELIV. (b) Sawtooth voltage waveform with slope  $A$  used to excite the sample. (c) Current response to the linear voltage transient (Lorrmann et al., 2010).

The method is shown schematically in Fig. 4.65. It employs the same vertical sample geometry used in TOF and DISLC, where the semiconductor is sandwiched between two charge-blocking metal electrodes. A linearly increasing voltage,  $V = At$  is applied to the sample that sweeps charge from a region of thickness,  $l(t)$ . This is called the *charge extraction length*, which corresponds to the charge depletion region width. The response is thus a combination of the displacement current, which is a square wave in response to a sawtooth voltage transient plus the charge extracted from the edge of the depletion region. This superposed charge on the square background creates a pulse with a maximum at time  $t_{max}$ . From Gauss' law we solve for the charge density,  $n$ :

$$F(0, t) - F(d, t) = \frac{qn l(t)}{\epsilon_r \epsilon_0}. \quad (4.167)$$

As voltage is ramped, the current response is

$$j(t) = \sigma F(d, t) = qn \frac{dl(t)}{dt}, \quad (4.168)$$

where the total charge per area from Gauss' law is  $Q(t) = qn l(t) = \epsilon_r \epsilon_0 (F(0, t) - F(d, t))$ . Now, Poisson's equation gives

$$V(t) = At = - \int_0^d F(x, t) dx = F(d, t)d - \frac{F(d, t) - F(0, t)}{2} l(t), \quad (4.169)$$

where the electric field in an undoped semiconductor decreases linearly within the depletion region in the

range  $0 < x < l(t)$ . Then combining Eqs. 4.167–4.169, we obtain the quadratic Riccati equation:

$$\frac{dl(t)}{dt} = \frac{\mu At}{d} - \frac{l^2(t)}{2\tau_\sigma d}, \quad (4.170)$$

where the dielectric response time is given by

$$\tau_\sigma = \epsilon_r \epsilon_0 / \sigma = \epsilon_r \epsilon_0 / nq\mu. \quad (4.171)$$

The current can be written in terms of the conduction and displacement components as in Eq. 4.158 to give the time-dependent solution:

$$j(t) = \frac{\epsilon_r \epsilon_0 A}{d} + \frac{\sigma}{d} \int_{l(t)}^d F(d, t) dx = \frac{\epsilon_r \epsilon_0 A}{d} + \frac{\sigma F(d, t)}{d} (d - l(t)), \quad (4.172)$$

where the first term is the displacement current ( $\epsilon_r \epsilon_0 \partial F / \partial t$ ) which is constant for a linearly increasing voltage transient. This eliminates the spike at the onset of the square voltage pulse in DISCL. Then, it follows using Eq. 4.168 and 4.170 that the current transient is described by (Juška et al., 2000)

$$j(t) = \frac{\epsilon_r \epsilon_0 A}{d} + \frac{\sigma}{\mu d} (d - l(t)) \left( \frac{\mu At}{d} - \frac{l^2(t)}{2\tau_\sigma d} \right) \quad (4.173)$$

From the initial slope at  $t = 0$ , when  $l(0) = 0$ , we obtain the film permittivity using  $j(0) = \frac{\epsilon_r \epsilon_0 A}{d}$ , and the conductivity,

$$\sigma = \epsilon_r \epsilon_0 \frac{1}{j(0)} \left. \frac{dj(t)}{dt} \right|_{t=0}. \quad (4.174)$$

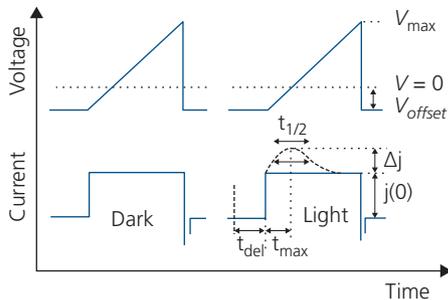

To extract further information from the transients in Fig. 4.65c, we must make a few approximations. For low conductivity, which is generally (although not always) the case for organics, then  $\tau_\sigma \gg t_{tr}$ . Then the electric field is unchanged by the extraction of charge during the transient, such that in Eq. 4.170, the  $l^2(t)$  term can be neglected. At  $t > t_{tr}$ , the displacement current is significantly larger than the conduction current such that  $j(t > t_{tr}) = j(0) = \frac{\epsilon_r \epsilon_0 A}{d}$  (see Fig. 4.66c). From this assumption,  $l(t) \approx \mu At / d$ , then at  $t \leq t_{tr}$ :

$$j(t) = \frac{A'}{d} \left[ \epsilon_r \epsilon_0 + \sigma t \left( 1 + \frac{\mu A' t^2}{2d^2} \right) \right]. \quad (4.175)$$

At the peak of the transient, the derivative of Eq. 4.175 gives

$$t_{max} = \frac{t_{tr}}{\sqrt{3}} = d \sqrt{\frac{2}{3\mu A}}, \quad (4.176)$$

from which we extract the mobility. For the less common case of high conductivity, then  $t_{tr} \gg \tau_\sigma$ , and

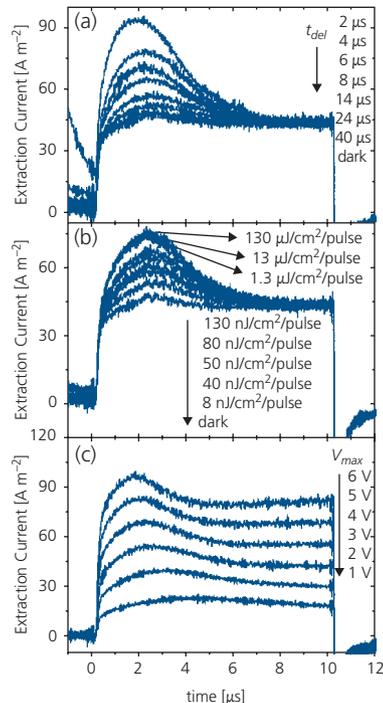

**Figure 4.66** (top) Sawtooth voltage sequence that swings through  $V=0$  in each cycle. The  $V_{\text{offset}}$  is used to counter the built-in potential from the contacts. (bottom) Current response. In the first cycle, the sample is in the dark and a square reactive current response is observed. After a voltage delay of  $t_{\text{def}}$ , the response is the sum of the extracted dark plus photocurrent.

$$t_{\text{max}} = \left( \frac{\tau_{\sigma} d^2}{\mu A} \right)^{1/3}. \quad (4.177)$$

Finally, in many conductive organic samples, the dielectric relaxation time is comparable to the transit time, in which case the full Riccati equation must be solved (Lorrmann et al., 2010). This leads to more complicated analysis of CELIV data that makes it less attractive for determining the mobility and other film properties compared to TOF and DISCL. Other complicating factors not considered here are bimolecular recombination (see Section 4.5), space charge effects, and bipolar charge injection.

The carrier lifetime can be determined using a variation of CELIV whereby an optical pulse is temporally offset from the electrical pulse by varying delay times. By measuring the decay rate of the CELIV peak in this so-called *photo-CELIV* method, both the charge recombination time and the mobility are obtained (Mozer et al., 2005, Bange et al., 2010). In photo-CELIV, a reverse bias pulse is applied, followed by a short optical pulse, as shown in Fig. 4.67. Under reverse bias, the only response is the square displacement current transient since no conduction charge is extracted. After a short delay following a nanosecond laser pulse, the voltage ramp is applied. The current following electrical and photoexcitation is the sum of the displacement plus the photocurrent. By varying the delay to the application of the forward bias voltage, the recombination time can be determined, and the mobility is calculated from the position of the current peak using Eq. 4.177. A voltage offset is used to counter the built-in potential from the contacts.

A set of photo-CELIV data for a 1:4 blend of the donor, MDMO-PPV, and the acceptor, PC<sub>61</sub>BM, are shown in Fig. 4.67 (Mozer et al., 2005). In Fig. 4.67a,

**Figure 4.67** Photo-CELIV data for a 1:4 MDMO-PPV:PC<sub>61</sub>BM sandwiched between a ITO/PEDOT:PSS anode and an Al cathode. (a) The voltage delay time is varied from 2  $\mu\text{s}$  to 40  $\mu\text{s}$ . (b) The light intensity is varied at a constant delay of 5  $\mu\text{s}$ . (c) The extraction voltage  $V_{\text{max}}$  is applied after a 15  $\mu\text{s}$  delay (Mozer et al., 2005).

the offset voltage is set at  $-0.75\text{V}$  which is close to the built-in potential, as determined by the near absence of a peak in conduction current in the dark. When the sample is illuminated by a 3 ns, 532 nm wavelength laser pulse, excitons are generated in the blend. The excitons dissociate at the donor-acceptor junction, and are subsequently extracted, giving rise to the peak after  $\sim 2 \mu\text{s}$ . The slight shift to longer times as the voltage delay is increased is due to the field-dependent mobility that decreases as the amount of charge (and hence field) is reduced. In Fig. 4.67b, the delay is fixed but the laser intensity is increased. The current saturates at a beam energy  $> 1.3 \mu\text{J}/\text{cm}^2$  due to bimolecular recombination (see Section 3.10). Finally, Fig. 4.67c shows the dependence on the extraction voltage,  $V_{\text{max}}$ . The peak position moves to shorter times with  $V_{\text{max}}$  also due to the field dependence of the mobility.

The data in Fig. 4.67a are fit by assuming that the electrons and holes recombine via a Langevin process (see Section 4.5.4). In this process, the hole density returns to equilibrium via  $\partial p/\partial t = -\gamma p^2$ , where  $\gamma$  is the bimolecular recombination coefficient. The fits yield a recombination time of  $t_{\text{rec}} = 1.7 \mu\text{s}$  and  $\gamma = 6 \times 10^{-11} \text{cm}^3/\text{s}$ . From the peak position, the mobility

is approximately  $\mu_p = 2 \times 10^{-4} \text{ cm}^2/\text{V s}$ . Clearly, a rich set of materials data, including the dielectric constant, conductivity, mobility and bimolecular recombination time can all be extracted from CELIV and photo-CELIV, albeit after making several assumptions whose validity should be confirmed by other, independent measurements.

#### 4.4.3.4 Hall effect mobility

The final technique we consider, and that is reliable yet rarely applied to organics due to their large contact and internal resistances, is the *Hall effect*. This method has the distinct advantage in that it provides both the charge density and mobility, as well as the carrier type (i.e. hole vs. electron). It employs samples in the lateral geometry, as shown in Fig. 4.68. If the series resistance of the material is high, the Hall current ( $j_x$ ) is small, and is difficult or even impossible to accurately measure.

The measurement entails placing the sample of length,  $L$ , width,  $w$ , and thickness  $d$ , in a magnetic field,  $B_z$ , oriented perpendicular to the sample plane and the direction of the current,  $j_x$  (see Fig. 4.68). Due to the Lorentz force, electrons or holes traversing the sample in the  $\hat{x}$ -direction are driven toward the edges of the sample in the  $\hat{y}$ -direction, creating a voltage drop along  $\hat{y}$  known as the Hall voltage,  $V_H$ . Both electrons and holes are driven in the same direction since they have opposite signs, but their current flow is also in opposite directions.

The Lorentz force on an electron is given by

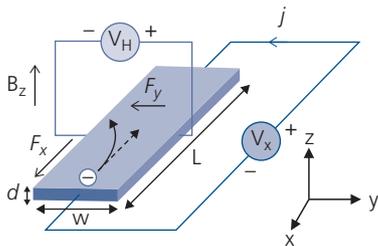

$$\mathcal{F} = q\mathbf{F} + q\mathbf{v} \times \mathbf{B}. \quad (4.178)$$

In the  $\hat{y}$ -direction, the net forces on holes and electrons are

$$\mathcal{F}_{py} = qF_y - qv_{px}B_z \quad (4.179a)$$

and

$$\mathcal{F}_{ny} = -qF_y - qv_{nx}B_z, \quad (4.179b)$$

**Figure 4.68** Hall effect measurement setup and sample geometry.

respectively. Since the drift velocity for holes is  $v_{py} = \mu_p F_y = \mu_p \mathcal{F}_{py}/q$ , with an analogous expression for electrons, we can substitute this into Eq. 4.179 to obtain

$$\frac{v_{py}}{\mu_p} = F_y - \mu_p F_x B_z \quad (4.180a)$$

and

$$\frac{v_{ny}}{\mu_n} = F_y + \mu_n F_x B_z. \quad (4.180b)$$

Now the net current in the  $\hat{y}$ -direction must be zero:

$$j_y = j_{ey} + j_{ny} = q(nv_{ey} + pv_{hy}) = 0, \quad (4.181)$$

which leads to  $nv_{ny} = -pv_{py}$ . Finally, for the current in the  $\hat{x}$ -direction we write

$$j_x = j_{nx} + j_{px} = (n\mu_n + p\mu_p)qF_x. \quad (4.182)$$

Substituting Eq. 4.182 and the solution of Eqs. 4.181 into Eq. 4.179 then gives

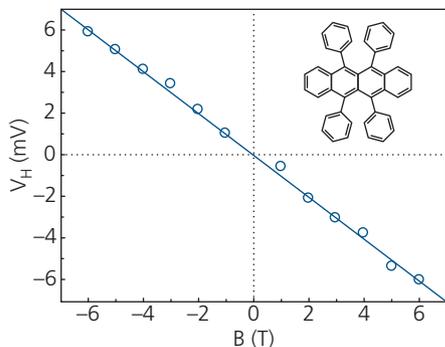

$$(n\mu_n + p\mu_p)^2 qF_y = (p\mu_p^2 - n\mu_n^2)j_x B_z. \quad (4.183)$$

Now the Hall coefficient is defined as

$$R_H = \frac{(p\mu_p^2 - n\mu_n^2)}{q(p\mu_p + n\mu_n)^2} = \frac{F_y}{j_x B_z} = -\frac{V_H}{w j_x B_z}. \quad (4.184)$$

Measurement of the Hall coefficient provides the mobilities and densities of each of the carriers. Also,  $R_H$  can be positive or negative, depending on the sign of the dominant charge carrier. The mobility or density of one charge should dominate to obtain clear results from Hall measurements. Thus, for example, if we take  $p\mu_p^2 > n\mu_n^2$ , then  $R_H \approx \frac{1}{qp} > 0$ . A measurement of the current, the magnetic field, and sign and magnitude of the Hall voltage therefore gives the hole density. Then, from  $j_x$  we can obtain the Hall effect mobility,  $\mu_p$ .

We caution that the Hall mobility can be different from that measured using drift techniques such as TOF, DISCL, and CELIV, since carrier scattering dynamics in a magnetic field are different than in an electric field. Indeed, when charge transport is via hopping, or there is a high density of traps, the treatment based on the classical Lorentz force is no longer applicable, leading to anomalous results for the Hall coefficient. Finally, while the treatment described is for an isotropic conductive medium, asymmetries in crystal structure make the Hall measurement, and indeed all mobility measurements, sensitive to

**Figure 4.69** Hall voltage vs. magnetic field for a rubrene single crystal in a thin film transistor structure. Inset: Molecular formula of rubrene. After Podzorov et al. (2005).

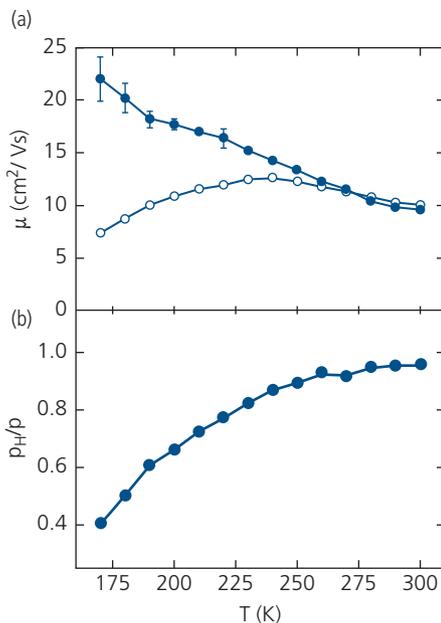

crystalline direction. Nevertheless, provided that sufficiently large currents can be obtained, the simplicity and accuracy of the Hall measurement makes it a powerful technique for measuring charge concentrations and mobilities.

Due to their high thin film resistance, there are only a handful of reports of Hall measurements of organic semiconductors (Heilmeier and Harrison, 1963, Imaeda et al., 1992, Podzorov et al., 2005). In Fig. 4.69 we show the Hall voltage vs.  $B$  for a single crystal of rubrene in an organic thin film field effect transistor (OTFT), where the gate insulator is a  $1\ \mu\text{m}$  vacuum gap between the crystal and the gate electrode. As predicted in Eq. 4.184,  $V_H$  is proportional to  $B$  (for a constant  $R_H$ ), and it changes sign with the field. The negative slope indicates the majority carriers are holes, consistent with the OTFT measurements. The Hall effect mobility and the hole concentration were both extracted as functions of temperature, and compared with data obtained from OTFT characteristics. The results of these measurements are provided in Fig. 4.70a. The mobility extracted from OTFT data (corresponding to the field effect mobility,  $\mu_{FE}$ ) is due to conduction of charges at the semiconductor/vacuum interface, and hence cannot be directly compared to the bulk mobility. Note that the Hall mobility at low temperature exceeds  $\mu_{FE}$  by over a factor of two.

The surface hole concentration determined from the OTFT characteristics is

$$p = \frac{C_{GS}}{q} (V_{GS} - V_{TH}(T)), \quad (4.185)$$

where  $C_{GS}$  is the gate-source capacitance,  $V_{GS}$  is the gate-source voltage, and  $V_{TH}(T)$  is the temperature dependent gate-source threshold voltage (see Chapter 8). The charge concentration obtained from

**Figure 4.70** (a) Hall mobility (closed circles) vs. that extracted from the conductivity and gate capacitance of an OTFT (open circles). (b) Ratio of the hole concentration measured from the Hall coefficient ( $p_H$ ) vs. that obtained from the OTFT ( $p$ ) (Podzorov et al., 2005).

Hall measurements differs from OTFT analysis (Fig. 4.70a), which is attributed to charge trapping that decreases the number of free charges at low temperatures (Podzorov et al., 2005). From the difference between  $p_H$  and  $p$ , the density of surface traps is found to be  $\sim 10^{10}\ \text{cm}^{-2}$ . This also results in a higher Hall mobility at low temperature than that derived from the conductivity ( $\sigma = qp\mu_p$ ) using Eq. 4.185, also due to trap filling inferred from Fig. 4.70a.

## 4.5 Charge recombination

In discussing charge transport, we noted that the mobility, and ultimately the current is strongly influenced by traps that can promote charge recombination. Traps can originate from many diverse sources, including static and/or dynamic disorder, impurities, crystalline imperfections, grain boundaries, or a myriad of other defects. In Chapter 3 we considered the various processes leading to exciton recombination, for example, triplet-triplet, singlet-polaron, singlet-triplet annihilation, etc. Exciton recombination is commonly referred to as *geminate recombination*, in that it involves a bound electron-hole pair (i.e. between oppositely charged “twins” with a common origin). In this section we consider the processes leading to recombination of electrons and holes

whose origins are from independent sources such as injection from contacts. This is known as *bimolecular recombination*, and can have either intrinsic (e.g. *Langevin* and *Auger recombination*) or extrinsic (e.g. *Shockley–Read–Hall*, or SRH, *recombination* via defects) origins.

To determine the probability for bimolecular recombination, we calculate the recombination rates for electrons or holes,  $R_n$  or  $R_p$ , respectively. The diffusion equations for the change in electron concentration in the absence of an electric field are given by

$$\frac{\partial n}{\partial t} = \frac{1}{q} \nabla \cdot \mathbf{j}_n - R_n + G_n, \quad (4.186)$$

and for holes by

$$\frac{\partial p}{\partial t} = -\frac{1}{q} \nabla \cdot \mathbf{j}_p - R_p + G_p. \quad (4.187)$$

Here, the total current density is equal to the sum of the hole and electron currents, viz.  $\mathbf{j} = \mathbf{j}_n + \mathbf{j}_p$ , and  $G_p$  ( $G_n$ ) is the hole (electron) generation rate. As shown below, there are conditions for which these variables are not independent, resulting in coupling of Eqs. 4.186 and 4.187.

From Fick's law of diffusion, the divergence of  $\mathbf{j}$  in terms of the diffusion current is:

$$\mathbf{j}_n = qD_n \nabla n \quad (4.188)$$

and

$$\mathbf{j}_p = -qD_p \nabla p, \quad (4.189)$$

where  $D_n$  and  $D_p$  are the electron and hole diffusion coefficients, respectively. Hence, Eqs. 4.186 and 4.188 now give the familiar charge diffusion equations:

$$\frac{\partial n}{\partial t} = D_n \nabla^2 n - R_n + G_n \quad (4.190)$$

and

$$\frac{\partial p}{\partial t} = D_p \nabla^2 p - R_p + G_p. \quad (4.191)$$

#### 4.5.1 Direct LUMO–HOMO recombination

Recombination is the mechanism that returns a semiconductor to equilibrium after it has been excited by electrical injection, illumination or a thermal transient. The non-equilibrium density of electrons is  $n_1$ , or holes,  $p_1$ , will therefore relax to their values at thermal equilibrium values,  $n_0$  and  $p_0$ , respectively. Then the

total electron density is  $\delta n = n_1 + n_0$ , and Eq. 4.177 becomes

$$\frac{\partial \delta n}{\partial t} = D_e \nabla^2 \delta n - R_e + G_e, \quad (4.192)$$

with a similar expression for excess holes ( $\delta p$ ) following Eq. 4.191. For direct electron–hole recombination in thermal equilibrium, the net recombination rate is  $R_e - G_e$ .

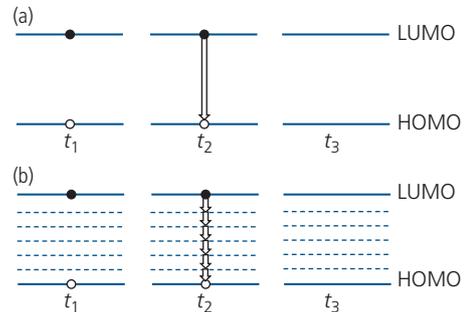

Band-to-band recombination in inorganic semiconductors occurs when minority carrier in loses energy to a distribution of majority carriers. Then, in the absence of diffusion currents (i.e. from injection or the presence of a junction), Eq. 4.192 yields the net recombination rate (assuming electrons are the minority carrier):

$$R_{tot} = R_n - G_n = k_n (n_p - n_0), \quad (4.193)$$

where  $k_n = 1/\tau_n$  is the electron recombination rate and  $\tau_n$  is its lifetime. This expression gives the rate that the electron density in p-type material,  $n_p$ , returns to its equilibrium value,  $n_0$ . In thermal equilibrium,  $R_n = G_n$ , and from the *law of mass action* (Sze, 1981), which relates the electron and hole densities to the intrinsic carrier density (see Eq. 4.113),

$$n_0 p_0 = n_i^2. \quad (4.194)$$

Organic semiconductors lack broad energy bands. Hence, the minority carrier (e.g. an electron) must *directly* recombine with its complementary charge (e.g. a hole). This can occur via one-step direct (radiative) recombination by an electron in the LUMO with a hole in the HOMO, as illustrated in Fig. 4.71. Alternatively, a multiphonon cascade is shown in Fig. 4.71b involves recombination from the LUMO to the HOMO via the non-radiative emission of several phonons through a distribution of defect state energies within  $E_G$ . We have seen that the phonon energy

**Figure 4.71** Direct electron recombination. (a) Single step LUMO–HOMO recombination, and (b) LUMO–HOMO recombination via a multi-step cascade. The times  $t_1 < t_2 < t_3$  for each step are shown.

is approximately 0.15 eV or less in organic molecules. Thus, the cascade can dissipate the full gap energy in only a few steps.

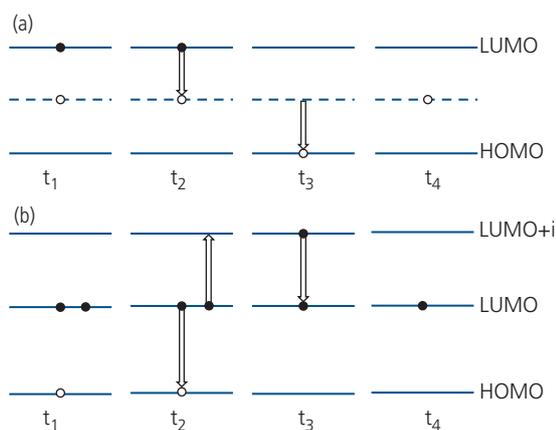

Since direct recombination requires that the electron and hole occupy the same molecule, the rate is proportional to the product of their densities, that is,  $R_n = k_{nc}np$  for an electron capture rate,  $k_{nc}$ . Note that  $k_{nc}$  is a bimolecular recombination constant, and hence differs from  $k_n$ . This is reflected in their units ( $[\text{cm}^3/\text{s}]$  vs.  $[\text{s}^{-1}]$ , respectively). For direct recombination, therefore, the net recombination rate is

$$R_n^{dir} = k_{nc}(np - n_i^2). \quad (4.195)$$

An identical expression is obtained for holes. As noted in Chapter 3, direct recombination in organics is via an intermediate, bound exciton. Hence, the photon energy must equal that of the relaxed molecular state rather than that of the LUMO-HOMO gap, which would be analogous to band-to-band recombination in inorganics.

#### 4.5.2 Recombination via mid-gap states

In Fig. 4.72 we show two additional sources of recombination that result in a loss of an electron polaron from the LUMO of an anionic molecule back to the HOMO. In Fig. 4.72a we show the process of sequential recombination and generation that occurs via a single defect state (or distribution of states) that lies approximately in the center of the energy gap. For this illustration, we assume that the mid-gap state is a hole trap occupied at  $t = t_1$ . At  $t_2$ , an electron in the LUMO is captured by the trap, that is, the electron and hole recombine, leaving the state unoccupied. At  $t_3$ , the trap captures a hole. The hole repopulates the state via transfer from the HOMO, returning the state to its

**Figure 4.72** Two possible routes to non-radiative electron recombination. (a) Recombination-generation via a mid-energy gap state and (b) Auger recombination. The time sequence for each process,  $t_1 < t_2 < t_3 < t_4$  is indicated.

original condition at  $t_4$ . The sequence can be repeated indefinitely. Recombination and generation processes are often thermally activated and may arise from optical generation or injection from contacts. This process is governed by Shockley–Read–Hall (SRH) statistics (Hall, 1951, Shockley and Read, 1952).

SRH recombination is a special case of the cascade process in Fig. 4.71b, where multiple steps have been replaced by a single step, although the most efficient recombination occurs via traps located at or near the center of the energy gap. In a cascade, the slowest transitions for either electrons or holes create rate-limiting bottlenecks that determine the overall rate (and hence the efficiency) of the recombination event.

Another non-radiative process is Auger recombination in Fig. 4.72b. Two electrons in the LUMO at  $t_1$  undergo a collision at  $t_2$ , resulting in the recombination of one electron with a hole in the HOMO, while delivering the excess electron energy to a second electron that is promoted into a higher excited state (i.e. to  $\text{LUMO} + i$ ,  $i > 0$ ). This “hot” electron polaron rapidly thermalizes, returning back to the LUMO at  $t_3$  via non-radiative emission of one or several phonons. Hence, while we started with two excess electrons, Auger recombination is complete when only a single excited electron remains at  $t_4$ . Auger recombination can also occur by the promotion of a hole deep into the bound ( $\text{HOMO} - i$ ,  $i > 0$ ) orbitals in a symmetric reaction to that in Fig. 4.72b. This will be discussed further in Section 4.5.3.

We now calculate the rates of generation and recombination via a single mid-gap state in Fig. 4.72a. First, consider the electron capture in the presence of a total trap density:

$$N_T = N_T^0 + N_T^-, \quad (4.196)$$

where  $N_T^0$  is the number of empty (or neutral) traps and  $N_T^-$  is the number of filled (or anionic) traps. Then, for an electron DOS in the LUMO,  $g_{LUMO}(E)$ , we obtain the incremental capture rate by the trap at energy,  $E$ :

$$dk_{nc} = k_{nc}(E)N_T^0 f_e(E)g_{LUMO}(E)dE. \quad (4.197)$$

Here,  $f_e(E)$  is the Fermi–Dirac distribution. Similarly, for hole capture into the same trap:

$$dk_{pc} = k_{pc}(E)N_T^- f_h(E)g_{HOMO}(E)dE, \quad (4.198)$$

where  $g_{HOMO}(E)$  is the HOMO DOS. Since generation results in emission from traps, we can write analogous expressions for these processes, viz.

$$dk_{ng} = k_{ng}(E)N_T^- (1 - f_e(E))g_{LUMO}(E)dE \quad (4.199)$$

and

$$dk_{pg} = k_{pg}(E)N_T^0 (1 - f_h(E))g_{HOMO}(E)dE, \quad (4.200)$$

where the subscripts ng and pg denote electron and hole generation, respectively, and  $1 - f(E)$  is the probability that a state at  $E$  will be unoccupied.

From this analysis, we obtain a net incremental recombination rate for electrons of:

$$\begin{aligned} dR_n^{SRH} &= dR_n - dG_n = dk_{nc} - dk_{ng} \\ &= [k_{nc}(E)N_T^0 f_e(E) - k_{ng}(E)N_T^0 (1 - f_e(E))] \\ &\quad \times g_{LUMO}(E)dE. \end{aligned} \quad (4.201)$$

Now we can write the fraction of occupied and unoccupied traps as  $f_T = N_T^-/N_T$ , and  $1 - f_T = N_T^0/N_T$ , respectively, where  $f_T$  is

$$f_T(E_T) = \frac{1}{1 + \exp((E_T - E_F)/k_B T)}, \quad (4.202)$$

where  $E_T$  is the trap energy. In equilibrium,  $dk_{ng} = dk_{nc}$ . Then from Eqs. 4.197 and 4.199 we find that

$$\frac{k_{ng}(E)}{k_{nc}(E)} = \frac{1 - f_T}{f_T} \frac{f_e(E)}{1 - f_e(E)}. \quad (4.203)$$

Now,

$$\frac{f_e(E)}{1 - f_e(E)} = \exp(-(E - E_F)/k_B T) \quad (4.204)$$

such that Eq. 4.203 becomes

$$\frac{k_{ng}(E)}{k_{nc}(E)} = \exp(-(E_T - E)/k_B T). \quad (4.205)$$

Substituting this back into Eq. 4.201 leads, after some algebra, to

$$\begin{aligned} dR_n^{SRH} &= [1 - \exp(-(E_T - E_F)/k_B T)] \\ &\quad \times (1 - f_T) f_e(E) k_{nc}(E) g_{LUMO}(E) N_T dE. \end{aligned} \quad (4.206)$$

To find the net recombination rate,  $R_n^{SRH}$ , Eq. 4.206 is integrated over energies greater than  $E_{LUMO}$ . Except at very high  $n$ , or low temperatures,  $f_e(E)$  can be replaced by the Maxwell-Boltzmann approximation. Also, the capture rate can be expressed in terms of the electron capture cross section by the trap,  $\sigma_e(E)$ , and the thermal velocity of the electron,  $v_e$ , viz.

$$k_{nc}(E) = \sigma_e(E) v_e, \quad (4.207)$$

where  $v_e = \sqrt{3k_B T/m^*}$ . Then we can write for the product of the electron density,  $n$ , and the weighted cross section,  $\bar{\sigma}_e$ :

$$\begin{aligned} n \bar{\sigma}_e &= \int_{E_{LUMO}}^{\infty} f_e(E) \sigma_e(E) g_{LUMO}(E) dE \\ &\approx \int_{E_{LUMO}}^{\infty} \exp(-(E - E_F)/k_B T) \sigma_e(E) g_{LUMO}(E) dE. \end{aligned} \quad (4.208)$$

Now, the electron density can be expressed in terms of the LUMO DOS,  $N_{LUMO}$ , as:

$$n = N_{LUMO} \exp(-(E_{LUMO} - E_F)/k_B T), \quad (4.209)$$

from which we finally obtain for the electron recombination rate:

$$\begin{aligned} R_n^{SRH} &= [n(1 - f_T) - N_{LUMO} \exp(-(E_{LUMO} - E_T)/k_B T) f_T] N_T v_e \bar{\sigma}_e \\ &= [n(1 - f_T) - n_1 f_T] N_T v_e \bar{\sigma}_e, \end{aligned} \quad (4.210)$$

where

$$n_1 = N_{LUMO} \exp(-(E_{LUMO} - E_T)/k_B T). \quad (4.211)$$

By a similar procedure we obtain the hole recombination rate:

$$R_p^{SRH} = [p f_T - p_1 (1 - f_T)] N_T v_h \bar{\sigma}_h, \quad (4.212)$$

with

$$p_1 = N_{HOMO} \exp((E_{HOMO} - E_T)/k_B T). \quad (4.213)$$

In steady state, there must be detailed balance, that is, the rate of electron recombination must be equal that of hole recombination:  $R_n^{SRH} = R_p^{SRH} = R_p^{SRH}$ . Further, we can use Eqs. 4.210 and 4.212 to obtain  $f_T$  in terms of the energy weighted rates,  $\bar{k}_{nc} = v_e \bar{\sigma}_e$  and  $\bar{k}_{pc} = v_h \bar{\sigma}_h$ :

$$f_T = \frac{\bar{k}_{nc} n + \bar{k}_{pc} p_1}{\bar{k}_{nc} (n + n_1) + \bar{k}_{pc} (p + p_1)}. \quad (4.214)$$

It is convenient to write the trap lifetimes in terms of their respective rates as follows:  $\tau_n = 1/N_T \bar{k}_{nc} = 1/N_T \bar{\sigma}_e v_e$  and  $\tau_p = 1/N_T \bar{k}_{pc} = 1/N_T \bar{\sigma}_h v_h$ . Using these relationships, and Eq. 4.214 in Eq. 4.210 or 4.212, we finally arrive at the SRH recombination rate (Hall, 1951, Shockley and Read, 1952):

$$R^{SRH} = \frac{np - n_1 p_1}{\tau_e (p + p_1) + \tau_h (n + n_1)}. \quad (4.215)$$

Now, if the trap exists far from the center of the energy gap, for example if it lies near to the LUMO, we have  $n_1 \gg p_1$ , and vice versa for traps near to the HOMO. In the former case,  $n_1 \rightarrow n \gg p$ , and the trap behaves as an electron donor rather than a recombination center. Also, we would expect that in this situation,  $\tau_p \gg \tau_n$ , such that the rate limiting step is recombination at the state farther from its respective transport energy level. All of these factors lead to  $R^{SRH} \rightarrow 0$ . Hence, effective recombination centers are mid-energy gap states where  $E_T \approx E_G/2$ . With these approximations and Eqs. 4.211 and 4.213, we find

$$n_1 p_1 = N_{LUMO} N_{HOMO} \exp(-E_G/k_B T) = n_i^2, \quad (4.216)$$

in which case the SRH recombination rate simplifies to

$$R^{SRH} = \frac{np - n_i^2}{\tau_e (p + p_1) + \tau_h (n + n_1)}. \quad (4.217)$$

The recombination rate has an exponential dependence on temperature arising from the charge densities,  $p_1$ ,  $n_1$ , and  $n_i^2$ . Indeed, one of the signatures of SRH recombination is the dark current that varies exponentially with  $T$  for large trap densities.

Disordered organic semiconductors are characterized by a distribution of traps whose density distribution is  $g_T(E_T)$  rather than a single, discrete mid-gap trap. For this situation, we integrate over the trap distribution to obtain the modified expression:

$$R^{SRH} = \int_{E_{HOMO}}^{E_{LUMO}} \frac{np - n_i^2}{\tau_e(p + p_1) + \tau_h(n + n_1)} g_T(E_T) dE_T. \quad (4.218)$$

### 4.5.3 Auger recombination

*Auger recombination* involves the recombination of an electron and a hole as in Fig. 4.72b. The energy gained in recombination is transferred to a second electron that is elevated to a higher energy than the LUMO. The hot electron subsequently “cools,” that is, it loses its excess energy by returning to the LUMO level, and subsequently relaxes. The initial condition is the existence of two electrons and a hole, and the final condition is only a single electron (with an analogous argument made for Auger recombination of holes). Thus, the probability for Auger recombination requires a three particle interaction proportional to  $n^2p$  (or  $p^2n$  for holes). Following the procedure used to calculate SRH recombination, we define the electron and hole capture rates as  $k_{nc} = C_{nc}n^2p$  and  $k_{pc} = C_{pc}np^2$ , where  $C_{nc}$  and  $C_{pc}$  are the Auger recombination capture coefficients for electrons and holes, respectively. This process must conserve both energy and momentum: that is the energy transferred to the secondary electron must be equal to that lost by the initial electron during recombination, and the momentum ( $\mathbf{k}$ ) must also be equal in the initial and final states.

Auger recombination is the opposite of the *avalanche multiplication* process, where a high energy (hot) electron accelerated in an electric field suffers an ionizing collision with a molecule, generating a secondary electron–hole pair. In that case, the initial condition is a single electron, and the final state is two electrons plus a hole.

Electron and hole generation rates are defined as  $k_{ng} = C_{ng}n$  and  $k_{pg} = C_{pg}p$ . In thermal equilibrium the emission and capture rates are equal. From the law of mass action, we obtain  $C_{ng} = C_{nc}n_i^2$  and  $C_{pg} = C_{pc}n_i^2$ .

The net Auger recombination rate is given by:  $R^{Auger} = (k_{nc} - k_{ng}) + (k_{pc} - k_{pg})$ . Hence,

$$R^{Auger} = (C_{nc}n + C_{pc}p)(np - n_i^2). \quad (4.219)$$

Due to its dependence on  $n^2$  and  $p^2$ , Auger recombination is important at very high charge density, which is in contrast to  $R^{SRH}$  that is present even as  $n, p \rightarrow 0$ .

### 4.5.4 Langevin recombination

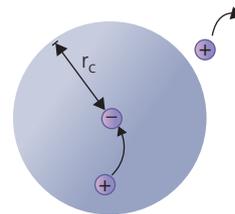

Finally, we consider bimolecular Langevin recombination where a free electron polaron is captured by a hole polaron, followed by non-radiative recombination, as illustrated in Fig. 4.73. When the carriers approach within a *capture radius*,  $r_c$ , their Coulomb attraction exceeds the thermal energy, preventing escape. Thus,  $r_c$  is the distance at which the Coulomb energy is equal to  $k_B T$ :

$$r_c = \frac{q^2}{4\pi\epsilon_r\epsilon_0k_B T}. \quad (4.220)$$

For a relative dielectric constant of  $\epsilon_r = 3$  typical of many organic materials, the capture radius at room temperature is  $r_c \approx 15$  nm. In organics, the mean free paths are  $\lambda \sim 0.4$  nm, which is on the order of the molecular separation (Helfrich and Schneider, 1965). Thus,  $r_c \gg \lambda$ . This meets the condition for Langevin recombination where the charges are fully thermalized and hence do not follow ballistic trajectories (Langevin, 1903).

The classical treatment of Langevin recombination assumes the material is isotropic, and that the charge motion is three dimensional. As we showed in Chapter 2, organic materials are rarely isotropic, and the presence of an electric field imposes a direction on the current. Nevertheless, these approximations can lead to simple expressions for the Langevin recombination rate,  $R^L$ .

The hole current due to the field,  $F$ , from a nearby electron is given by

**Figure 4.73** Langevin recombination of a hole within the capture radius,  $r_c$ , of an electron. If the hole is a distance greater than  $r_c$  there is insufficient Coulomb attraction to overcome thermal energy, and no recombination occurs.

$$\mathbf{j}_h = qp_1 v_{rel} = qp_1(\mu_e + \mu_h)\mathbf{F} = \frac{q^2 p_1(\mu_e + \mu_h)}{4\pi\epsilon_r\epsilon_0 r_c^2} \hat{\mathbf{r}}, \quad (4.221)$$

where the relative approach velocity of the electron and hole is proportional to the sum of their individual mobilities:  $v_{rel} = (\mu_e + \mu_h)F$ . The thermalized hole current flowing toward the electron is along the radial direction,  $\hat{\mathbf{r}}$ . The sphere of radius  $r_c$  has a surface area  $4\pi r_c^2$ , resulting in a current flux of

$$\phi_h = \frac{q^2 p_1(\mu_e + \mu_h)}{\epsilon_r\epsilon_0} = \gamma_L(qp_1), \quad (4.222)$$

where the Langevin recombination rate constant is

$$\gamma_L = \frac{q}{\epsilon_r\epsilon_0}(\mu_e + \mu_h) = \frac{q}{\epsilon_r\epsilon_0}\mu_T. \quad (4.223)$$

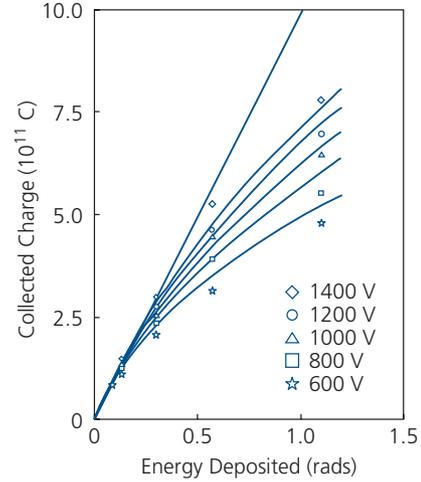

Here,  $\mu_T$  is sum of the mobilities of electrons and holes. The total rate of recombination is equal to the product of the hole current flux and the electron density,  $\phi_h n$ , giving

$$R^L = \gamma_L(p_1 n_1) = \gamma_L(pn - n_i^2). \quad (4.224)$$

As for other recombination processes,  $R^L$  is important when  $p$  and  $n$  are large, in which case Eq. 4.224 simplifies to  $R^L \approx \gamma_L pn$ .

The dominant role of Langevin recombination in both small molecule and polymer systems has been verified by several experiments spanning at least five decades. An investigation of bipolar conduction in anthracene was perhaps the first direct substantiation of this recombination mechanism (Kepler and Copping, 1966). In that work, anthracene crystals were irradiated with  $\sim 0.25$  MeV X-rays to create a high density of secondary electrons and holes that were subsequently collected in an external circuit. The total charge generated by each  $0.1 \mu\text{s}$  X-ray pulse gives the non-equilibrium electron and hole densities. In the absence of recombination, the relationship between charge collected and X-ray intensity should be linear. Deviations from linearity therefore provide the number of electrons and holes that recombine prior to collection. That is, since  $n = p$  in optically pumped materials, Eq. 4.224 gives  $\frac{\partial n}{\partial t} \cong -\gamma_L n^2$ .

Figure 4.74 shows the charge collected vs. total x-ray energy deposited (which is proportional to  $n$ ), at different applied voltages. The straight line corresponds to no recombination (i.e. the charge collected is proportional to the number generated), whereas the curved lines are fits to Eq. 4.224 assuming  $\gamma_L = 3 \times 10^{-6} \text{ cm}^3/\text{s}$ . The density of charge

**Figure 4.74** Charge collected vs. X-ray energy deposited in a single crystal of anthracene grown by the Bridgeman process (see Section 5.4.1). The data (points) are taken for several different applied voltages. The curved lines are fits to Langevin recombination theory assuming a voltage-independent recombination rate of  $\gamma_L = 3 \times 10^{-6} \text{ cm}^3/\text{s}$ . The straight line corresponds to  $\gamma_L = 0$  (Kepler and Copping, 1966).

decreases with increasing voltage as a result of their higher velocities.

Langevin recombination has also been identified by comparing the  $j$ - $V$  characteristics of hole-only and double injection devices comprising a PPV active region. Charge injection is controlled by the contact barriers. The ITO/PPV/Au devices permit only hole injection, whereas ITO/PPV/Ca devices inject holes from ITO and electrons from the Ca cathode. From the diffusion equations Eqs. 4.186 and 4.187, we model the one-dimensional  $j$ - $V$  characteristics under double injection using (Blom et al., 1997a)

$$j = q\mu_p F(x)p(x) + q\mu_n F(x)n(x), \quad (4.225)$$

$$\frac{\partial F(x)}{\partial x} = \frac{q}{\epsilon_r\epsilon_0}[p(x) - n(x) - n_T(x)], \quad (4.226)$$

and

$$\frac{\partial n}{\partial t} = -\frac{\partial p}{\partial t} = \gamma_L p(x)n(x). \quad (4.227)$$

Here,  $n_T(x)$  is the trap density at distance  $x$  from the

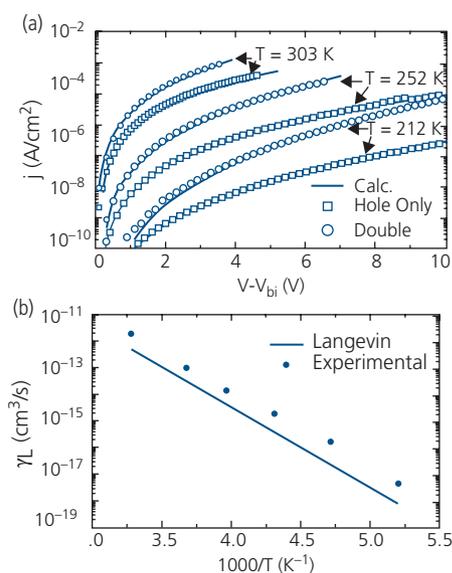

Au or Ca cathode given by  $n_T(x) = N_T \left( \frac{n(x)}{N_{LUMO}} \right)^{T/T_0}$

(cf. Eq. 4.142). The hole mobility is assumed to be thermally activated, viz.

$$\mu_p(F) = \mu_0 \exp(-\Delta E_a/k_B T) \exp\left[\frac{\beta}{k_B} \left( \frac{1}{T} - \frac{1}{T_1} \right) \sqrt{F}\right], \quad (4.228)$$

with a similar expression for electrons (see Section 4.3.2). It is assumed  $\mu_n = \mu_p$ . Here,  $\Delta E_a$  is the activation energy and  $\mu_0$ ,  $\beta$ , and  $T_1$  are constants. In Fig. 4.75a we show fits to a numerical solution to Eqs. 4.225–4.227 for the hole only ( $n(x) = 0$ ), and double injection devices using  $\Delta E_a = 0.59$  eV,  $\mu_0 = 1.7 \times 10^{-5}$  cm<sup>2</sup>/V s,  $\beta = 3.13 \times 10^{-4}$  eV/(cm/V)<sup>1/2</sup>,  $T_1 = 540$  K,  $N_T = 5 \times 10^{17}$  cm<sup>-3</sup>, and  $T_0 = 1500$  K. The difference between the two sets of data is attributed to Langevin recombination in the double injection device which is absent when the current is due only to holes in the ITO/PPV/Au device.

From the double injection fits, the Langevin coefficient is found and plotted vs.  $1000/T$  in Fig. 4.75b. At room temperature,  $\gamma_L = 2 \times 10^{-12}$  cm<sup>3</sup>/s, with thermal activation arising from the electron and hole mobilities. The theoretical fit (solid line) gives the same trends but with a value slightly below those observed. This difference is due to the asymmetry between the electron and hole mobilities, where the “faster” charge reaches a grain boundary within the film, and then “waits” for the slower charge to arrive and recombine (Groves and Greenham, 2008). Although there is a minor quantitative difference in  $\gamma_L$  between theory and experiment, the trends are similar, indicating the importance of Langevin recombination and its dependence on mobility in polymers.

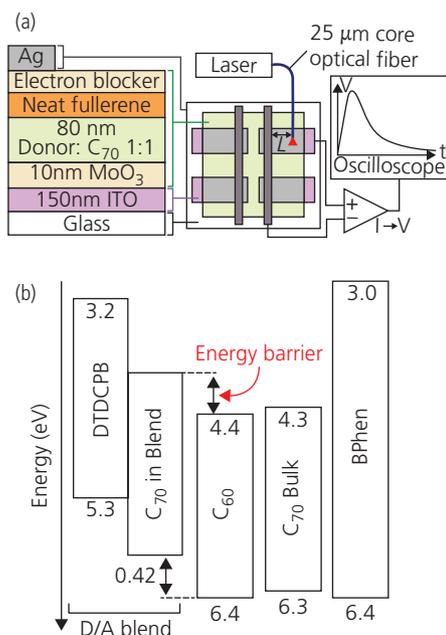

**Figure 4.75** (a) Fits (lines) to the measured  $j$ - $V$  characteristics (data points) of hole-only and double injection PPV devices based on space charge limited and diffusion theory described in text. (b) Langevin recombination coefficient and diffusion length  $L_D$  as obtained from a theoretical fit (line) to the data in (a) (Blom et al., 1997a).

#### 4.5.5 Long range charge diffusion in organic thin films

We have seen that numerous recombination processes can conspire in organics to decrease the charge lifetime, and hence its diffusion length  $L_D = \sqrt{D\tau}$ . The origins range from intrinsic disorder, to both structural and impurity-related defects within the films or crystals. Yet, if the structures are sufficiently free of defects, the charge carrier diffusion lengths in organics can be as long as those found in the highest quality inorganic semiconductors. Indeed, electron diffusion lengths ( $L_{De}$ ) exceeding several centimeters have been reported for fullerene channels that have nearly defect-free interfaces with energy barriers that confine the charges within the conducting material (Burlingame et al., 2018).

Devices with the structure shown in Fig. 4.76a were used to quantify electron transport over long distances in a fullerene ( $C_{60}$  and  $C_{70}$ ) channel. The device active region beneath a Ag cathode comprises a DTDCB: $C_{70}$  (1:1) donor/acceptor junction abutting a neat fullerene electron transport channel. A wide energy gap Bphen layer forms the second channel surface. From the energy level diagram in Fig. 4.76b, the conduction

**Figure 4.76** (a) Device structure, layout and experimental setup for measuring electron diffusion lengths in a neat fullerene channel. (b) Energy levels of the materials used in the structure in (a) (Burlingame et al., 2018).

(LUMO) level of the channel is well below the barriers presented by the Bphen and mixed HJ.

Electrons are injected into the channel by locally illuminating the active region with a focused optical beam of 500  $\mu\text{s}$  pulses at 405 nm wavelength that is primarily absorbed by the donor. The generated excitons are dissociated at the donor–acceptor junction. The resulting hole is swept out at the anode while the electron enters the channel. By varying the distance,  $L$ , of the excitation illumination from the collecting cathode, the time of flight of electrons, as well as the attenuation of the signal due to recombination losses, can be determined.

As  $L$  increases from 1 to 10 mm, the amplitude and arrival time of the current in the  $C_{60}$  channel varies by nearly two orders of magnitude, although the total integrated charge collected for each transient is the same, independent of distance to the excitation source. This indicates that the electron diffusion length,  $L_{Dn}$ , is considerably greater than 1 cm. In contrast, the integrated signal decreased by 50% over a distance of 5 mm in  $C_{70}$  channels, suggesting that  $L_D$  is small compared with  $C_{60}$ .

The temperature dependence of the current transients in  $C_{60}$  and  $C_{70}$  devices was also obtained, with results shown in Figs. 4.77a and b at  $L = 2$  mm and  $L = 1$  mm, respectively. The current transients were fit using the electron diffusion model in Eq. 4.186 as shown by solid lines in Figs. 4.77c and d.

The lifetime of electrons in the channel is determined by the rates of trapping at defects and thermal emission into the HJ where recombination can occur. A sufficiently high HJ energy barrier and low defect densities are therefore required to enable transport over macroscopic distances. In devices with a DTDCTB donor, the energy levels of  $C_{70}$  undergo a polarization shift due to the large dipole moment (14.5 D) of this asymmetric molecule (Ting et al., 2014, Griffith et al., 2015). This shift forms the required energy barrier at the  $C_{60}$  channel/HJ interface ( $0.42 \pm 0.1$  eV for DTDCPB) that confines electrons within the channel. Materials presenting smaller barriers result in electron emission from the channel and subsequent recombination with holes in the underlying HJ. The centimeter-scale  $L_{Dn}$  observed suggests that in addition to the large  $E_{Bv}$ , the channel and its

**Figure 4.77** Temperature dependent transient photocurrent data at 20 K intervals from 300 K to 120 K in response to 2 ms pulses of 637 nm wavelength illumination on a (a) 10 nm  $C_{60}$  channel at  $L = 2$  mm and (b) a 10 nm  $C_{70}$  channel at  $L = 1$  mm. Data (points) and corresponding charge diffusion model fits (lines) at 300 K, 200 K, and 120 K for the (c)  $C_{60}$  and (d)  $C_{70}$  devices. Lines show best fits to the data, from which diffusivity,  $D_n$ , and recombination rate,  $k_r$ , are obtained (Burlingame et al., 2018).

Reprinted from Burlingame, Q., Coburn, C., Che, X., Panda, A., Qu, Y. & Forrest, S. R. 2018. Centimetre-scale electron diffusion in photoactive organic heterostructures. *Nature*, 10.1038/nature25148 with permission from Springer Nature. Copyright 2018.

interfaces have a remarkably low density of deep electron traps and recombination centers. This is surprising for fullerenes, which, despite their high mobility and diffusivity among molecular solids, form disordered and phase-separated amorphous and crystalline domains (Liu et al., 2016b).

Drift-dominated lateral spreading of charges over long time periods has also been observed in unipolar devices at organic/insulator interfaces due to the lack of recombination (Bürge et al., 2003). In this case, electron transport is entirely diffusive through the bulk, and is observed despite the presence of optically generated holes.

Replacing the  $C_{60}$  channel with  $C_{70}$  reduces  $D_n$  from  $0.67 \text{ cm}^2/\text{s}$  to  $0.16 \text{ cm}^2/\text{s}$  at room temperature. Using the Einstein relation, the room temperature mobilities of  $\mu_n = 26 \text{ cm}^2/\text{V s}$  for  $C_{60}$  and  $6 \text{ cm}^2/\text{V s}$  for  $C_{70}$  are inferred. In general, mobilities in bulk semiconductors are larger than those at interfaces due to interfacial traps, while mobilities and diffusivities in disordered semiconductors typically increase with charge density due to filling of shallow traps and low-energy states in the conduction band tail, as discussed in Section 4.3. The devices in Fig. 4.76 are nearly ideal for achieving high mobility, as charge transport occurs in the bulk of the channel with electron densities  $>10^{17} \text{ cm}^{-3}$ .

## 4.6 Injection from contacts

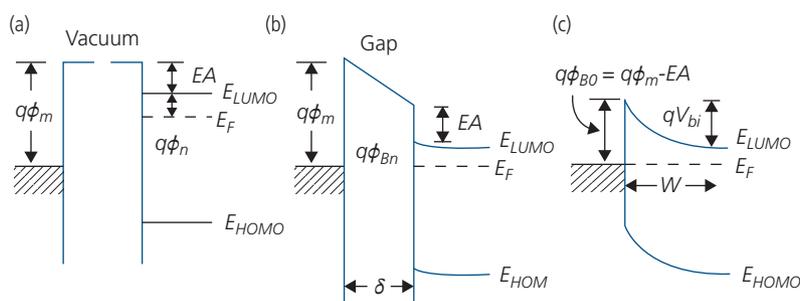

The most simple rectifying junction is the semiconductor–metal contact, or *Schottky barrier diode*. Schottky barrier devices were used in the earliest demonstrations of organic solar cells (Simon and André, 1985). In contrast to the Schottky barrier, some metals and process conditions lead to very small or non-existent energy barriers. The barriers are thus easily surmounted by charge under low injection conditions. The resulting Ohmic contacts are formed by doping the surface of the organic with a charge

donating impurity, or by damage to the organic during metal contact deposition. We will show in Section 4.6.3, that molecular disorder near the metal–organic interface can also result in efficient charge injection. Before one can develop the contact chemistry and properties suited to a particular application, it is necessary to understand the factors that determine the energy barrier at the organic surface. In the following section we consider many of the most important properties of contacts, and means for their analysis and ultimately, their control.

### 4.6.1 The ideal Schottky barrier

The metal–semiconductor contact is an essential element in every electronic device. Up until this point, we have considered current limited by the properties of the thin film itself, whether that limitation arises from intrinsic properties such as disorder, or from extrinsic characteristics such as traps, dopants, or impurities. However, in many cases, the conduction is limited by injection from contacts due to an energy barrier at the interface between the electrode and the semiconductor.

The fundamental origin and treatment of charge injection from contacts was developed by Schottky and Mott for the case of a trap-free metal–semiconductor junction (Mott, 1938, Schottky, 1938). The formation of this ideal Schottky barrier diode is illustrated in Fig. 4.78. A metal with a work function,  $\phi_m$  is brought into contact with a semiconductor with electron affinity,  $EA$  (Fig. 4.78a). We will assume for this example that the material is n-type, and that  $EA < \phi_m$ . As the gap,  $\delta$ , between the metal and semiconductor is reduced, alignment of  $E_F$  with  $q\phi_m$  results in the formation of a surface dipole that repels electrons from the interface that terminates further transfer of electrons (Fig. 4.78b) once the Fermi energies of the metal and semiconductor are completely aligned (Fig. 4.78c). The energy (or Schottky) barrier is then

**Figure 4.78** Schottky barrier formation defining energies and dimensions used in text.

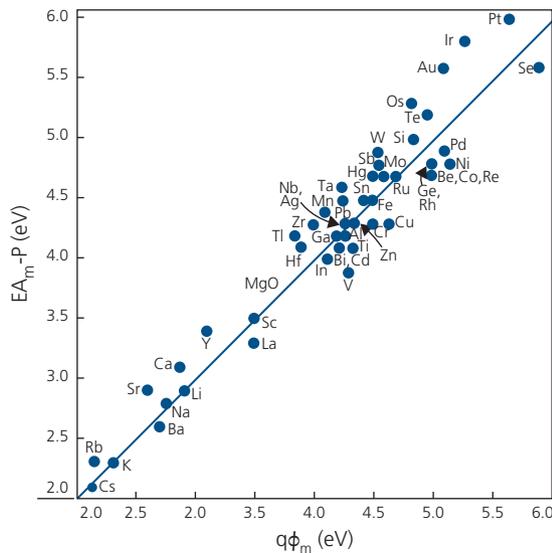

simply equal to the difference between the work function and electron affinity:

$$q\phi_{B0} = q\phi_m - EA. \tag{4.229}$$

The band bending required to maintain an equilibrium charge distribution extends over the depletion region width,  $W$ . The junction built-in potential is then

$$qV_{bi} = q\phi_{B0} - E_F. \tag{4.230}$$

According to Eq. 4.229, the barrier height varies linearly with  $\phi_m$ . A compilation of work functions for elemental metals is shown in Fig. 4.79. In practice, the surface of the semiconductor is never completely free of defect states. Hence,  $q\phi_m$  measured at the metal surface (using, for example, UPS) is not the same as the bulk  $EA$  of that same metal (Michaelson, 1978). Furthermore, in organics, the deposition of the metal induces defect states due to the loss of kinetic energy of the metal atom as it is adsorbed onto the organic surface. Most metals are evaporated at temperatures  $>1000^\circ\text{C}$ . The latent heat of condensation as the metal atoms are adsorbed can be sufficient to break molecular bonds, resulting in a defect at the initial point of contact. The resulting traps typically reside within the HOMO-LUMO gap, reducing the

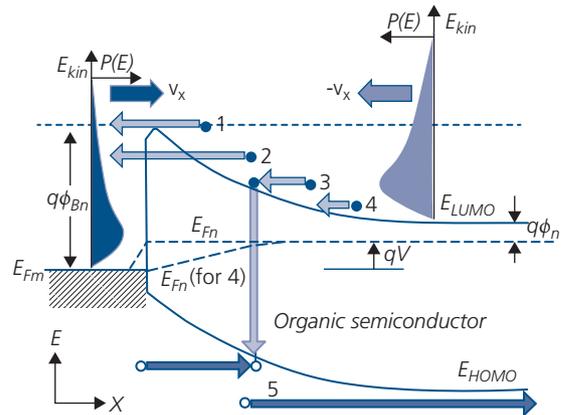

**Figure 4.79** Work functions of elemental metals. The vertical axis is the metal electron affinity to within a correction,  $P$ , for each periodic grouping of metals (e.g. alkali halides, transition metals, etc.) Here  $EA_m$  is a bulk property of the metal and  $q\phi_m$  is a surface property. The factor  $P$  (which can be as large as 1 eV) corrects for the measured differences between these quantities (Michaelson, 1978).

energy barrier to below the ideal value calculated using Eq. 4.229 (Ioannidis et al., 1998, Parthasarathy et al., 1998).

Trap formation during electrode deposition is found to be an effective means for forming Ohmic contacts, that are defined by  $q\phi_{Bn} \lesssim k_B T$ . Here,  $q\phi_{Bn}$  is the barrier height including image charge effects (Section 4.6.2). An Ohmic contact is one whose  $j$ - $V$  characteristics follow Ohm’s law, that is, there is no inflection of the current about  $V = 0$ . To ensure Ohmic contact formation, a low work function metal (e.g. Mg, Ca, Cs) is preferred for injection into an electron transporting layer, or a high work function metal (e.g. Al, Ag, Pd, Au) for hole injection. We will return to the effects of interface traps and interface dipole layers that result in deviations in barrier height from Eq. 4.229 in subsequent sections.

To calculate the current across a metal-semiconductor barrier, we consider all potential sources illustrated in Fig. 4.80. Process 1 is due to electron thermionic emission over the barrier, 2 is thermionic emission-assisted tunneling, 3 is via recombination of electrons and holes, 4 is electron diffusion, and 5 is minority carrier hole diffusion. Schottky barrier injection is typically unipolar, and hence we can ignore process 5 due to the very low minority carrier concentration.

Most treatments of transport in inorganic semiconductors focus on thermionic emission. To surmount the barrier, the charges must have a

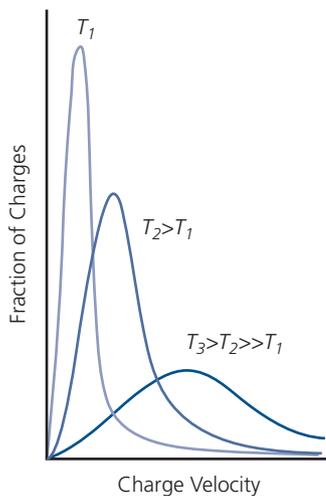

**Figure 4.80** Sources of current across a metal/n-type Schottky junction under forward bias,  $V$ . The barrier height is  $q\phi_{Bn}$ . The sources are 1, thermionic emission, 2, tunneling, 3, recombination, 4 majority carrier (electron) diffusion, and 5 minority carrier (hole) diffusion. The electron kinetic energy ( $E_{kin}$ ) probability distributions ( $P(E)$ ) impinging on the junction from the metal (left) and semiconductor (right) are shown. The upper horizontal dashed line is the energy above which thermionic emission occurs. The directions of electron velocities ( $v_x$ ) are shown.

minimum kinetic energy,  $E_{kin}^- = \frac{1}{2}mv_x^2 > qV_{bi}$  for charges traveling with velocity  $-v_x$  toward the junction. That is,  $E_{kin}^+ > q\phi_{Bn}$  for charges with velocity  $+v_x$ . Then, to calculate the total current, we add the contributions from each direction,  $j = j(+v_x) + j(-v_x)$ , by integrating over a *Maxwell–Boltzmann distribution* of energies (and hence velocities) multiplied by the DOS. From the kinetic theory of gasses, the probability of finding a particle with velocity between  $v_x$  and  $v_x + dx$  is

$$f(v_x)dv_x = \left(\frac{m^*}{2\pi}\right)^{1/2} \exp\left(-\frac{1}{2}m^*v_x^2/k_B T\right)dv_x, \quad (4.231)$$

where only velocities in one dimension are used to model electrons incident on the interface. The probability distribution function at different thermal energies is plotted in Fig. 4.81. As temperature increases, the distribution broadens and the peak decreases.

The classical picture for inorganic semiconductors depicted in Fig. 4.80 must be modified for organics that lack broad, parabolic conduction and valence bands. As we have shown previously, the DOS of the conduction level (for electrons, the LUMO) is more accurately represented by a Gaussian distribution whose origin lies in the inherent disorder of the solid. The Gaussian width may be sufficiently broad that it overlaps into higher lying conduction levels (e.g. LUMO+1) that are also broadened. Thus, as previously, the total number of conduction electrons incident on the barrier with velocities,  $-v_x$ , is

**Figure 4.81** Maxwell–Boltzmann distribution at several different temperatures.

$$n(-v_x) = N_{LUMO} \int g_{LUMO}(E_{kin})f(E_{kin})dE_{kin}. \quad (4.232)$$

In forward bias,  $V$  measured relative to the metal contact is positive. Then  $E_{kin}^- > E_{kin}^+$  and the current increases exponentially with voltage; that is,  $j(-v_x) \sim \exp(qV/k_B T)$ . In reverse bias,  $V < 0$ , such that  $j \rightarrow j(v_x) \sim \exp(-q\phi_{Bn}/k_B T)$ . Thus, it is limited by thermionic emission over the Schottky barrier. Summing these contributions yields the familiar expression for the current across an ideal (i.e. trap-free) metal–inorganic semiconductor junction (Sze, 1981):

$$j = j_0(\exp(qV/k_B T) - 1), \quad (4.233)$$

where for the specific case of thermionic emission of a Maxwell–Boltzmann distribution of electron kinetic energies, the saturation current is

$$j_0 = A^*T^2 \exp(-q\phi_{Bn}/k_B T). \quad (4.234)$$

The constant  $A^* = 4\pi qm^*k_B^2/h^3$  for a conventional semiconductor is known as the *effective Richardson constant* for thermionic emission. Hence, thermionic emission-limited current decreases exponentially with increasing barrier height and decreasing temperature. The Richardson constant is derived by assuming a parabolic DOS at the semiconductor band edge. It is left to Problem 4.9 to derive the constant for a Gaussian DOS more relevant to organic semiconductors.

We will show in Section 4.7 that, independent of the physical origins of the current (i.e. diffusion vs. thermionic emission, etc.) or the nature of the junction (e.g. metal–semiconductor, p–n junction, or HJ) the ideal diode current always has the form in Eq. 4.233 since the underlying process leading to the dark current is charge recombination. This can occur at contacts, within the semiconductor bulk, or at junctions between dissimilar semiconductors.

In the presence of illumination at wavelength,  $\lambda$ , carriers generated introduce an additional photocurrent:

$$j_{ph}(\lambda) = \eta_{EQE}(\lambda) \frac{q\lambda P_{opt}(\lambda)}{hc}, \quad (4.235)$$

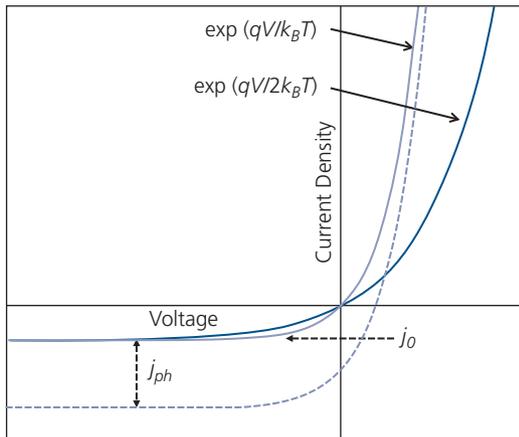

where  $P_{opt}(\lambda)$  is the optical power, and  $\eta_{EQE}(\lambda)$  is the external quantum efficiency of the diode, equal to the ratio of photogenerated charges detected in an external circuit to the total number of incident photons. If the incident light comprises more than a single wavelength, then  $j_{ph}$  is obtained by a suitable integration over  $\lambda$ . The photocurrent flows in the direction of the leakage,  $j_0$ , and is therefore subtracted from the expression, Eq. 4.233.

Equation 4.233 is generalized to include the effects of charge trapping (see Section 4.7) and photocurrent to give

$$j = j_0(\exp(qV/nk_B T) - 1) - j_{ph}, \quad (4.236)$$

where  $n$  is the *ideality factor*. For an ideal diode without recombination,  $n = 1$  as in Eq. 4.233. However, in the presence of recombination,  $1 < n < 2$ , where  $n = 2$  corresponds to recombination via mid-gap states. The dark current characteristics of diodes with  $n = 1$  and 2 and under illumination are shown in Fig. 4.82.

Although Eq. 4.234 has frequently been used to model metal/organic junction characteristics (Singh and Prakash, 2012, Liu et al., 2014), it is almost certainly incorrect (Arkhipov et al., 1998). Indeed, it has been found that  $A^*$  obtained for conventional semiconductors can be ten orders of magnitude larger than observed in organic thin films (see Problem 4.9) (Campbell et al., 1999, Wolf et al., 1999). We have shown previously that charge transport is primarily dominated by incoherent hopping, where the charge mean free path is on the order of the intermolecular separation. Even in ultrapure or ordered organic semiconductor crystals, coherent band-like transport can only occur over a few lattice constants due to their large effective masses and narrow energy BWs. Hence, “hot” carriers arriving at the barrier from the semiconductor side of the junction never gain sufficient kinetic energy to allow for thermionic emission. It is, therefore, more reasonable to consider majority carrier diffusion (process 4 in Fig. 4.80) as the

**Figure 4.82** Diode characteristics in the dark (solid lines) and under illumination (dashed line) following Eq. 4.236 with ideality factors,  $n = 1$  and 2, and photocurrent,  $j_{ph}$ .

dominant transport mechanism. The electron current then found from the drift-diffusion equation:

$$\mathbf{j} = qn\bar{\mu}\mathbf{F} + qD\nabla n. \quad (4.237)$$

Considering that the current in one dimension is dominated by electrons, then

$$\begin{aligned} j &= q\left(n(x)\mu_n F(x) + D_n \frac{\partial n(x)}{\partial x}\right) \\ &= qD_n \left(\frac{n(x)}{k_B T} \frac{\partial E_{LUMO}(x)}{\partial x} + \frac{\partial n(x)}{\partial x}\right). \end{aligned} \quad (4.238)$$

Here, we use  $F(x) = \frac{1}{q} \frac{\partial E_{LUMO}(x)}{\partial x}$  along with the Einstein relation in Eq. 4.36. Equation 4.238 is solved by multiplying both sides by  $\exp(E_{LUMO}(x)/k_B T)$ :

$$\begin{aligned} j \exp(E_{LUMO}(x)/k_B T) &= qD_n \left(\frac{n(x)}{k_B T} \frac{\partial E_{LUMO}(x)}{\partial x} + \frac{\partial n(x)}{\partial x}\right) \exp(E_{LUMO}(x)/k_B T) \\ &= qD_n \frac{\partial}{\partial x} [n(x) \exp(E_{LUMO}(x)/k_B T)]. \end{aligned} \quad (4.239)$$

Integrating both sides from  $x = 0$  (i.e. the location of the metal/organic contact) to the edge of the depletion region at  $x = W$  yields

$$j = \frac{qD_n \{n(x) \exp(E_{LUMO}(x)/k_B T)\}_0^W}{\int_0^W \exp(E_{LUMO}(x)/k_B T) dx}. \quad (4.240)$$

Using the relationships between various energies in Fig. 4.80 and listed in Table 4.4, it follows that

$$j = \frac{N_{LUMO} \mu_n k_B T (\exp(qV/k_B T))}{W \int_0^W \exp(E_{LUMO}(x)/k_B T) dx}. \quad (4.241)$$

Our final task is to determine  $W$ , and evaluate the integral in Eq. 4.240. From a solution to Poisson’s equation for a one-sided abrupt junction, which is indeed the case for a metal–semiconductor junction, the depletion region width is (Streetman and Banerjee, 2006)

**Table 4.4** Variables used in Fig. 4.80.

$x$	$n(x)$	$E_{LUMO}(x)$
0	$N_{LUMO} \exp(-q\phi_{Bn}/k_B T)$	$q\phi_{Bn}$
$W$	$N_{LUMO} \exp(-q\phi_n/k_B T)$	$q(\phi_n + V)$

$$W = \begin{cases} \sqrt{\frac{2\epsilon_r\epsilon_0}{qN_D}(V_{bi} - V)} & W < d \\ d & \text{otherwise} \end{cases} \quad (4.242)$$

and the maximum field at the contact at  $x = 0$  is

$$F_m(0) = \sqrt{\frac{2qN_D}{\epsilon_r\epsilon_0}(V_{bi} - V)} = \frac{2(V_{bi} - V)}{W}, \quad (4.243)$$

where  $N_D$  is the donor concentration (again, assuming an  $n$ -type semiconductor) and  $V < 0$  in reverse bias. In many cases there are few if any free carriers in these typically wide energy gap organic semiconductors. Then,  $N_D \approx 0$ , and  $W = d$ , the total film thickness at all voltages. Solving Gauss' law we obtain

$$F(x) = F_m - \frac{qN_D}{\epsilon_r\epsilon_0}x, \quad (4.244)$$

from which it follows that

$$E_{LUMO}(x) = q\phi_{B0} - \frac{q^2N_D}{\epsilon_r\epsilon_0}\left(Wx - \frac{1}{2}x^2\right). \quad (4.245)$$

Substituting this into Eq. 4.241, we arrive at the current density across a metal–organic contact of the general form of Eq. 4.233 with a saturation current of

$$\begin{aligned} j_{0D} &= q\mu_n N_{LUMO} F_m \exp(-q\phi_{B0}/k_B T) \\ &= 2q\mu_n N_{LUMO} \frac{(V_{bi} - V)}{W} \exp(-q\phi_{B0}/k_B T) \end{aligned} \quad (4.246)$$

for  $W < d$ . When the organic thin film is undoped, and for  $W > d$ , then  $F_m = (V_{bi} - V)/d$ .

Note that the diffusion-limited current is similar to that for thermionic emission, although the former is dependent on the applied voltage-mobility product, whereas the latter has a  $T^2$  dependence. Their ratio is given by

$$\frac{j_{0D}}{j_{0TE}} = \frac{2q\mu_n N_{LUMO}(V_{bi} - V)}{WA^*T^2}. \quad (4.247)$$

Hence, by measuring the forward biased current, the distinction between these mechanisms should be resolved. The assumption is that both the mobility and the DOS are temperature and voltage independent. While that is generally true of  $N_{LUMO}$  which is proportional to the molecular density, we have shown in Section 4.4 that  $\mu_n$  is a function of both of these variables. Distinguishing these differences under reverse bias is possible if the only leakage source is the saturation current. However,  $j_0$  tends to be small, and is therefore easily overwhelmed by other sources such as surface current around the periphery of the contact, shunt resistance, or recombination (process 3 in Fig. 4.80).

## 4.6.2 Barrier lowering and tunneling at metal–organic junctions

As charge diffuses toward the barrier, it can be transported from the semiconductor into the metal (or vice versa) via tunneling if the barrier is sufficiently low or narrow, corresponding process 2 in Fig. 4.80. Due to image-force and barrier lowering in an electric field, tunneling can substantially increase the current beyond that predicted in Eq. 4.233 for either thermionic emission or diffusion.

Image force lowering, known as the *Schottky effect*, is a result of classical electrostatics: a charge in the semiconductor is attracted to its image in the metal. This attraction results in an effective barrier height lowering of  $q\Delta\phi$ . From Coulomb's law the attractive force of the image charge at a distance  $x$  from the interface is

$$\mathcal{F}(x) = -\frac{q^2}{16\pi\epsilon_r\epsilon_0x^2}. \quad (4.248)$$

In the presence of an electric field, an additional force of  $-qF$  is added, such that the total potential energy (equal to the integral of  $\mathcal{F}$  over  $x$ ) is

$$q\Delta\phi(x) = -\frac{q^2}{16\pi\epsilon_r\epsilon_0x^2} - qFx. \quad (4.249)$$

Setting the first derivative of Eq. 4.249 to zero, the energy is maximum at

$$x_m = \sqrt{\frac{q}{16\pi\epsilon_r\epsilon_0F_m}}, \quad (4.250)$$

resulting in an energy barrier lowering of

$$q\Delta\phi = \sqrt{\frac{q^3F_m}{4\pi\epsilon_r\epsilon_0}}. \quad (4.251)$$

Substituting Eq. 4.243 for  $F_m$  then gives

$$\begin{aligned} q\Delta\phi(V) &= q \left[ \frac{q^3N_D|\phi_{B0} - \phi_{Bn}|}{8\pi^3(\epsilon_r\epsilon_0)^3} \right]^{1/4} \\ &= q \left[ \frac{q^3N_D|\phi_{B0} - V_{bi} - V|}{8\pi^3(\epsilon_r\epsilon_0)^3} \right]^{1/4}, \end{aligned} \quad (4.252)$$

and for a fully depleted sample of thickness  $d$ :

$$q\Delta\phi(V) \approx \left[ \frac{q^3|\phi_{B0} - V_{bi} - V|}{2\pi\epsilon_r\epsilon_0d} \right]^{1/2}. \quad (4.253)$$

An illustration of the energy levels in the presence of barrier lowering as a function of applied voltage is shown in Fig. 4.83. The total barrier height is therefore voltage dependent, and is reduced from  $\phi_{B0}$  by

$$q\phi_{Bn} = q\phi_{B0}(V) - q\Delta\phi(V). \quad (4.254)$$

When the sample is forward biased, the barrier lowering is reduced ( $q\phi_F < q\phi(0)$ ), whereas under reverse bias it is increased ( $q\phi_F > q\phi(0)$ ); see Fig. 4.83.

Accounting for image force lowering, the diffusion saturation current for an undoped semiconductor becomes (cf. Eq. 4.246):

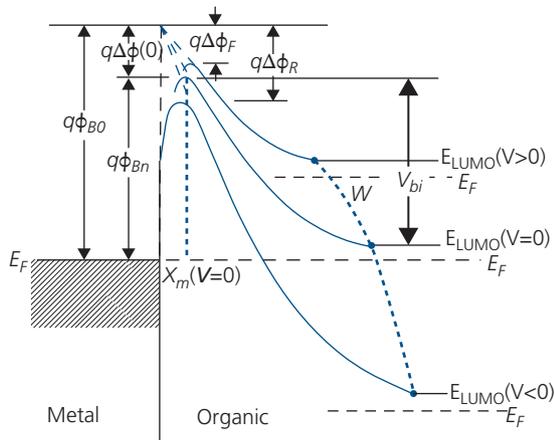

$$j_{0D} = q\mu_n N_{LUMO} \frac{V_{bi} - V}{d} \exp[-(q\phi_{B0} - q\Delta\phi(V))/k_B T]. \quad (4.255)$$

In Fig. 4.84 we show evidence for the Schottky effect in 0.73  $\mu\text{m}$  thick dialkoxy-substituted PPV (OPPV) with a low work function Ca cathode (Rikken et al., 1994). Using internal photoemission spectroscopy, the energy barrier was determined by measuring the quantum yield (QY) of electrons excited from the Ca as a function of applied voltage. The QY is the ratio of the charge detected vs. the number of incident photons, and hence is proportional to  $j_{ph}$ . Only photons with sufficient energy to surmount the barrier result in photocurrent (block arrows, Fig. 4.84, inset). By varying the bias across the illuminated sample, a plot of QY vs. the difference between the barrier energy and the photon energy should follow (Fowler, 1931)

$$QY = j_{ph} \propto (E_{ph} - q\phi_{Bn})^2. \quad (4.256)$$

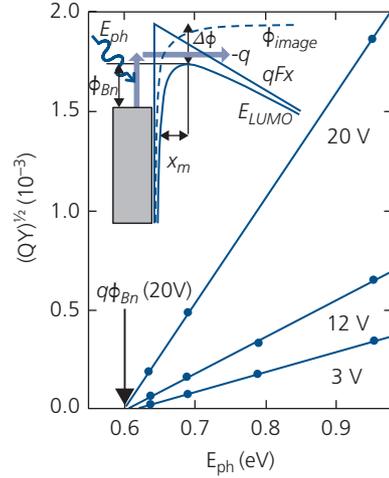

This expression implies that when  $QY = 0$ , then  $q\phi_{Bn}(V) = E_{ph}$ .

The data in Fig. 4.84 vs. reverse bias show the decrease in barrier height is consistent with Eqs. 4.253

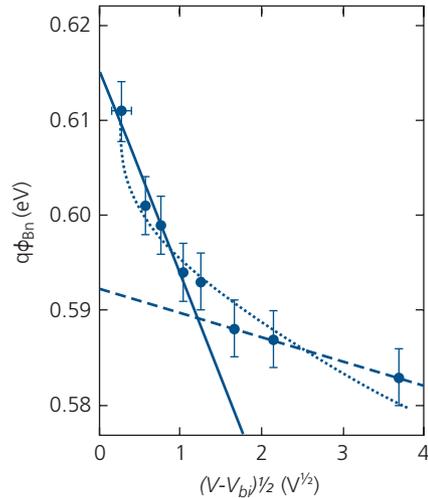

**Figure 4.83** A Schottky barrier contact at equilibrium ( $V = 0$ ), forward bias ( $V > 0$ ), and reverse bias ( $V < 0$ ). The equilibrium barrier height is  $q\phi_{Bn} = q\phi_{B0} - q\Delta\phi(0)$ . The curved dashed line shows the limit of the depletion region under the condition of  $W < d$ , the sample thickness. Also shown is the position of the barrier maximum at equilibrium,  $x_m(V = 0)$ .

and 4.254. The results of this experiment, including fits to Eqs. 4.252 and 4.253, are shown in Fig. 4.85. At low applied bias, the barrier maximum is far from the interface at  $x_m = 30$  nm, implying that this region is nearly completely depleted. Hence, Eq. 4.253 applies and the data lie along a line where  $q\phi_{Bn} \sim V^{1/2}$ . As the bias is increased to  $(V - V_{bi})^{1/2} = 1.2V^{1/2}$ , the maximum moves towards the contact such that  $x_m = 6.5$  nm, and the quartic dependence (i.e.  $q\phi_{Bn} \sim V^{1/4}$ )

**Figure 4.84** Photoemission quantum yield (QY) vs. photon energy ( $E_{ph}$ ) for a Ca/OPPV junction. The intercepts at  $QY = 0$  give the barrier height vs. voltage. The barrier height,  $\phi_{Bn}$ , at 20 V is indicated. Inset: Photoemission experiment, showing the contributions to barrier lowering by the electric field  $F$ , and the image potential,  $\phi_{image}$ . After Rikken et al. (1994).

**Figure 4.85** Barrier height of a Ca/OPPV Schottky barrier diode vs. reverse bias (data points) measured using data in Fig. 4.84. Straight lines are fits to the high and low voltage data assuming a quadratic dependence. The curved line is a fit to Eq. 4.253 with  $N_D = 2 \times 10^{13} \text{ cm}^{-3}$  and  $V_{bi} = 1.4\text{V}$  (Rikken et al., 1994).

Eq. 4.252 is observed. A fit to the data is shown by the dotted line in Fig. 4.85.

Since the width of the barrier decreases as energy is increased from the Fermi energy of the metal towards  $\phi_{Bn}$ , it becomes increasingly transparent to charge conduction, giving rise to tunneling (process 2, Fig. 4.80). In effect, this is equivalent to an additional lowering of the barrier beyond that due to image charges and the external electric field. The tunneling process can be calculated for these approximately triangular barriers using the Fowler–Nordheim model (Fowler and Nordheim, 1928). We briefly describe the approach to this derivation, leaving a detailed treatment to Problem 4.10.

As previously, we assume that the current in the  $\hat{x}$ -direction is equal to the difference of the currents injected from the metal to the semiconductor ( $m \rightarrow s$ ) and vice versa ( $s \rightarrow m$ ):

$$j_{tun} = j_{m \rightarrow s} - j_{s \rightarrow m}. \quad (4.257)$$

In terms of the densities of states,  $g(k_x)$ , Fermi–Dirac functions,  $f(E)$ , velocities, barrier transmission coefficients,  $T(k_x)$ , and the wavevector along  $\hat{x}$ ,  $k_x$ , the incremental current densities are given by

$$dj_{m \rightarrow s} = qT(k_x)v_x g_m(k_x) f_m(E)(1 - f_s(E)) dk_x \quad (4.257a)$$

and

$$dj_{s \rightarrow m} = qT(k_x)v_x g_s(k_x) f_s(E)(1 - f_m(E)) dk_x. \quad (4.257b)$$

Since  $g(\mathbf{k}) = 1/4 \pi^3$  and

$$g(k_x) = \int_0^\infty \int_0^\infty g(\mathbf{k}) dk_y dk_z, \quad (4.259)$$

then, using  $E_x = \hbar^2 k_x^2 / 2m^*$  and  $v_x = \frac{1}{\hbar} \frac{\partial E}{\partial k_x}$ , Eq. 4.258 becomes

$$dj_{m \rightarrow s} = \frac{q}{4\pi^3 \hbar} T(E_x) dE_x \int_0^\infty \int_0^\infty f_m(E)(1 - f_s(E)) dk_y dk_z \quad (4.260a)$$

and

$$dj_{s \rightarrow m} = \frac{q}{4\pi^3 \hbar} T(E_x) dE_x \int_0^\infty \int_0^\infty f_s(E)(1 - f_m(E)) dk_y dk_z. \quad (4.260b)$$

In polar coordinates, we substitute  $E_r = \hbar^2(k_y^2 + k_z^2)/2m^*$  into Eq. 4.260. Subtracting the two currents gives

$$j_{tun} = \frac{qm^*}{2\pi^2 \hbar^3} \int_{E_{min}}^{E_{max}} T(E_x) dE_x \int_0^\infty \int_0^\infty (f_m(E) - f_s(E)) dE_r. \quad (4.261)$$

To substantially simplify the solution, we assume that the Fermi functions can be replaced by step functions, that is,  $f_m(E) = 1$  for  $E < E_{Fm}$  and  $f_m(E) = 0$  for  $E > E_{Fm}$ , with a similar relationship for  $f_s(E)$ . For an n-type semiconductor, Eq. 4.261 thus becomes

$$j_{tun} = \frac{qm^*}{2\pi^2 \hbar^3} \left( \int_{-\infty}^{E_{Fn}} T(E_x)(E_{Fm} - E_{Fn}) dE_x + \int_{E_{Fn}}^{E_{Fm}} T(E_x)(E_{Fm} - E_x) dE_x \right). \quad (4.262)$$

Here, we have assumed that  $E_{Fm} > E_{Fn}$ . Since tunneling is between isoenergetic initial and final states. Since states below  $E_{Fn}$  are in the energy gap, the first integral vanishes.

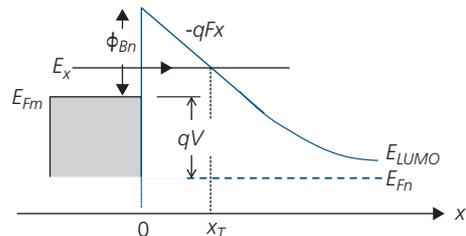

To determine the tunneling probability,  $T(E_x)$ , we assume an approximately triangular barrier (Fig. 4.86). Using the WKB approximation, we assume that the electrons are plane waves (Merzbacher, 1961). Thus,

$$T(E_x) = \exp\left(-2 \int_0^{x_T} k_x dx\right) = \exp\left(-\frac{2}{\hbar} \int_0^{x_T} \sqrt{2m^*(E_{LUMO}(x) - E_x)} dx\right), \quad (4.263)$$

where the factor of 2 comes from the relationship of  $T \sim |\psi_e|^2$  ( $\psi_e$  is the electron wavefunction), and the integral is between the classical turning points of  $x = 0$  and  $x_T$  in Fig. 4.86. Also,  $E_{LUMO}(x) = q\phi_{Bn} - qFx$ , where we have arbitrarily chosen  $E_{Fm}$  to be the reference energy. One classical turning point is at  $x_T = (q\phi_{Bn} - E_x)/qF$ . Substituting these expressions into 4.263 and integrating gives a transmission coefficient:

$$T(E_x) = \exp\left(-\frac{4\sqrt{2m^*}}{3\hbar qF} (q\phi_{Bn} - E_x)^{3/2}\right) \quad (4.264)$$

The argument in this expression approximates the barrier height “experienced” by a tunneling charge, which is less than  $q\phi_{Bn}$ .

**Figure 4.86** Tunneling of an electron of energy  $E_x$  through a triangular barrier of slope,  $-qF$ . The classical turning points are at  $x = 0$  and  $x_T$ .

The transmission coefficient used with Eq. 4.262 results in an integral that cannot be solved analytically unless we expand the term  $(q\phi_{Bn} - E_x)^{3/2} \approx (q\phi_{Bn})^{3/2} + \frac{3}{2}E_x(q\phi_{Bn})^{1/2} + \dots$ . Then we arrive at

$$j_{tun} = \frac{q^2 F^2}{(4\pi)^2 \hbar \phi_{Bn}} \exp\left(-\frac{4\sqrt{2m^*}}{3\hbar q F} (q\phi_{Bn})^{3/2}\right). \quad (4.265)$$

This expression is similar to tunneling in a p-n junction, where the Schottky barrier height is replaced by the energy gap,  $E_C$  (Sze, 1981). The tunneling current is an exponential function of the barrier height and the effective mass. The tunneling probability increases exponentially with  $1/F$ , and hence  $1/V$ , for fully depleted films. Thus, for organics where  $m^* \sim m_0$ , the tunneling current is generally negligible except for large electric fields or small barrier heights. Unlike currents originating entirely from recombination, tunneling is not thermally activated. In fact the only component with a weak temperature dependence is  $\phi_{Bn}$ , which increases with decreasing temperature due to lattice contraction, as inferred from tight binding in Section 4.1.

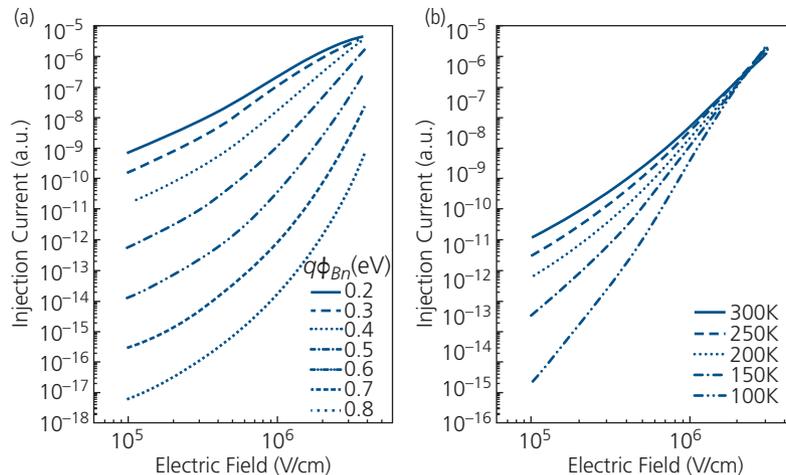

Tunneling currents have been numerically calculated based on an analytical theory of charges hopping among localized states. The distribution of tunneling states is assumed to be Gaussian with width  $\sigma = 0.08$  eV, and the intermolecular distance is  $a = 0.6$  nm. Results of these calculations, shown in Fig. 4.87, illustrate both the weak temperature and strong barrier height dependence predicted by Eq. 4.265, where the temperature dependence primarily arises from the

thermally activated hops between an energetic distribution of sites. Fits of the model to the  $j$ - $V$  characteristics for several archetype polymers suggest that tunneling can play an important role for organics with contact barriers  $\phi_{Bn} \sim 0.5$  eV or larger (Arkhipov et al., 1998).

### 4.6.3 Metal–organic junctions in the presence of traps

Traps arising either from the properties of the organic itself, from purposely functionalizing the organic surface prior to contact deposition, or from process conditions (whether intended or not) employed in fabricating the contact (Liu et al., 2014) can affect the magnitude of the injection barrier. The role of traps in determining the Schottky barrier height is well known in inorganic semiconductors such as Si, GaAs, and InP, where a high density of defect levels arising from dangling atomic bonds at the surface can “pin” the Fermi level at the defect energy. This results in a barrier height that is independent of applied voltage.

The role of interface defects in determining the barrier height is illustrated in Fig. 4.88. The quantitative relationship between the interfacial layer of thickness,  $\delta$ , the density of interface charge states,  $D_{IT}$ , and  $q\phi_{Bn}$ , is determined by the net surface charge on the organic,  $Q_{SO}$ . Defining the neutral energy or *charge neutrality level*,  $q\phi_0$  as the energy above which the states are acceptor-like (i.e. they are neutral when empty and negative when charged), and below which they are donor-like (neutral when charged,

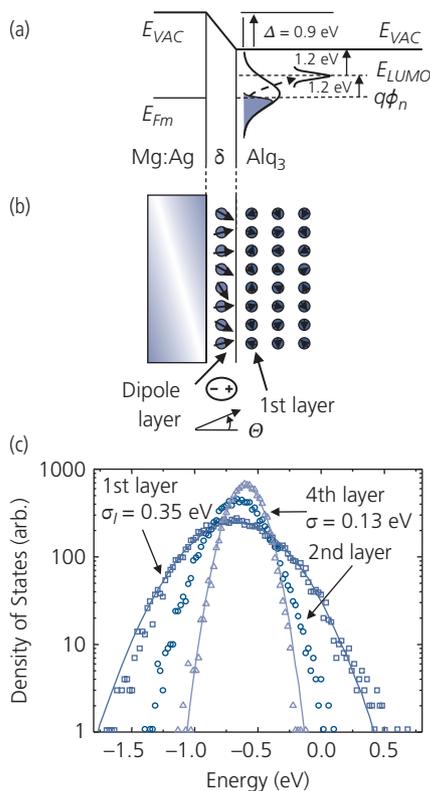

**Figure 4.87** Calculated tunneling current as a function of electric field vs. (a) barrier height and (b) temperature at metal–organic semiconductor junctions. For (a),  $T = 300$  K, and for (b),  $q\phi_{Bn} = 0.4$  eV. Here, the Gaussian disorder width is  $\sigma_{GDM} = 0.08$  eV, the intersite hopping distance is  $a = 0.6$  nm, and the hopping localization radius is  $\gamma = 10^8$  cm $^{-1}$  (see Section 4.3). Note both the strong dependence on electric field and weak temperature dependence characteristic of tunneling (Arkhipov et al., 1998).

(Fig. 4.89b). It is also assumed that these dipoles have a strength of  $p = 30$  D, corresponding to charges separated by  $\sim 6$  Å, which is on the order of the expected metal–organic molecular separation at the interface.

With these parameters, the mean energy of the distribution is calculated to be  $-0.7$  eV below the LUMO (see Fig. 4.89c), consistent with the  $\Delta \sim 1$  eV in Table 4.5. With increasing distance from the interface, the center of the distribution approaches the reference  $E_{LUMO} = 0$  eV, and its width ( $\sigma_B = 0.13$  eV) also approaches that of the bulk. For a dipole angular distribution of  $\sigma_\theta = 1.5$  rad, the energetic distribution in the first organic layer is broadened to  $\sigma_I = 0.35$  eV.

To describe the effects of the interfacial sites on charge injection and the  $j$ - $V$  characteristics, the charge density per unit energy near the metal is determined

**Figure 4.89** (a) Charges are initially injected into the interface between Mg:Ag and Alq<sub>3</sub> where the distribution of energy sites is broadened by randomness in molecular interface dipole orientations. (b) The total interface dipole energy is due to a collection of molecular dipoles oriented in a Gaussian distribution about the perpendicular ( $\theta = 0$ ). (c) Calculation of the electron DOS relative to  $E_{LUMO}$ , for interface dipoles  $p = 30$  D and a Gaussian angular distribution of width  $\sigma_\theta = 1.5$  rad. The resulting energy distribution width is  $\sigma_I = 0.35$  eV for the layer immediately adjacent to the interface. With increasing distance into the film, the distribution approaches the bulk value of  $\sigma_B = 0.13$  eV, with a mean energy of  $E = 0$  eV referenced to the LUMO After Baldo and Forrest (2001).

by Fermi–Dirac statistics, weighted by the energy distribution of dipole states. Thus,

$$n_I(E_I, q\phi_n) = \frac{N_I / \sqrt{2\pi\sigma_I^2}}{1 + \exp[(E_I - q\phi_n)/k_B T]} \exp\left[-\frac{1}{2}\left(\frac{E_I}{\sigma_I}\right)^2\right], \quad (4.269)$$

where  $N_I$  and  $E_I$  are the density and energy of interfacial sites, respectively. Assuming that hopping out of these sites limits the current density, the distribution of transport bulk sites are initially assumed to be unoccupied. Then the current density is given by (Baldo and Forrest, 2001)

$$j(q\phi_n) = \frac{aq}{\sqrt{2\pi\sigma_B^2}} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} n_I(E_I, q\phi_n) k_{ET} \times (E_B - E_I - aqF) \exp\left[-\frac{1}{2}\left(\frac{E_B}{\sigma_B}\right)^2\right] dE_I dE_B, \quad (4.270)$$

where  $E_B$  is the energy of the charge in the bulk, and  $a$  is the average intermolecular spacing. The hopping rate is  $k_{ET}(E)$ , where  $E$  is the energy difference between adjacent hopping sites. To simplify calculations, the hopping occurs from one monolayer to the next, until the bulk is reached at a distance of  $\delta = 150$  Å. The charge at the interface determines the electric field,  $F$ , and voltage  $V = \frac{qn_T d \delta}{\epsilon_r \epsilon_0}$ , where  $n_T$  is obtained by integrating Eq. 4.269 over all  $E_I$ . As expected for injection-limited transport, the bias voltage is directly proportional to the film thickness,  $d \gg \delta$ .

The injection model is completed by describing the dependence of the hopping rate,  $k_{ET}$ , on electric field and temperature. We assume the small polaron model of intermolecular hopping in disordered systems (Section 4.3.2). Then the low temperature hopping regime follows (Emin, 1975)

**Table 4.5** Energies characteristic of several metal/Alq<sub>3</sub> interfaces

Metal contact	Dipole energy ( $\Delta$ , eV)	Reference
Al/LiF	1.7	(Lee et al., 1998, Ishii et al., 1999)
	1.4	(Schlaf et al., 1998)
Al	1	(Ishii et al., 1999)
Ag	1.1	(Ishii et al., 1999, Hill et al., 2000b)
Au	1.1	(Lee et al., 1998, Rajagopal and Kahn, 1998, Ishii et al., 1999)

$$k_{ET}(E) \propto \exp\left(-\frac{E + |E|}{2k_B T}\right) \frac{(2E_b/\hbar\omega_0)^{|E|/\hbar\omega_0}}{(|E|/\hbar\omega_0)!}, \quad (4.271)$$

and at higher temperatures,

$$k_{ET}(E) \propto (E_b k_B T)^{-1/2} \exp\left(-\frac{E_b}{2k_B T} \left(1 + \frac{E}{2E_b}\right)^2\right). \quad (4.272)$$

This latter expression is from Marcus electron transfer over an energy barrier,  $E_b = \lambda_{reorg}/2$ , and  $E = \Delta G^0$ , the change in Gibbs free energy (cf. Eq. 4.89).

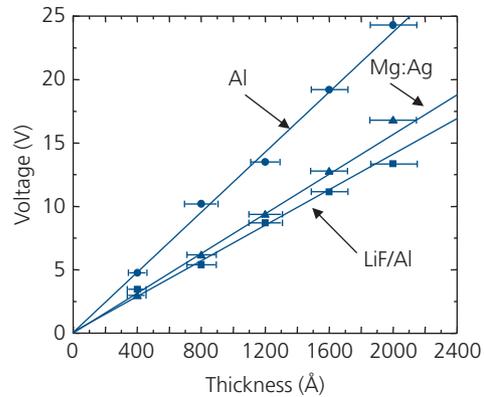

Thus, there are *two* processes that affect the temperature dependence of injection: energetic disorder that determines the width of the DOS and the likelihood of resonant, temperature-independent hops, and the temperature dependence of the phonon distribution. For a charge carrier that hops from initial energy  $E_i$  to final energy  $E_f$ , Eqs. 4.270–4.272 give

$$j = C J_0 \int_{-\infty}^{\infty} \exp\left[\frac{(2E_b + E_f - E_i)^2}{8E_b k_B T}\right] \times \exp\left[-\frac{1}{2} \left(\frac{E_f}{\sigma_B}\right)^2\right] dE_i \propto \exp\left[-\frac{(2E_b - E_i)^2}{8E_b k_B T + 2\sigma_B^2}\right], \quad (4.273)$$

where  $C$  is a constant, and  $J_0$  is the intermolecular overlap integral.

A significant complication in distinguishing between bulk- and interface-limited transport arises from the field and temperature dependence of the mobility. Because of the low density of free charge, the injected space charge determines the electric field in the bulk transport limit. The thickness dependence of the current allows for discrimination between injection and bulk limits, assuming an approximately field-independent mobility (Brütting et al., 2001). In injection-limited transport, the voltage at a given current density is proportional to the film thickness, that is,  $V \propto d$ , whereas for bulk-limited transport,  $V^{m+1} = K d^{2m+1}$  (cf. Eq. 4.148) where  $m \geq 1$  and  $K$  is a constant. For  $m \gg 1$  as is often the case, then  $V = K d^2$ .

The predictions of the interface disorder model have been tested using thin-film electron-injection-only amorphous Alq<sub>3</sub> devices. The device structure comprised an injecting cathode, various thicknesses of Alq<sub>3</sub>, and a 100 nm-thick 25:1 Mg:Ag anode that prevents hole injection. Cathodes consisted of either Al, 25:1 Mg:Ag, and a 0.5 nm thick LiF layer followed by Al. The Alq<sub>3</sub> thickness dependence for each cathode is given in Fig. 4.90 vs. applied voltage at  $j = 10$  mA/cm<sup>2</sup>. The three cathodes show that  $V \propto d$ ,

**Figure 4.90** Drive voltage at  $j = 10$  mA/cm<sup>2</sup> vs. Alq<sub>3</sub> thickness using LiF/Al, Mg:Ag and Al cathodes. All three cathodes exhibit a linear thickness dependence in the range  $200 \text{ nm} \geq d > 40 \text{ nm}$  (Baldo and Forrest, 2001).

consistent with injection-limited transport, although similar devices have also exhibited  $V \propto d^2$  consistent with SCL transport (Burrows et al., 1996, Campbell et al., 1997, Brütting et al., 2001). At  $T = 30$  K the plot of  $V$  versus  $d$  at  $j = 0.1$  mA/cm<sup>2</sup> remains linear.

Fits to the  $j$ - $V$ - $T$  data are shown in Fig. 4.91a using Eq. 4.273 for the Mg:Ag/Alq<sub>3</sub>, consistent with injection limited conduction. Similar fits are obtained for the Al and LiF/Al contacts. The parameters used in the fits are listed in Table 4.6. The temperature dependence of the voltage power law,  $m$ , may provide a clue as to the origin of the dark current. Recall for SCL current, we expect  $m = T_0/T$  for a characteristic trap temperature,  $T_0$ . In contrast, the prediction for injection-limited transport in Eq. 4.273 provides a more complicated temperature behavior. Both functional forms are plotted in Fig. 4.91b. Unfortunately, there is no clear distinction or obvious contradiction with either model that would allow us to claim that the current is limited by either injection or bulk processes.

At very low temperatures ( $T < 30$  K), all the cathodes possess nearly identical  $j$ - $V$  characteristics. This unambiguously breaks the link between the cathode work function and its injection efficiency, demonstrating that the initial hop from the metal Fermi level into the organic is not the most energetically costly event in current injection. Since the injection characteristics are determined by the interface energy distribution, the similarity between contacts at  $T \sim 30$  K suggests that the organic interfacial site distributions are similar in all cases.

Of the various models competing to explain the unipolar transport characteristics of amorphous

semiconductor materials, we have seen two approaches have proved attractive: starting from the observed shape and temperature dependence of transport, the trapped charge models in Section 4.4 can accurately describe characteristics at  $T > 100$  K; whereas starting from a fundamental understanding of charge transport in amorphous materials, disorder models in Section 4.3 have successfully described the field and temperature dependence of charge mobility.

**Figure 4.91** (a) Temperature dependence of the  $j$ - $V$  characteristics (solid lines) of Mg:Ag/Alq<sub>3</sub> devices compared to the interface hopping theory (points). The parameters used in the fits are given in Table 4.6. (b) Temperature dependence of the power law slope,  $m$ , where  $j \propto V^m$ . Circles denote the experimental data between  $j = 0.1$  and  $10$  mA/cm<sup>2</sup>. The solid line is a calculation based on injection limited current. The straight dashed line is a fit to bulk limited SCL transport theory. After Baldo and Forrest (2001).

**Table 4.6** Parameters the interface dipole model (Baldo and Forrest, 2001)

Device structure	Fixed parameters			Fit parameters		
	Polaron transition temperature	Width of bulk distribution	Width of interface distribution	Polaron binding energy	Interface site density	Intermolecular overlap integral
	$T_p = \frac{\hbar\omega_0}{3k_B}$	$\sigma_B$ (eV)	$\sigma_I$ (eV)	$E_b$ (eV)	$N_d I$ (cm <sup>-2</sup> )	$J_0$ (meV)
Mg:Ag/Alq <sub>3</sub>	60	0.13	0.34	0.16	$50 \times 10^{12}$	6
LiF/Al/Alq <sub>3</sub>	60	0.13	0.34	0.16	$43 \times 10^{12}$	10
Al/Alq <sub>3</sub>	60	0.13	0.40	0.10	$30 \times 10^{12}$	2

In some respects, the interfacial model is a synthesis of these approaches. The broad DOS at the interface and the narrower bulk distribution is qualitatively similar to trapped charge limited models, and it can generate the correct power law dependencies. The interfacial model involves limited energetic disorder in the bulk and larger dipole-induced disorder at the interface to explain these distributions. In doing so, it seeks to provide a microscopic model of charge hopping in amorphous semiconductors.

So where does all of this leave us? How do we unambiguously determine whether the current is due to bulk or interface limited conduction? We have seen in this and previous sections that the models often lead to similar results, both providing reasonable fits to the data often over large ranges of temperature and electric field. As noted above, the effects of transport across interfaces often have similar origins to those in the bulk: intermolecular hopping that is well described by small polaron theory. In spite of these ambiguities, careful experimental procedures and analysis can be helpful in eliminating uncertainties in interpretation. Below are a few methods one can use to distinguish between the sources of conduction:

1. The thickness dependence of the voltage at constant current provides perhaps the most reliable means to discriminate between bulk and interface limited transport. Particularly as  $d$  is increased, the effects of injection are decreased, and those of the bulk are increased.
2. Samples and contacts that support only single carrier injection eliminate ambiguities that arise from double injection.
3. Ohmic contacts can be assured in samples that exhibit a linear  $j$ - $V$  characteristic (i.e. one without inflections or asymmetries independent of the voltage polarity) over a wide range of temperature and applied voltage. Indeed, symmetric  $j$ - $V$

characteristics may be the single most important indicator that Ohmic conduction is dominant.

- Independent measurement of  $\mu(F, T)$  is important for use in the several expressions describing bulk and interface limited injection. The most reliable means to determine this most important quantity is via TOF measurements described in Section 4.4.3.

## 4.7 Organic semiconductor junctions

When two semiconductors are brought into contact, they form a junction. If prior to contact, the Fermi levels of the two materials are at different energies relative to the vacuum level, they must equalize to achieve equilibrium. This introduces energy level bending and a built-in potential,  $V_{bi}$ , due to the differences in chemical potentials of the materials. When the materials have the same composition, but their background free carrier concentrations differ, the contact and subsequent energy level bending results in an energy barrier. This is known as a *homojunction*. More commonly, the contacting organic materials are different, resulting in a *heterojunction* (HJ) whose built-in potential is the sum of the difference in chemical potentials and energy level (e.g. HOMO or LUMO) offsets of the two materials. When the majority carrier type is the same on both sides of the junction (i.e. both n-type or p-type), it is known as an *isotype HJ*, whereas if they are different the contact is called an *anisotype HJ*.

In the previous section we discussed the special case of a metal/organic HJ. In this section we consider the fundamental governing principles of both organic homo- and heterojunctions. Indeed, HJs are found in nearly all organic optoelectronic devices, sometimes in electronic devices such as OTFTs.

Homojunctions are the simplest junctions that can be formed between organic materials, and are discussed along with the fundamental theory of p-n junction operation in Section 4.7.1. The concepts of inorganic semiconductors have often been borrowed to describe the  $j$ - $V$ - $T$  characteristics of organic HJs. However, the principles governing charge conduction in materials systems as different as organic and inorganic semiconductors must reflect those striking dissimilarities. A theory developed specifically for the transport across organic junctions is the subject of Section 4.7.2. The theory has also been adapted to the increasingly important class of hybrid HJs consisting of contacts between organic and inorganic semiconductors, a topic left for Section 4.7.3.

One final note: while our purpose here is to derive “ideal diode equations” describing charge transport across p-n junctions, excitonic junctions and *hybrid*

*organic-inorganic HJs* (or OI-HJs), it is very rare indeed that a diode exhibits purely ideal characteristics. That is, just because you can derive an ideal diode equation, does not mean you have an ideal diode. Indeed, since Shockley developed the first theory of the ideal diode (for Ge) in 1949, the literature has overflowed with examples of devices that do not follow the predicted fundamental behavior. While it might be puzzling, then, that we spend effort deriving such formalisms, it is essential to remember that understanding the fundamental nature of the ideal p-n junction serves as a trustworthy and extremely powerful foundation on which all of our subsequent understanding of junction diode behavior can be built.

### 4.7.1 Organic homojunctions

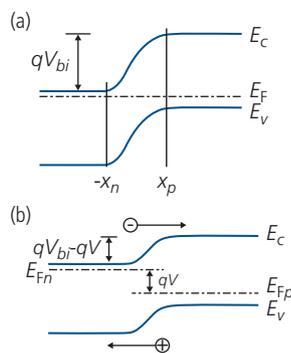

The treatment of inorganic p-n junctions was developed by Shockley in a classic paper that presents the derivation of what is known as the *ideal diode*, or *Shockley equation* (Shockley, 1949). In the following, we give the derivation, allowing us to determine the physics that underlies transport across homojunctions, and ultimately to understand how it fails to adequately describe the properties of excitonic junctions.

The energy band diagram of a p-n junction is shown in Fig. 4.92. The current is derived using the drift-diffusion model (Eq. 4.237) for both electrons and holes. At equilibrium, or close to it (i.e. so-called *quasi-equilibrium*), the current is given by:

$$j = q \left( n(x)\mu_n F(x) + D_n \frac{\partial n(x)}{\partial x} \right) \approx 0 \quad (4.274a)$$

for electrons and

$$j = q \left( p(x)\mu_p F(x) + D_p \frac{\partial p(x)}{\partial x} \right) \approx 0 \quad (4.274b)$$

**Figure 4.92** Energy bands for a p-n junction diode (a) in equilibrium and (b) under forward bias,  $V$ .

for holes. The total current is the sum of these two currents, that is,  $j = j_n + j_p$ . Without loss of generality, we assume that the current is dominated by electrons. Then solving for  $F(x)$  and the applied voltage,  $V$ ,

$$F(x) = -\frac{D_n}{\mu_n} \frac{1}{n} \frac{dn(x)}{dx} = -\frac{k_B T}{q} \frac{1}{n} \frac{dn(x)}{dx}, \quad (4.275)$$

yielding a junction voltage of

$$V_J = V_{bi} - V = -\int_{-x_n}^{x_p} F(x) dx = \frac{k_B T}{q} \ln n(x) \Big|_{n(-x_n)}^{n(x_p)}. \quad (4.276)$$

This results in an expression for the free electron concentration at the two edges of the depletion region,  $-x_n$  and  $x_p$ :

$$n(-x_n) = n(x_p) \exp(q(V - V_{bi})/k_B T). \quad (4.277)$$

Here, the total depletion region width is  $W = x_n + x_p$ .

Equation 4.277 can be simply rewritten as  $n_n = n_p \exp(q(V - V_{bi})/k_B T)$ , where  $n_p = n(x_p)$  is the minority electron concentration on the p-side of the junction, and  $n_n = n(-x_n)$  is the majority carrier concentration on the n-side. Now,

$$\begin{aligned} n_{n0} p_{p0} &= N_C N_V \exp(-E_G/k_B T) \exp(qV_{bi}/k_B T) \\ &= n_i^2 \exp(qV_{bi}/k_B T), \end{aligned} \quad (4.278)$$

where  $qV_{bi} = E_{Fp} - E_{Fn}$  is the difference in the quasi-Fermi levels on the two sides of the junction, and  $n_{n0}(p_{p0})$  is the equilibrium electron (hole) concentration on the n-(p)-side of the junction. Using the law of mass action, that is,  $n_{p0} p_{p0} = n_{n0} p_{n0} = n_i^2$  (Eq. 4.194), we obtain for the excess minority carrier density on each side of the junction, that is,  $\Delta p_n = p_{n0} - p_n$  and  $\Delta n_p = n_{p0} - n_p$  at voltage,  $V$ ,

$$\Delta n_p = n_{p0} (\exp(qV/k_B T) - 1) \quad (4.279a)$$

and

$$\Delta p_n = p_{n0} (\exp(qV/k_B T) - 1). \quad (4.279b)$$

These expressions are now used in the diffusion equation at  $j_e, j_h \approx 0$  (and therefore in the absence of drift), Eqs. 4.188 and 4.189, to obtain

$$\Delta n_p(x) = n_{p0} (\exp(qV/k_B T) - 1) \exp(-x/L_n), \quad (4.280a)$$

$$\Delta p_n(x) = p_{n0} (\exp(qV/k_B T) - 1) \exp(-x/L_p). \quad (4.280b)$$

Here,  $L_n^2 = D_n \tau_n$  and  $L_p^2 = D_p \tau_p$  are the electron and hole diffusion lengths, respectively. Finally, the electron current is

$$\begin{aligned} j_n(x) &= -qD_n \frac{d\Delta n(x)}{dx} \\ &= \frac{qD_n n_{p0}}{L_n} (\exp(qV/k_B T) - 1) \exp(-x/L_n). \end{aligned} \quad (4.281)$$

But current is constant throughout the sample, such that  $j_n(x) = j_n(0)$ . Using a similar relationship for  $j_p$ , the two components are summed to obtain the total current:

$$j = q \left[ \frac{n_i^2}{N_A} \sqrt{\frac{D_n}{\tau_n}} + \frac{n_i^2}{N_D} \sqrt{\frac{D_p}{\tau_p}} \right] (\exp(qV/k_B T) - 1) - j_{ph}. \quad (4.282)$$

Here, as in Eq. 4.236, we have added the contribution from the photocurrent,  $j_{ph}$ . In this expression, we have once more used the law of mass action, for example,  $n_{p0} N_A = n_i^2$  where  $N_A$  is the number of ionized acceptors (and hence the number of majority carrier holes at the p-side of the junction) and  $N_D$  is the number of ionized donors.

Equation 4.282 is in the same form as Eq. 4.236 for the Schottky barrier diode. We note that the current is determined by the minority carrier diffusion constant and lifetime, as well as the doping concentrations on each side of the junction. This equation is based on current generation processes that are substantially different from those relevant to organic HJs, where exciton generation and the formation of tightly bound and oppositely charged polaron pairs at the hetero-interface are the sources of dark and photocurrent. This deficiency will be addressed in the following section.

To complete our analysis, we calculate the ideality factor,  $n$ , in the presence of recombination. For SRH recombination in Section 4.5.2 to be effective, the trap state must be near the middle of the energy gap. Then the hole and electron recombination rates are approximately equal, that is, the effective recombination time is  $\tau_{eff} = \tau_e \approx \tau_h$ . Under forward bias, there is an excess of space charge. Thus, both  $n$  and  $p$  are much larger than charges released from traps residing at mid-gap, and  $n = p \gg n_1 = p_1 \approx n_i$ . Since recombination is only efficient when the number of holes and electrons are approximately equal, then Eq. 4.217 is simplified under forward bias:

$$R^{SRH} = \frac{np - n_i^2}{\tau_e(p + p_1) + \tau_h(n + n_1)} \approx \frac{n}{2\tau_{eff}}. \quad (4.283)$$

Recombination is most probable in the depletion region due to the coexistence of a high density of both electrons and holes. Multiplying Eq. 4.283 by the volume and the total number of charges in the depletion

region yields the forward-biased recombination current of

$$j_{rec} = \frac{qWn}{2\tau_{eff}} = \frac{qWn_i}{2\tau_{eff}} \exp(qV/2k_B T), \quad (4.284)$$

where, in the center of the forward-biased space charge region,  $n = p = n_i \exp(qV/2k_B T)$ .

Under reverse bias,  $n_i^2 \gg np$  since there is very little charge in the depletion region. Also, again for mid-gap states,  $n_1 = p_1 \approx n_i$  such that

$$j_{rec} = -j_0 = -\frac{qWn_i}{2\tau_{eff}}. \quad (4.285)$$

Combining Eqs. 4.284 and 4.285 gives the expression for the total recombination current:

$$j_{rec} = \frac{qWn_i}{2\tau_{eff}} (\exp(qV/2k_B T) - 1). \quad (4.286)$$

This differs from the ideal diode equation based on diffusion since the reverse current (at  $V < 0$ ) is no longer voltage independent. That is,  $j_0 \propto W \propto \sqrt{V}$  for uniformly doped semiconductors, with a somewhat different dependence of  $W$  on  $V$  depending on the doping profile in the junction region. In any case, this voltage dependence results in a small slope in the reverse-biased characteristics that can be useful in distinguishing between current sources. Note that if the sample is completely depleted at  $V = 0$ , or becomes depleted by an applied voltage, then  $W = d$  and recombination currents, too, are voltage independent.

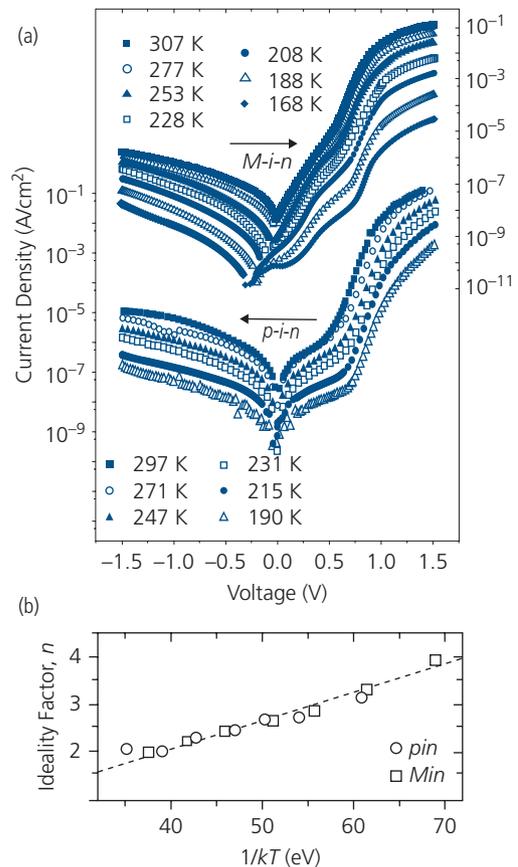

The total current is generally a combination of both recombination and diffusion, and may also be limited by other processes such as series and shunt resistances. To account for contributions from the several non-ideal current sources, the ideality factor,  $n$ , is introduced in the exponential argument, where  $1 < n < 2$ . For  $n = 1$ , diffusion is the dominant source of current, and as  $n \rightarrow 2$ , recombination becomes increasingly important. It is frequently observed in organic (and inorganic) junctions that  $n > 2$ . There is no analytical interpretation of such high  $n$ -values, which are typically due to a combination of series and/or shunt resistances, space charge effects, etc. Including the photocurrent, we can thus rewrite the Shockley equation as

$$j_{rec} = j_0 (\exp(qV/nk_B T) - 1) - j_{ph}, \quad (4.287)$$

which is identical to Eq. 4.236 for Schottky diodes. The ideality factor is found from the forward biased slope of the  $j$ - $V$  characteristics, that is,

$$n = \frac{q}{k_B T} j \frac{\partial V}{\partial j}. \quad (4.288)$$

The theory thus far presented does not consider the key physical phenomena that govern organics. Hence, it is not surprising that the Shockley equation does not often accurately model the  $j$ - $V$  characteristics of organic homojunction p-n diodes (Harada et al., 2005, Tsuji et al., 2009, Cai et al., 2011, Tripathia and Mohapatra, 2012, Kubo et al., 2013). An example of the characteristics of a p-i-n diode ( $i$  = intrinsic or undoped region separating the p and n zones) and a Schottky-type metal-i-n (M-i-n) diode is shown in Fig. 4.93. The p-i-n homojunction diode comprises a 30 nm thick ZnPc i-layer sandwiched between a 15 nm thick ZnPc layer doped p-type with  $F_4$ -TCNQ, and a third, 40 nm thick n-type ZnPc doped with Ru(terpy)<sub>2</sub>. The n-layer is contacted with a metal cathode (Al or Au), and the anode was ITO. The M-i-n device eliminates the p-layer and

**Figure 4.93** (a) Dark current vs. voltage characteristics as a function of temperature of a metal (M)-i-layer-n organic Schottky junction, and an all-organic p-i-n diode. (b) Ideality factor vs.  $1/k_B T$  for diodes in (a) (Harada et al., 2005).

uses ITO to form the Schottky barrier to the i-region (Harada et al., 2005).

The forward biased current shows an inflection at 0.5 V, above which an exponential increase with voltage is observed until it rolls off due to series resistance at  $V > 1.0$  V. Further, there is no apparent dependence on the *i*-layer thickness in the p-i-n diodes. Thus, space charge effects are ruled out as limiting the current. Under reverse bias, the voltage dependence is much more pronounced than predicted for recombination in Eq. 4.286.

The Shockley equation for both p-i-n and M-i-n devices implies that the ideality factor is temperature independent. According to Eq. 4.288, the forward biased slope of the  $j$ - $V$  characteristics for a constant  $n$ -factor decreases with increasing temperature. However, the data in Fig. 4.93 do not show this behavior: the slopes are nearly constant over the range  $307\text{ K} > T > 168\text{ K}$ . Furthermore, the current should increase rapidly with voltage under both forward and reverse bias if it is thermally activated with an energy approaching half the energy gap of ZnPc. Again, this does not appear to be the case.

The discrepancies with the ideal diode theory, that is, the temperature independence of  $n$  and the inflection in the forward characteristics at  $V < 1$  V are eliminated if we modify the conventional semiconductor equations to account for recombination governed by an effective medium with a Gaussian density of transport states of width,  $\sigma$  (Section 4.3.2). The junction region of the M-i-p device can be understood using the energy level diagram in Fig. 4.94, with only minor adjustments needed to describe a p-i-n homojunction. For purposes of this discussion, the p- and i-regions

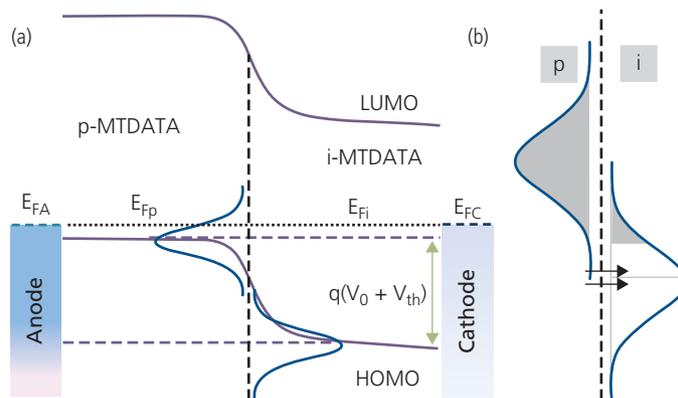

comprise MTDATA, and the p-type dopant is, once again, F<sub>4</sub>TCNQ.

Recombination occurs via tunneling at the junction over a very short distance between filled, nearly degenerate hole states from the p-region into only partially filled states within the i-region. That is, as voltage is increased under forward bias, the density of available, unoccupied states in the i-region increases, thereby resulting in an exponentially increasing current. At  $V < V_{th}$  (where  $V_{th}$  is the threshold voltage), the current is small due to an overlap of the filled tail of the *i*-region with that of the p-region. This accounts for the low current “shelf” at low voltages in Fig. 4.93a. The current under forward bias is, therefore, equal to the integral of the product of the DOS from the both sides of the junction. Thus, the current is given by

$$j = j_0 \int \exp\left[-(E(V) - E_0)^2/2\sigma^2\right] \exp\left[-E_0^2/2\sigma^2\right] f_p(1 - f_i) dE, \quad (4.289)$$

where  $E(V)$  is the energy offset between the peaks of the Gaussian DOS which is a function of applied voltage, and  $E_0$  is the energy of the peak in the p-region which, due to the near degeneracy of the organic, is independent of voltage. Also,  $f_p$  and  $f_i$  are the occupancies of states on the p- and i-sides of the junction, respectively, and we have assumed that the Gaussian widths are the same on both sides of the junction. This latter assumption may not be strictly valid, given that a large concentration of dopants in the semiconductor may increase the degree of disorder.

Setting  $E_0 = qV_0$ , and  $q\Delta V = E(V) - E_0$ , and eliminating all but linear terms in  $\Delta V/V_0$  yields (Tripathia and Mohapatra, 2012)

**Figure 4.94** (a) Energy level diagram of an M-i-p diode defining the voltages and densities of states in the junction region. (b) A detail of the Gaussian density of states at the junction. Shaded areas denote states filled with holes (Tripathia and Mohapatra, 2012).

$$j = j_0 \exp\left(-\frac{q^2 V_0}{2\sigma^2} \left(\frac{V_0}{2} - \Delta V\right)\right) \quad \text{for } V > V_{th}. \quad (4.290)$$

Here, we assume that  $V > V_{th}$  corresponds to the condition that  $f_p(1 - f_i) \approx 1$ , that is, there are empty states in the *i*-region that are at the same energy as filled states in the *p*-region, allowing for tunneling to occur. A key feature of this expression is that the slope of the  $\ln j - \Delta V$  characteristics is temperature independent, and is equal to  $\zeta = q^2 V_0 / 2\sigma^2$ . That is, the slope gives the Gaussian width of the DOS, and is independent of thickness of the *i*-region, as shown in Fig. 4.95a. Note at high voltages, the slope of the  $j$ - $V$  characteristics in both Figs. 4.93 and 4.95 is reduced. The dependence on layer thickness, temperature and voltage in this regime are signatures of space charge limited transport.

The last step in the derivation is to determine  $V_{th}$  which is obtained by fitting the exponential region of the  $j$ - $V$  characteristics to Eq. 4.290. Figure 4.95 shows that the threshold voltage increases linearly as temperature is decreased. This can be found from the relationship between voltage and charge density:

$$p_j = p_0 \exp(qV_{th}/k_B T), \quad (4.291)$$

where  $p_j$  is the hole concentration at the edge of the depleted *i*-region, and from Boltzmann statistics:

$$p_0 = N_{HOMO} \exp(-(E_{Fi} - E_{HOMO})/k_B T) \quad (4.292)$$

(see Fig. 4.94). Using these two expressions and solving for  $V_{th}$  gives

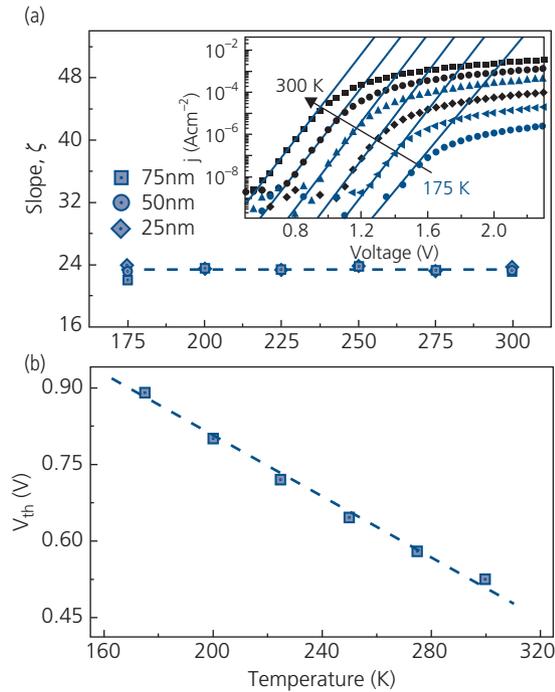

$$qV_{th} = k_B T \log\left(\frac{p_j}{N_{HOMO}}\right) + (E_{Fi} - E_{HOMO}). \quad (4.293)$$

This yields a linear dependence on temperature consistent with the data in Fig. 4.95b. The slope of the data give  $p_j/N_{HOMO}$ , and the intercept yields the position of the Fermi energy of the intrinsic region,  $E_{Fi}$ . For the *p*-*i* MTDATA devices in Fig. 4.95, the value of  $p_j$  is vanishingly small within the depletion region. Also, the Fermi energy is only slightly thickness dependent between 25 nm and 75 nm, possibly due to depletion of the entire *i*-region to the cathode. It is found that  $E_{Fi} - E_{HOMO} \approx 1.4$  eV.

As a final note, the tunneling model is supported by the rapid rise of current in the reverse direction (see Fig. 4.93a). This dependence has been fit by *Fowler–Nordheim tunneling*, viz.

$$j = AF^2 \exp\left(-8\pi\sqrt{2m^*}\phi^{3/2}/3qhF\right), \quad (4.294)$$

where  $\phi$  is the tunneling barrier height. Indeed, the reverse characteristics of similar *M*-*i*-*p* devices are reasonably consistent with this dependence over a temperature range of 200–300 K and over six decades of current using  $\phi \sim 0.5$ – $0.7$  eV, weakly depending on the *i*-layer thickness (Kumar et al., 2017).

**Figure 4.95** (a) Slope of the forward biased  $j$ - $V$  characteristics vs. temperature for different *i*-layer thicknesses of an Al-*i*-*p* diode, where the *i*- and *p*-regions are MTDATA. Inset: Forward biased  $j$ - $V$  characteristics vs. temperature. The lines are fits to the data in the exponentially increasing  $j$  region. (b)  $V_{th}$  vs. temperature for the devices in (a) (Tripathia and Mohapatra, 2012).

#### 4.7.2 Excitonic heterojunctions

Nearly every high performance organic electronic device comprises a combination of layers of different composition. This allows each individual material to be optimized to perform a function: electron and hole transport materials are selected for their correspondingly high electron or hole mobilities, light emission layers use materials that are optimized for emission efficiency at a particular wavelength, and materials used for solar cells and photodetectors are selected based on their exciton transport and optical absorption properties. The contact between two dissimilar semiconductors is known as a HJ. A feature of HJs is that an energy barrier forms at the interface (the heterointerface) between the semiconductors. The barrier controls charge and energy transport, as well as

exciton dissociation into free charges (in the case of organic photovoltaics). In this section we consider both the origin of the rectifying energy barrier, and its energy and transport properties. Our theoretical treatment will also be briefly adapted to understanding the dynamics of charge and exciton transport in organic p-n homojunctions, clearing up some of the mysteries encountered in their analysis in Section 4.7.1.

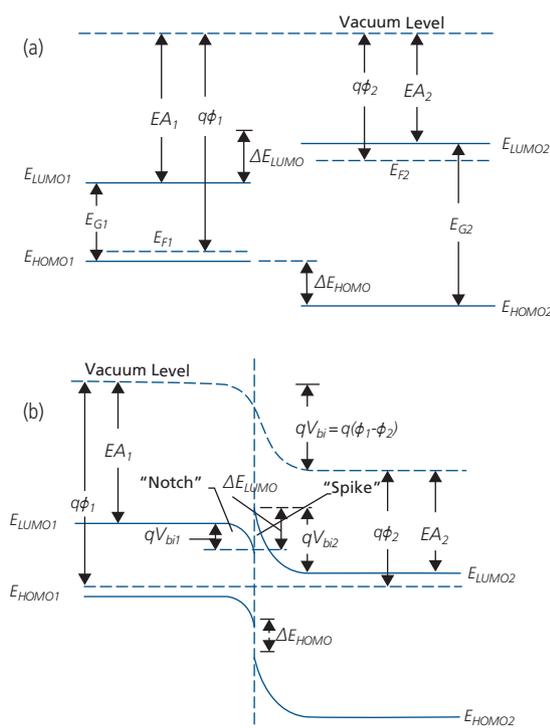

#### 4.7.2.1 Excitonic HJ fundamentals

In Fig. 4.96 we show the relevant energies of two contacting semiconductors with electron affinities,  $EA_1$  and  $EA_2$ . In the absence of traps or other non-ideal HJ properties, the difference in conduction band energies following their contact is

$$\Delta E_{LUMO} = |EA_1 - EA_2|, \quad (4.295)$$

and the difference in the HOMO energies is equal to the difference in IPs:

$$\begin{aligned} \Delta E_{HOMO} &= |IP_1 - IP_2| = |EA_1 - EA_2 + E_{G1} - E_{G2}| \\ &= \Delta E_G - \Delta E_{LUMO}. \end{aligned} \quad (4.296)$$

**Figure 4.96** A p-n, anisotype heterojunction consisting of two semiconductors (a) before and (b) after contact. Energies are defined in the text. This picture is more aptly applied to inorganic semiconductors or electronically doped organics. Undoped organics often have little or no energy level bending near the HJ.

Equation 4.295 is known as the *Anderson rule* (Anderson, 1960) and for many years was accepted as the means for determining HJ energy band offsets in inorganic semiconductor systems. While the Anderson rule provides a useful conceptual framework for understanding HJ energy level offsets, its predictions are inaccurate for several fundamental reasons. (i) It ignores the importance of charge redistribution and the subsequent formation of dipoles at the interface required to establish equilibrium between the semiconductors. (ii) The electron affinity, and in practice the IPs of the semiconductors are measured using surface sensitive probes such as UPS. These probes can measure the surface energies to within only a few monolayers with reasonable accuracy (typically ~50–100 meV), but the HJ lies deep within the bulk of the material whose Fermi energy may differ considerably from its value at the surface. (iii) UPS and similar surface probes are very sensitive to surface charge, surface lattice reconstruction and other properties unique to a free surface. These may not be characteristic of the bulk, but can significantly impact the energies measured. The effects of surface defects and traps can also strongly distort the surface potential from the bulk. Hence, the Anderson model is not considered to be an accurate method for determining energy level offsets at HJs buried within the bulk. Additional complications arise at organic semiconductor junctions that further influence the measured energy level offsets.

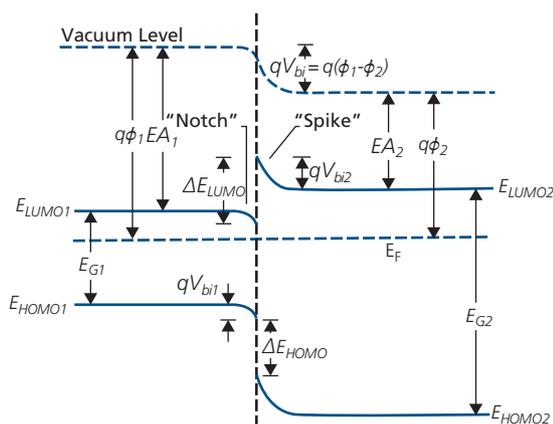

As shown in Fig. 4.96, redistribution of charge at equilibrium due to matching of the Fermi energies of the contacting semiconductors results in depletion (the energy “spike”) on one side of the junction, and accumulation of an equal amount of charge on the opposite side (resulting in an energy “notch”). The HJ shown consists of a p-N junction (and hence is an anisotype HJ) with  $EA_1 > EA_2$ . The semiconductor convention is that the small letter (p) refers to the small band gap, and the capital letter (N) refers to the large band gap constituent. The spike and notch are reversed if the relative magnitudes of the electron affinities are likewise inverted. The total built-in potential is equal to the sum of the built-in potentials on each side of the HJ (i.e.  $V_{bi} = V_{bi1} + V_{bi2}$ ). In organics where there may be very little free charge, and in the absence of interface dipoles, the band bending at the HJ is small, resulting in flat bands that extend up to the interface, with  $V_{bi} = 0$ .

In Fig. 4.97 we show an isotype, n-N HJ. As for the anisotype junction, a spike and notch form at the heterointerface, and the junction offsets result in rectification, although the total barrier height is reduced

to only the energy level offsets of  $\Delta E_{LUMO}$  and  $\Delta E_{HOMO}$ .

The energy level alignments in Figs. 4.96 and 4.97 show that the conduction and valence levels of the narrow energy gap semiconductor are nested within the gap of the wide energy gap constituent. This is known as a Type I heterojunction. Different alignments are possible, and indeed are required for different device purposes. Possible alignments are classified in Fig. 4.98. The *Type I HJ*, known as a *nested* or *straddling gap*, is useful for confining charges in luminescent devices such as OLEDs and lasers. The *staggered gap* (*Type II heterojunction*) is essential for the dissociation of excitons into free charge employed in photodetectors and solar cells. And finally, the less common *broken gap* (*Type III heterojunction*) is found in some thin film organic transistor applications. In this offset arrangement, electrons in the semiconductor with the large electron affinity recombine with holes from the contacting semiconductor since the LUMO of the first material is below the HOMO of the second.

The HJs depicted have been constructed to describe inorganic semiconductors with their broad energy bands, small effective masses, and a significant

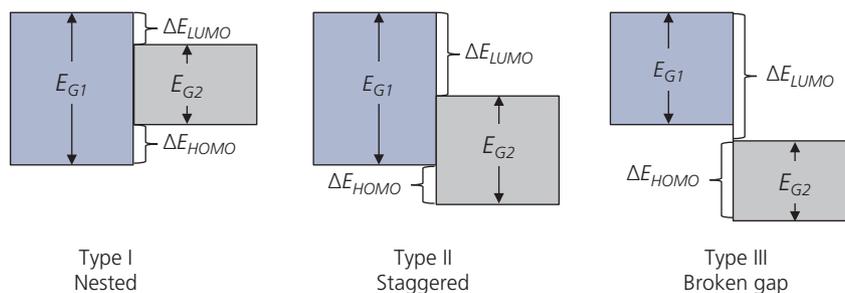

**Figure 4.97** An n-n isotype heterojunction.

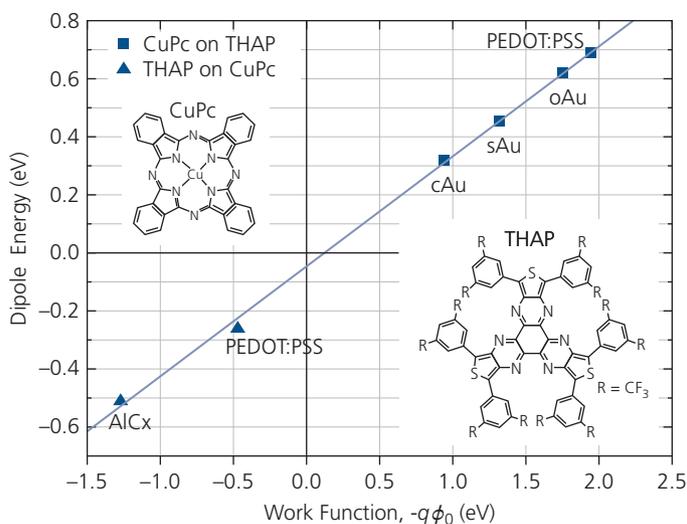

density of background free carriers. Earlier in this chapter, we have found that this picture is not directly applicable to organic semiconductors, characterized instead by very narrow conduction levels for holes and electrons, considerable static and dynamic disorder that results in large effective masses and hence low mobilities, and often very low densities of free charge. Nevertheless, the analogy to inorganic semiconductors is a helpful starting point, as long as these differences are recognized. At this point, we will extend our view to accommodate the important differences that exist between inorganic and organic systems in an effort to adapt the energy diagrams of Figs. 4.96 and 4.97 to the specific physics of organic semiconductors.

One distinct property of organics is that measurements of the energetics of the contact using such techniques as UPS and Kelvin probes, reveals an interface energy dipole of  $\Delta \sim 0.1\text{--}0.5$  eV. This results from charge redistribution across the interface following contact of the two layers (Vázquez et al., 2005, Molodtsova and Knupfer, 2006, Osikowicz et al., 2007). We have seen that dipoles are found at metal-organic contacts (Fig. 4.89 and Table 4.5) which is attributed to static disorder of molecules at the junction (Baldo and Forrest, 2001). Also, the presence of surface traps can lead to the creation of a dipole (Fig. 4.88).

One of the most interesting effects is that *the dipole between organics at a HJ depends on the surface on which it is deposited* (Tang et al., 2006, Zhao et al., 2008). A central assumption of an ideal HJ is that the order of layer deposition should not affect the magnitude of the band offsets. That is, depositing material A on material B should result in the same energy level offsets as B on A (Margaritondo and Perfetti, 1987). This *commutative property* of the HJ holds true for interface-trap-free inorganic HJs, yet has not been found to obtain for organic semiconductors. In Fig. 4.99 we plot the interface dipole energies vs. the difference between the substrate work function

**Figure 4.98** Classification of HJ types.

**Figure 4.99** Energy dipole at HJs between CuPc and THAP on several different substrates. Molecular structural formulae for the compounds are shown. The letters preceding the Au contact refer to different surface preparations: c = solvent cleaned, s = sputter cleaned in 1 keV Ar<sup>+</sup>, and o = treated in UV ozone for 1 h. The charge neutrality energy is  $q\phi_0$ . After Zhao et al. (2008).

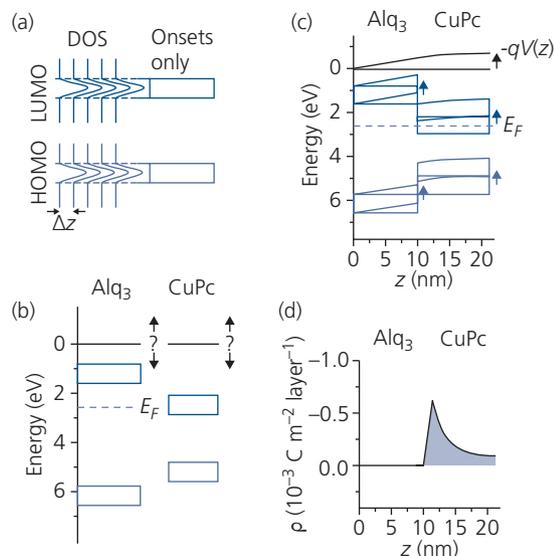

and the charge neutrality level,  $q\phi_0$  (see Section 4.6.3) for two organic semiconductors, CuPc and THAP. Starting with the substrate, CuPc is deposited on THAP, and vice versa (Zhao et al., 2008). These data show both the violation of the commutative rule and the strong dependence on substrate preparation. The non-commutative property is exemplified by deposition on PEDOT:PSS, where the dipole energy varies from +0.7 eV for CuPc on THAP, to -0.25 eV for THAP on CuPc.

A comprehensive explanation for the substrate dependence of the dipole energy, and the resulting charge redistribution across organic HJs relies on understanding the role played by disorder (Oehzelt et al., 2015). Figure 4.100a shows an approximate representation of the transport levels at an Alq<sub>3</sub>/CuPc HJ. The energetic disorder is approximated by a Gaussian DOS of full width,  $2\sigma$ , extending both above and below the LUMO or HOMO level, represented by the rectangles in the figure. The individual molecular layers are represented by their own Gaussian, separated by an interlayer distance,  $\Delta z$ . The fractional occupation of the DOS at each molecule is determined by the separation of the DOS from the Fermi energy,  $E_F$ , at each position,  $z$ . Once the materials are in contact, thermodynamic equilibrium is established, resulting in a flat  $E_F$ . The ability to establish local and global equilibria is a condition for current flow without charge build-up within the layers.

Figure 4.100b shows the Alq<sub>3</sub> and CuPc energies prior to contact. Apparently, if nothing is perturbed

by the contact, the Fermi energy extends into the LUMO of CuPc with its high density of electrons. The metal contact  $E_F$  is taken at the same energy as  $E_F$  of the first layer of Alq<sub>3</sub>. The total internal electrostatic potential across the film,  $V(z)$ , is calculated from Poisson's equation. The contact results in band bending, shown in Fig. 4.100c, such that the Fermi energy now lies outside of the LUMO band of the CuPc. Also, pinning the Alq<sub>3</sub> Fermi energy the metal  $E_F$  yields an Ohmic contact. This impacts the charge distribution all the way to the HJ located at  $z = 10$  nm. The calculated charge distribution is shown in Fig. 4.100d. We see that electrons accumulate on the CuPc side (with charge neutrality established by an equal and oppositely charged hole distribution at the contact), and the Alq<sub>3</sub> layer is completely depleted of charge, resulting in a uniform electric field in this layer. Hence,  $V(z)$ , and the vacuum level vary linearly across the Alq<sub>3</sub>, and then flatten in the CuPc. The maximum electrostatic potential that is achieved at  $\frac{\partial V}{\partial z} = 0$  is the total dipole energy.

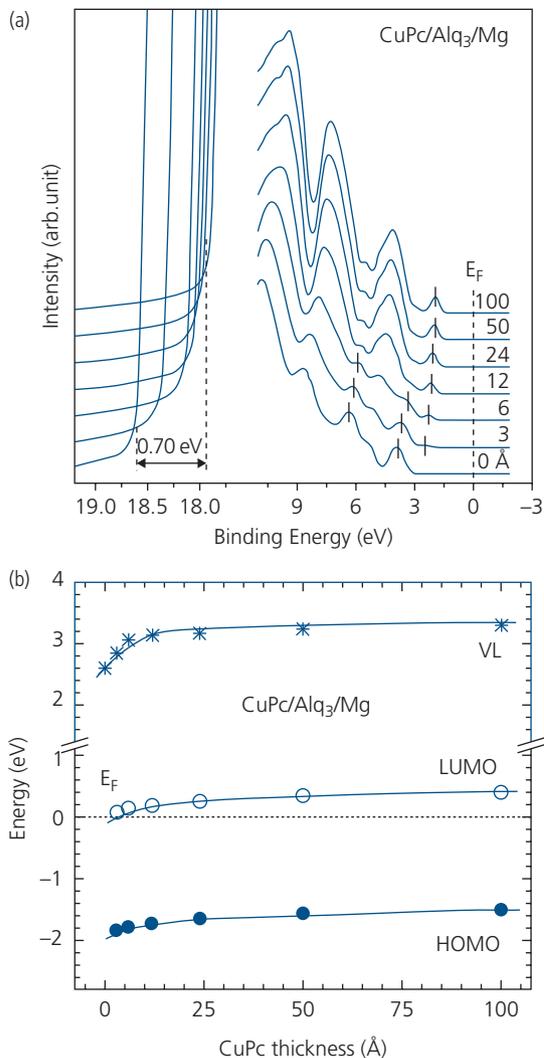

This layer-by-layer shift in  $V(z)$  is observed using Kelvin probe and UPS measurements for numerous semiconductor systems. For example, a series of UPS spectra taken for various levels of coverage of a 10 nm thick layer of Alq<sub>3</sub> pre-deposited on a low work function Mg thin film is shown in Fig. 4.101a (Tang et al., 2006). The shift in the ionization energy is noted by the peak at approximately 2 eV below  $E_F$ , which corresponds to the onset of the photoelectron current (Hüfner, 2003). The Alq<sub>3</sub> valence features are resolved

**Figure 4.100** Interpretation of the Alq<sub>3</sub>/CuPc heterojunction offset dependence on the substrate. (a) Representation of the transport band as the envelope of the disorder-induced Gaussian density of states (DOS). Each monolayer is indicated by its own Gaussian DOS separated by distance,  $\Delta z$ . The Alq<sub>3</sub> rests on a metal layer located at  $z \leq 0$ . (b) The positions of the LUMO (upper rectangles) and HOMO (lower rectangles) transport and Fermi ( $E_F$ ) levels prior to, and (c) following HJ formation. Here,  $V(z)$  is the internal potential at position  $z$ . (d) Electron distribution,  $\rho(z)$ , after contact (Oehzelt et al., 2015).

at 0 Å coverage, and become increasingly attenuated, and then dominated by CuPc features as its thickness is increased. The IP shifts at the high energy cutoffs of the spectra are accompanied by a similar shift of 0.7 eV in the vacuum level energy as coverage is increased from 0 Å to ~25 Å. At greater layer thicknesses the energy level bending is complete, and thermal equilibrium is established. These data are also shown in Fig. 4.101b. The LUMO energy equals the sum of the IP and the charge transport gap. The latter quantity is obtained from the energy difference between the onset of the CuPc UPS spectrum (which yields the ionization energy) and the inverse photoelectron spectrum (IPES), which gives the lower energy edge of the LUMO (Hill et al., 2000a, Tang et al., 2007). In IPES, low energy electrons (typically  $\leq 20$  eV) are incident on the organic surface. Photons are emitted as the electrons relax to the LUMO. The resulting photoemission spectrum vs. electron energy is measured, with the lowest energy photons providing the LUMO edge relative to  $E_F$  (see Appendix C) (Hill et al., 2000a, Hüfner, 2003, Tang et al., 2007). The LUMO follows the HOMO energy, as required for a material with a defined energy gap.

**Figure 4.101** Ultraviolet photoelectron He I spectra of CuPc deposited on Alq<sub>3</sub> on a Mg thin film. The CuPc layer thicknesses increasing from bottom to top, are in Å (Tang et al., 2006). (b) The HOMO, LUMO, and vacuum level (VL) as functions of CuPc thickness. Also shown is the Fermi energy,  $E_F$  (dashed line) (Tang et al., 2007).

The extent of the band bending in Fig. 4.103 due to charge accumulation on the CuPc side of the HJ (forming the potential “notch” at the heterointerfaces) is consistent with calculations leading to the energy level diagram in Fig. 4.100. Hence, the UPS data lead to a consistent explanation of the origin of the HJ dipole energy level diagrams for Type I, II, and III HJs (Oehzelt et al., 2015). For example, Fig. 4.102 shows a series of Type II staggered HJs for contacts with a range of Fermi energies. In Fig. 4.102a,  $E_F$  is positioned near the HOMO of the material with the smallest IP energy in the left-most diagram, with  $E_F$

**Figure 4.102** Energy level diagrams for Type II staggered organic HJs for various Fermi energy positions relative to the semiconductor frontier orbitals. (a) The material with a small ionization potential contacts the surface, and (b) the situation where the material positions are reversed. The charge distributions  $\rho(z)$  are shown for each HJ along with the spatially dependent electrostatic potential. To the left are the relative energies assumed for the individual organics prior to their contact (Oehzelt et al., 2015).

becoming progressively larger, and hence closer to the HOMO from left to right. For  $E_F = 3$  eV, there is bending in the energy levels for both materials, resulting in electron accumulation. The Fermi energy is centered within both energy gaps at 5 eV, resulting in flat bands, and consequently there is no electrostatic potential (or dipole) nor charge accumulation within the layers. Finally, as  $E_F$  approaches the HOMO, excess holes are accumulated at the contact, and the dipole energy is reversed.

In Fig. 4.102b the layers are reversed. It is clear that the dipole energies in this case are different from in Fig. 4.102a, accounting for the absence of the commutative property for excitonic HJs. The analysis leading to Figs. 4.100 and 4.102 assumes that the interface is free of defect states.

The influence of the substrate on the HJ energy level alignment can be used to create an Ohmic contact where  $\phi_{Bn,p} \rightarrow 0$ . Indeed, it has been shown that insertion of a very thin organic layer between a high work function metal oxide electrode (e.g.  $\text{MoO}_3$ ,  $\text{V}_2\text{O}_5$ ,  $\text{WO}_3$ ) and a thick organic “device” layer can reduce the hole barrier to zero as long as the IE of the interlayer is larger than the IP of the organic (Kotadiya et al., 2018). This strategy apparently is

successful in achieving Ohmic contacts independent of the conducting oxide or the organic layer as long as this relative energy criterion is met. The interlayer, itself an organic, must be sufficiently thin to allow for charge transport via tunneling or only a few hopping transitions. As in the HJ energy level alignment, the interposition of the ultrathin layer results in broadening of the surface DOS, allowing for overlap between the electronic states in the contact with the relatively narrow conduction states of the organic. This overlap promotes injection while also possibly pinning the organic layer Fermi energy at the metal  $E_F$ .

#### 4.7.2.2 Ideal diode equation for current transport in a trap-free excitonic HJ

The  $j$ - $V$  characteristics of organic semiconductor HJs are often similar to those of inorganic p-n junctions. As a consequence, theoretical treatments based on the generalized Shockley equation derived for inorganic devices have been extended to model the operation of organic solar cells (Dyakonov, 2004, Rand et al., 2007, Potscavage et al., 2008, Giebink and Forrest, 2009, Li et al., 2009). While this phenomenological approach often yields a reasonably accurate fit to the data, the

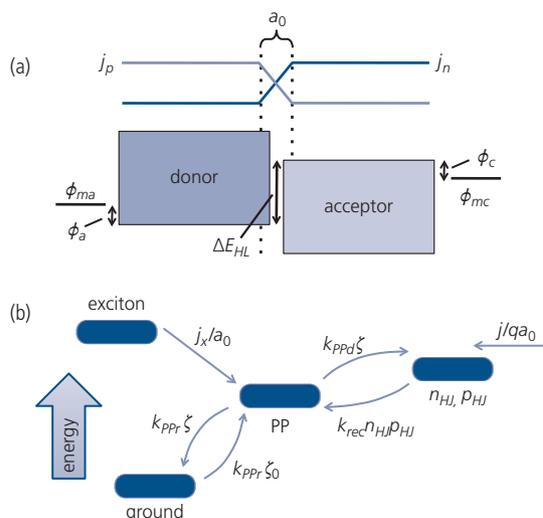

application of inorganic semiconductor models obscures the inherently different physics of transport in organic semiconductors. In particular, the Shockley equation in Section 4.7.1 applies to inorganic p-n junctions with well-developed energy band structures with a sea of delocalized free charge carriers. We have seen throughout this chapter, however, that organic semiconductors are characterized by hopping transport and tightly bound, localized exciton states that require significant energy to dissociate into free charges.

In this section, we follow the derivation of Giebink, et al. for an ideal diode equation adapted to describe fully organic (i.e. excitonic) Type II HJs (Giebink et al., 2010a, 2010b). Note that the dynamics of Types I and III HJs are different from those of Type II junctions, and hence are beyond the scope of this particular analysis. Type II junctions used in organic photovoltaics must consider bipolar injection, that is, the staggered energy level line-up allows holes and electrons injected from their opposite electrodes to traverse the heterointerface. Hence, the Type II symmetry allows for rectification similar to that experienced by carriers in a conventional p-n junction. In contrast, Type I, nested junctions support unipolar injection since the hole and electron barriers are positioned to prevent the free flow of charge of both polarities across the interface. As a result, the current in these HJs is typically Ohmic or space charge limited, and is modeled in Section 4.4. Finally, the current in Type III HJs is limited by electron-hole recombination at the broken energy gap in Fig. 4.98, and hence conduction occurs by transfer from the LUMO to HOMO levels across the HJ. These will be discussed further in the context of OPV blocking and injection layers in Chapter 7.

Polaron pair generation, recombination, and dissociation at a Type II HJ provide a distinct departure from considerations of charge diffusion that lead to the Shockley equation. Among the differences between organic and inorganic semiconductor junctions, a more physically justifiable representation predicts the correct temperature dependence of the dark current, the intensity and temperature dependence of the open circuit voltage ( $V_{oc}$ ) and short-circuit current ( $j_{sc}$ ), and the maximum  $V_{oc}$  attainable under one sun illumination for a given small molecule or polymer HJ material pair. Additionally, the temperature-dependent diode ideality factor in Section 4.7.1 arises from recombination via disorder-induced traps at the heterointerface. In the following section we specifically treat the case of traps with an exponential energetic distribution extending into the energy gap.

This treatment is ideal, insofar in that it assumes that current is governed solely by generation and recombination at the HJ, and that both processes proceed through the *polaron pair* (PP) intermediate state (Giebink et al., 2010a, Vandewal et al., 2014). That is, we ignore all losses that occur prior to the exciton arriving within the HJ “interaction volume” of width  $a_0$ , which gives the polaron pair separation distance across the heterointerface. These extrinsic losses include incomplete optical absorption in the donor or acceptor layers, geminate and bipolar recombination, thermal generation and thermalization. As in the Shockley diode equation, these non-idealities can be added later to describe the characteristics of less than ideal devices.

We define a polaron pair as the lowest energy CT state at the HJ, where the electron on the acceptor side is Coulombically bound to a hole on the donor side of the heterointerface. The configuration of the Type II excitonic HJ is shown in Fig. 4.103a. Current outside of the active region is unipolar, with pure hole ( $j_h$ ) and electron ( $j_e$ ) currents flowing in the donor and acceptor bulks, respectively. The interfacial energy gap,  $\Delta E_{HL}$ , in Fig. 4.103a is the difference between the donor HOMO and the acceptor LUMO that includes shifts due to an interface dipole. The hole and electron injection barriers at the anode and cathode are  $q\phi_a$  and

**Figure 4.103** (a) Energy level diagram of a Type II excitonic (donor–acceptor) heterojunction defining the hole and electron currents ( $j_p$ ,  $j_n$  respectively) and the “interaction volume,”  $a_0$ , within which the polaron pair (PP) is formed.  $\Delta E_{HL}$  is the HOMO–LUMO energy difference. (b) State energies involved in PP production, showing the various transition rates ( $k$ ) involved in the generation of charge, and exciton currents ( $j$ ,  $j_x$ , respectively). Terms are defined in the text (Giebink et al., 2010b).

$q\phi_c$ , respectively. These energies include interface dipoles that might exist. The built-in potential is given by the corresponding difference in contact work functions:  $qV_{bi} = q\phi_{ma} - q\phi_{mc}$ .

Figure 4.103b shows the processes that occur within the HJ volume. The steady state recombination of polaron pairs is described via two coupled equations:

$$\frac{d\zeta}{dt} = \frac{j_X}{a_0} - k_{PPr}(\zeta - \zeta_0) - k_{PPd}\zeta + k_{rec}n_{HJ}p_{HJ} = 0, \quad (4.297)$$

and for free charges:

$$\frac{dp_{HJ}}{dt} = k_{PPd}\zeta - k_{rec}n_{HJ}p_{HJ} + \frac{j}{qa_0} = 0, \quad (4.298)$$

where  $\zeta$  is the PP density,  $j_X$  is the exciton current density diffusing to the interface, and  $n_{HJ}$  and  $p_{HJ}$  are the free electron and hole densities at opposite sides of the HJ, respectively.

Time-dependent solutions that elucidate the dynamical nature of these processes can be obtained by evaluating the full transient solutions to Eqs. 4.297 and 4.298. These solutions provide the time evolution of both the polaron and hole populations, respectively (Giebink et al., 2010a).

Polaron pairs recombine to the ground state at rate  $k_{PPr}$ , which is also linked to the thermal equilibrium PP population,  $\zeta_0$ , determined by detailed balance (Kirchartz and Rau, 2008). Polaron pairs dissociate at rate  $k_{PPd}$ , which is a function of temperature and the electric field at the interface according to the *Onsager–Braun model* (see below). Finally, free carriers bimolecularly recombine to form PPs with rate constant,  $k_{rec}$ , approximated by its bulk Langevin value,  $q\mu_{tot}/\epsilon_r\epsilon_0$ .

Solving Eq. 4.297 for the PP density and substituting the result into Eq. 4.298 gives

$$j = qa_0k_{rec} \left( \frac{k_{PPr}}{k_{PPd} + k_{PPr}} \right) \left( n_{HJ}p_{HJ} - \frac{k_{PPd}}{k_{PPd0}} n_{HJ0}p_{HJ0} \right) - qj_X \left( \frac{k_{PPd}}{k_{PPd} + k_{PPr}} \right). \quad (4.299)$$

The subscript “0” indicates the value at thermal equilibrium. Similar to the Shockley equation, we assume quasi-equilibrium. Hence, the carrier densities at the interface ( $n_{HJ}$ ,  $p_{HJ}$ ) and contacts ( $n_c$ ,  $p_c$ ) are related via

$$n_{HJ} = n_c \exp[q\delta_A(V - V_{bi})/k_B T] \quad (4.300a)$$

and

$$p_{HJ} = p_c \exp[q\delta_D(V - V_{bi})/k_B T], \quad (4.300b)$$

where  $\delta_D$ , and  $\delta_A$  are the fractions of the potential dropped across the donor (D) and acceptor (A) layers, respectively. Thus,  $\delta_D + \delta_A = 1$ . These relations are strictly valid only when  $j = 0$ , but are a good approximation at low current when both diffusion and drift are small.

Substituting Eqs. 4.300 into Eq. 4.299 yields

$$j = qa_0k_{rec}N_{HOMO}N_{LUMO}(1 - \eta_{PPd}) \exp(-\Delta E_{HL}/k_B T) \times \left[ \exp(qV/k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right] - q\eta_{PPd}j_X, \quad (4.301)$$

where  $\eta_{PPd} = k_{PPd}/(k_{PPd} + k_{PPr})$  is the PP dissociation probability (Braun, 1984, Mihailetchi et al., 2004), and we have assumed that the density of charge at the cathode can be written in terms of the LUMO DOS,  $N_{LUMO}$ , such that  $n_c = N_{LUMO} \exp(-q\phi_c/k_B T)$ . At the anode,  $p_a = N_{HOMO} \exp(-q\phi_a/k_B T)$ . Here, effects that are appreciable at high electric field and low temperature such as tunneling have been neglected. Also, we define the HOMO–LUMO offset energy (cf. Fig. 4.103a):

$$\Delta E_{HL} = q\phi_a + q\phi_c + qV_{bi}. \quad (4.302)$$

Hence, Eq. 4.301 is the ideal diode equation for an excitonic Type II HJ in the absence of traps, and can be written in the form of Eq. 4.236:

$$j = j_0 \left( \exp(qV/k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right) - j_{ph}, \quad (4.303)$$

where the photocurrent is given by

$$j_{ph} = q\eta_{PPd}j_X. \quad (4.304)$$

That is,  $j_{ph}$  is simply the product of the exciton current, its dissociation efficiency at the HJ, and  $q$ . Importantly, Eq. 4.303 differs from the Shockley equation in that it includes the rate of polaron pair dissociation,  $k_{PPd}$ , which is a function of both electric field and temperature. An applied field can polarize the PP, inducing pair ionization at high reverse bias. At  $V = 0$ , the system is in equilibrium such that  $k_{PPd}(V = 0) = k_{PPd0}$ , in which case the term in parentheses vanishes.

The field dependence of PP dissociation is obtained from the theory of Onsager for ion pairs (Onsager, 1938), and extended to symmetric excitonic states by Braun (1984). This is a classical model based on Langevin recombination dynamics: if the charge pair is at a capture (or thermalization) radius  $r_{th} < q^2/(4\pi\epsilon_r\epsilon_0k_B T)$ , the charges recombine, otherwise they

escape their mutual Coulomb attraction and remain free charges. This radius is  $\sim 2\text{--}10$  nm at room temperature. In an electric field, the charge pair is polarized, resulting in a higher probability for dissociation. Thus, there is a competition between field-induced ionization, and thermalization leading to geminate recombination.

Figure 4.104a shows the probability for dissociation as a function of PP radius,  $a_0$ , and at three different electric fields in an isotropic medium whose dielectric constant,  $\epsilon_r = 3.02$ , is equal that of anthracene (Batt et al., 1969). For this calculation, it is assumed that the initial pair orientation and distribution is independent of the external electric field. The escape probability is shown in Fig. 4.104b, with the initial PP radii ranging from 0.6 to 1.0 nm. The probability increases with field, until it saturates at  $P(F) = 1$  at  $F \approx 10^5$  V/cm.

The dissociation rate  $k_{PPd}$  is given by (Braun, 1984, Giebink et al., 2010b)

$$k_{PPd} = \frac{3}{4\pi a_0^3} k_{rec} \exp(-E_B/k_B T) \frac{J_1(2\sqrt{-2b})}{\sqrt{-2b}}, \quad (4.305)$$

where  $E_B$  is the PP binding energy,  $b = q^3 F_{HJ} / (8\pi\epsilon_r\epsilon_0 k_B^2 T^2)$ ,  $J_1$  is the Bessel function of order one, and  $F_{HJ}$  is the electric field at the HJ. The validity of Eq. 4.305 for negative fields (i.e. when  $F_{HJ}$  reverses direction under forward bias) is unclear, and its numerical evaluation becomes unstable for  $F_{HJ} < -10^4$  V/cm.

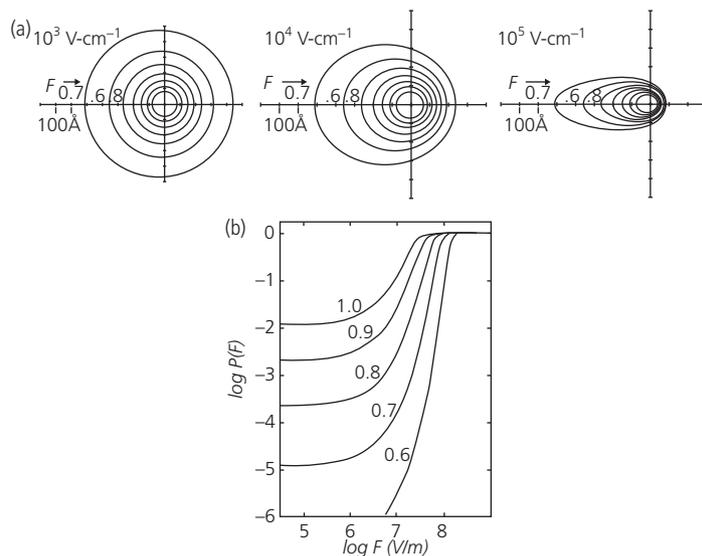

The theory of Braun has been extended to consider electrons and holes that can only “sample” the half-space occupied by the acceptor and donor layers,

respectively. This is a situation found in Type II HJs with  $\Delta E_{LUMO}$  and  $\Delta E_{HOMO}$  sufficiently large to prevent electron or hole transfer back over the HJ energy offsets at the HOMO and LUMO edges where they would recombine (Fig. 4.105a) (Peumans and Forrest, 2004). The energy of the bound pair is given by

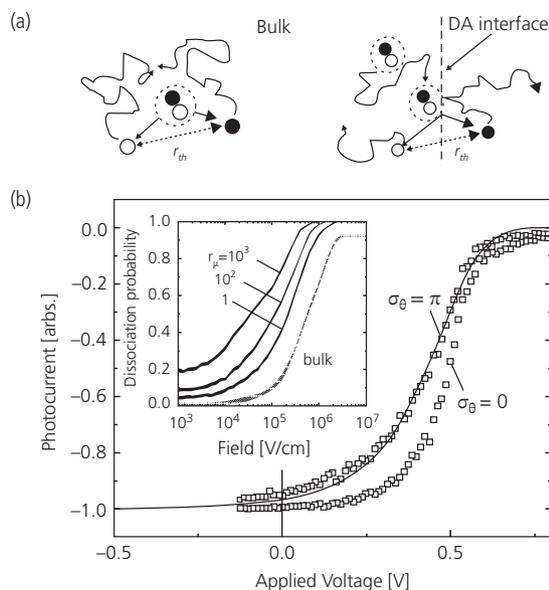

$$E_{PP} = \frac{q^2}{4\pi\epsilon_r\epsilon_0|\mathbf{r}_e - \mathbf{r}_h|} - q\mathbf{F}\cdot(\mathbf{r}_e - \mathbf{r}_h) + E_{LUMO,A}(\mathbf{r}_e) + E_{HOMO,D}(\mathbf{r}_h), \quad (4.306)$$

where  $\mathbf{r}_e$  ( $\mathbf{r}_h$ ) is the position of the electron (hole),  $E_{LUMO,A}$  is the energy of the acceptor LUMO, and  $E_{HOMO,D}$  is the energy of the donor HOMO. Given that the electron must reside on the acceptor and the hole on the donor, the initial condition requires that the PP dipole moment is preferentially aligned perpendicular to the plane of the heterointerface (i.e. the orientation distribution of dipoles has a width,  $\sigma_\theta = 0$ ); a striking departure from the conditions assumed in the Onsager–Braun model. Hence, the orientation of the PP dipole is no longer random relative to the applied field, which is also assumed to be normal to the interface plane.

Results of Monte Carlo simulations of the dissociation (or escape) probability of the electron and hole show a strong dependence on the asymmetry of mobilities of the two carriers on opposite sides of the HJ (see inset, Fig. 4.105b). That is, the volume sampled by the more mobile carrier is far larger than that of the less mobile carrier, resulting in a higher opportunity for escape than if both charges have the same

**Figure 4.104** (a) Ionization probability at three different electric fields for a polaron pair in anthracene at  $T = 300$  K. Each contour is separated by a probability interval of 0.1 (Batt et al., 1969). (b) Ionization probability vs. electric field for an initial starting radius (in nm) shown for each curve. For these calculations, the total Langevin mobility is  $\mu_{tot} = 1$   $\text{cm}^2/\text{V s}$  (Braun, 1984).

**Figure 4.105** (a) The capture process of an electron and hole in the bulk and at a donor–acceptor HJ. Here,  $r_{th}$  is the thermalization radius. The dashed circles denote bound electron–hole pairs. (b) Monte Carlo simulations of the photocurrent from a CuPc/C<sub>60</sub> heterojunction (squares) assuming a thermalization distance for both electrons and holes of  $r_{th} = 24 \text{ \AA}$ , an initial polaron pair separation of  $8 \text{ \AA}$ , and  $T = 300 \text{ K}$ . The electrons and holes are either randomly distributed relative to the HJ ( $\sigma_\theta = \pi$ ) or are oriented perpendicular to it ( $\sigma_\theta = 0$ ). Here,  $\sigma_\theta$  is the width of the distribution of dipole orientations. The line indicates data. Inset: Simulated dissociation probability at the HJ vs. electric field for various ratios of electron-to-hole mobilities  $r_\mu$  (assuming the larger mobility is in the numerator) (Peumans and Forrest, 2004).

mobility, and hence are pinned at the interface where the recombination probability increases.

The inset in Fig. 4.105b shows the dissociation probability at a DA HJ as a function of electric field for several mobility ratios,  $r_\mu \geq 1$ , where the larger mobility is in the numerator. This calculation shows that the dissociation probability substantially increases with electric field, saturating for  $r_\mu = 1$  at  $F > 10^5 \text{ V/cm}$ . This is higher than the bulk dissociation probability (with randomly oriented dipoles) of  $\sim 0.9$  at the highest fields (Peumans and Forrest, 2004).

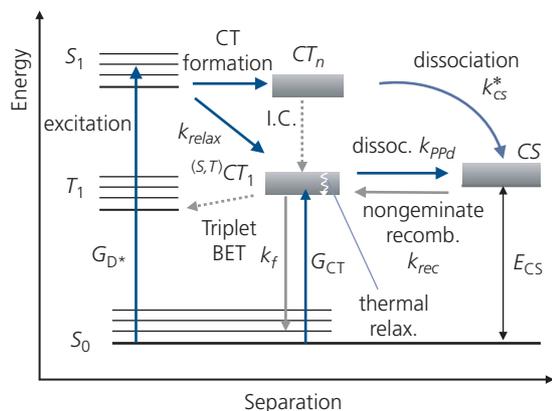

This extension of Onsager–Braun theory to a Type II excitonic HJ has been tested by measuring the photocurrent from a 20 nm CuPc/20 nm C<sub>60</sub> junction as a function of applied voltage, with results shown in Fig. 4.105b. The fit by integrating over the half-space is substantially improved from that obtained assuming a totally random, bulk orientation (squares). The photocurrent saturates at high voltages, consistent with the probabilities calculated in Fig. 4.104a.

The field dependence of  $k_{PPd}$  in Eq. 4.305 suggests that the reverse current increases with voltage, contrary to predictions of the Shockley equation where the diffusion current is voltage independent. This voltage dependence is consistent with observation for excitonic HJs (Potsavage et al., 2008, Li et al., 2009). Under forward bias,  $k_{PPd}$  is similar to or less than  $k_{PPd0}$ . Further, the current density increases exponentially with an ideality factor  $n = 1$ , and the photocurrent (Eq. 4.304) is directly proportional to the PP dissociation efficiency that diminishes with increasing forward bias. Note that while the formulation of Onsager and Braun extended to ionization at a HJ provides an analytical form for  $k_{PPd}$  in Eq. 4.305, it is unlikely that it is valid at fields  $\geq 10^4 \text{ V/cm}$ , as will be discussed in Chapter 7 (Renshaw et al., 2012).

The central assumption of the preceding analysis is that the relaxed state polaron pair (or CT exciton) is a precursor to charge generation. That is, according to Fig. 4.103, excitons that migrate to the heterointerface form the PP precursor state that is driven to dissociation via the energy level offsets,  $\Delta E_{LUMO}$  and  $\Delta E_{HOMO}$ . If  $k_{PPr} \gg k_{PPD}$ , the efficiency for dissociation is less than for recombination, and the excitation is lost to thermalization.

In Chapter 3 we discussed the dynamics and photo-physics of CT states in DA complexes, or between molecules of similar composition (i.e. excimeric states). In the context of the current analysis, we must consider whether or not the dissociation of the CT or PP state bridging a HJ comprising a contact between otherwise homogeneous donor and acceptor layers is the precursor to charge generation.

Evidence that such states lead to free charge generation at CuPc/C<sub>60</sub> and SubPc/C<sub>60</sub> junctions has been reported (Giebink et al., 2010a), and the participation of CT states in a variety of small molecule HJs has been inferred from comprehensive studies of their open circuit voltages (Rand et al., 2007). However, what was lacking in those earlier studies was convincing evidence that the photocurrent predominantly originates from a relaxed CT versus a hot, charge separated (CS) state. These competing scenarios for the generation of charge from an excited donor molecule ( $D^* = S_1$  in this example) are illustrated by the Jablonski diagram in Fig. 4.106. Direct generation to  $D^*$  is denoted by  $G_{D^*}$ . Then  $D^*$  can decay to the CT manifold at rate  $k_{relax}$  followed by internal conversion to  $CT_1$ . Due to the spatially distributed nature of CT and CS states, there are no well-defined vibronic levels. Once the excitation has reached  $CT_1$ , it can fluoresce at rate  $k_f$  or it can gain energy to reach the

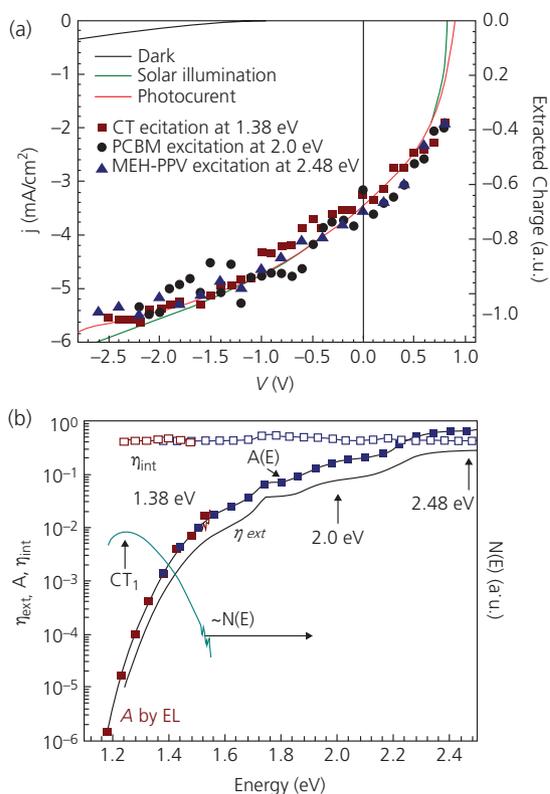

**Figure 4.106** Processes leading to charge generation. Here,  $S_1 = D^*$  = excited singlet donor state,  $CT$  = charge transfer state,  $G_{CT}$  = optical energy to excite a polaron to the lowest CT state ( $CT_1$ ),  $CS$  = charge separated state, BET = back electron transfer, IC = internal conversion. The rates are labeled  $k$  with the subscripts:  $relax$  = relaxation,  $f$  = fluorescence,  $rec$  = reverse  $CS \rightarrow CT$  transfer,  $PPd$  = forward  $CT \rightarrow CS$  transfer.  $G$  indicates direct generation processes.

charge separated state,  $CS$ , ultimately generating free charges. This transition occurs at rate  $k_{PPd}$ , which competes with direct  $CS$  formation from  $D^*$  at rate,  $k_{CS}^*$ , and with back transfer from  $CS$  to  $CT$  at rate  $k_{rec}$ . The  $CT$  state can be directly excited at rate  $G_{CT}$ , providing a powerful tool for investigating its oscillator strength and energetics. We show in the following that direct transitions of  $D^*$  to  $CS$  are unlikely, and that the most likely route to free charge generation is via  $CT_1$  and subsequently to  $CS$ .

Direct transfer from  $D^*$  to  $CS$  at the HJ bears similarities to direct charge generation in the bands of an inorganic semiconductor, where a photon of energy  $E_{D^*}$  results in generation of a free electron polaron (Bakulin et al., 2012, Grancini et al., 2013). Its direct excitation requires that the transfer occur without thermalization into  $CT$ , which is unlikely due to the very short mean free path of charges (equal approximately to the intermolecular separation), and the high phonon energies that lead to rapid thermalization in organic semiconductors.

The question is not whether  $CS$  states can be produced directly from exciton dissociation, but whether these, or  $CT$  states are the immediate precursor to photocurrent generation. The  $CT$  states can be directly accessed by optical pumping at wavelengths longer than those needed to excite the donor and acceptor states (i.e.  $E_{CT} \approx \Delta E_{HL} < E_{D^*, A^*}$ ), and then observing the resulting  $CT$  state photoluminescence (Loi et al., 2007, Liu et al., 2016b). Alternatively, the HJ can be forward biased, and the quantum efficiency of the long wavelength electroluminescence from the  $CT$

**Figure 4.107** (a) Photo and dark current characteristics of a MEH-PPV/PC<sub>61</sub>BM HJ. The photocurrent (red line) is the difference between response under simulated solar illumination and the dark current (black line). (b) External quantum efficiency ( $\eta_{ext}$ ), absorption ( $A(E)$ ), and internal quantum efficiency ( $\eta_{int}$ ) of the HJ in (a).  $N(E)$  is the  $CT$  photon flux spectrum (Vandewal et al., 2014).

state can be used to quantitatively determine the population of these states (Vandewal et al., 2010, Rivan et al., 2014).

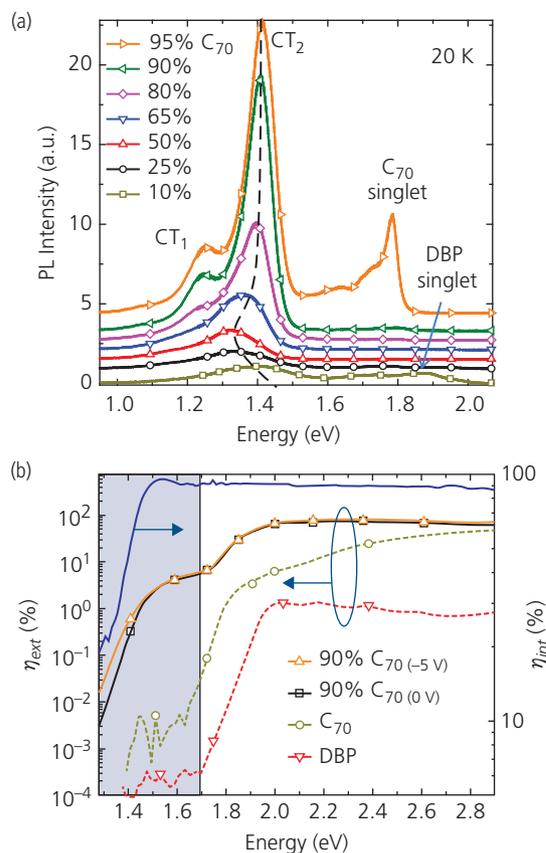

Figure 4.107a shows the dark and photocurrent vs. voltage characteristics of a MEH-PPV/PC<sub>61</sub>BM HJ. Also shown is the photocurrent arising from direct  $CT$  excitation at 1.38 eV, and from direct excitation of the  $D^*$  (MEH-PPV) state at 2.48 eV, and  $A^*$  (PC<sub>61</sub>BM) at 2.0 eV. The similarities between the field dependence of the current generated by direct excitation of the  $CT$  state,  $D^*$  and  $A^*$ , and the total photocurrent suggests that all photocurrent sources have the same origin. In contrast, no field dependence is expected from an unbound  $CS$  state since it does not undergo Onsager-like ionization.

A quantitative comparison of the measured external quantum efficiency ( $\eta_{ext}$ ) spectrum for this HJ with calculations assuming 100% of the photocurrent arises via an intermediate  $CT$  state is shown in Fig. 4.107b. To determine what fraction of the photo-generated charge arises from  $CT$  dissociation, the  $CT$  state absorption spectrum,  $A(E)$  is needed. In thermal

equilibrium,  $A(E) \propto N(E) \exp(E/k_B T)/E^2$ , where  $N(E)$  is the flux of photons emitted at energy,  $E$  (Vandewal et al., 2014). The CT emission spectrum shown in Fig. 4.107b has been measured at low injection to assure that near-equilibrium conditions exist. The calculated absorption spectrum is given by the solid line. The ratio between the measured  $\eta_{\text{ext}}$  and calculated  $A(E)$  then gives the internal quantum efficiency ( $\eta_{\text{int}}$ ), also shown in Fig. 4.107b (squares). That is,  $\eta_{\text{int}}$  is the ratio of charges generated to photons absorbed in the active region, that is,  $\eta_{\text{int}}(E) = \eta_{\text{ext}}(E)/A(E)$ . The lack of spectral dependence of the  $\eta_{\text{int}}$  spectrum extending to low energies where only the CT state is excited ( $<1.4$  eV) is evidence that the CT, otherwise known as the bound PP state, is the intermediate between exciton and photocurrent generation. This analysis has been applied to both polymer as well as small molecule systems, some with a field-dependent photocurrent and others without, but all leading to the same conclusions regarding the pivotal role played by the CT state (Vandewal et al., 2014).

Another, less model-dependent example of photocurrent generation via CT states is shown in Fig. 4.108 for the small molecular weight HJ consisting of the donor, DBP, and the acceptor,  $C_{70}$  (Liu et al., 2016b). Both the electroluminescence and photoluminescence spectra show intense emission from two clearly distinguishable CT states; the lowest energy feature ( $CT_1$ ) is identified with electrons confined in amorphous phases of  $C_{70}$ , and the higher energy (corresponding to lower binding energy)  $CT_2$  state is due to electrons in  $C_{70}$  crystalline domains (see Section 7.4.3). Both CT states are observed at energies well below the  $C_{70}$  and DBP singlet emission lines. In Fig. 4.108  $\eta_{\text{int}}$  is obtained from the  $\eta_{\text{ext}}$  spectrum after directly measuring the absorption spectrum of the blended HJ thin films. Since  $\eta_{\text{int}}$  approaches 100% at energies as low as 1.4 eV, this unambiguously implicates the CT state as the precursor to photogeneration, even via absorption of photons at the highest energies measured.

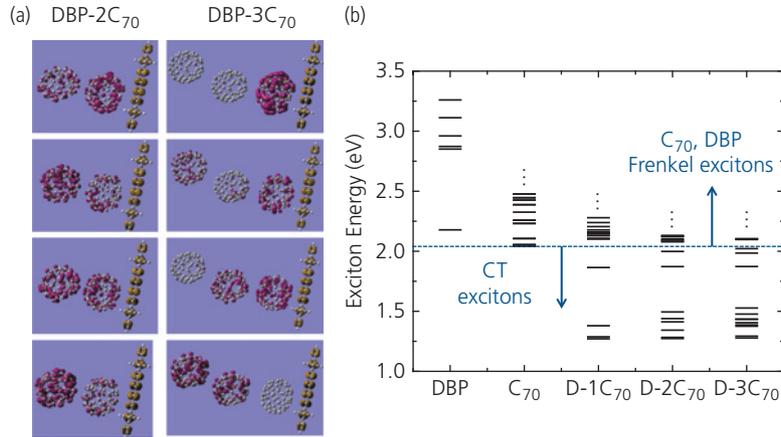

The long wavelength features are associated with the CT state since it is absent in devices consisting solely of  $C_{70}$  or DBP. These latter devices exhibit very low  $\eta_{\text{ext}}$  due to the lack of a charge-separating interface. Calculations using time dependent density functional theory were employed to investigate the CT spectra and to ensure that the origin of the low energy states are indeed due to charge transfer between the monomeric species. The charge density distribution of CT states for several different  $C_{70}$  dimer and trimer configurations with DBP clusters are shown in Fig. 4.109a. These calculations show the electron

**Figure 4.108** (a) Photoluminescence (PL) intensity as a function of energy for HJ blends where the ratio of the acceptor,  $C_{70}$  to the donor, DBP is varied. Emission from two CT states is identified well below the  $A^*$  and  $D^*$  emission:  $CT_1$  is associated with the electron in amorphous regions of  $C_{70}$ , and  $CT_2$  is for electrons in crystalline islands of  $C_{70}$ . (b) External ( $\eta_{\text{ext}}$ ) and internal quantum efficiency ( $\eta_{\text{int}}$ ) spectra at 0 V and  $-5$  V for 10% DBP/90%  $C_{70}$  HJs. Also shown are the  $\eta_{\text{ext}}$  spectra for non-HJ devices consisting of only DBP or  $C_{70}$  singlet features (Liu et al., 2016b).

(purple) and hole (yellow) densities comprising the CT states span the  $C_{70}$  and DBP molecules, respectively. Including additional  $C_{70}$  molecules into the complex to form trimers and tetramers leads to moderate electron delocalization and creates several higher energy CT states. These calculations consider only a few of the many possible DBP- $C_{70}$  molecular configurations, with those provided serving as examples. The energies of the molecular combinations are provided in Fig. 4.109b. The  $C_{70}$  monomer has a singlet energy of  $E_S = 2.04$  eV, while the DBP monomer has  $E_S = 2.18$  eV. Other high order singlet state energies are also shown. The singlet energies of the DBP- $C_{70}$

physical dimer, trimer (one DBP-two C<sub>70</sub> molecules) and tetramer (one DBP-three C<sub>70</sub> molecules) that lie below the DBP and C<sub>70</sub> monomer states are CT states, consistent with the spectra in Fig. 4.108. The calculated oscillator strengths of dimer CT states are in the range 10<sup>-4</sup>–10<sup>-3</sup>, which are 100 to 1000 times lower than for the monomers, but higher than for trimer and tetramer CT states.

There is apparently no voltage dependence of  $\eta_{\text{ext}}$  due to CT<sub>2</sub>, although there is indication that CT<sub>1</sub> does undergo limited field ionization at  $E < 1.24$  eV. Quantitative analysis of the field dependence of the ratio of  $\eta_{\text{int}}$  at  $E < 1.4$  V where current originates, from the more tightly bound CT<sub>1</sub> vs.  $\eta_{\text{int}}$  at higher energies, suggests that CT<sub>2</sub> contributes 88% of the total photocurrent, with the remainder due to CT<sub>1</sub> (Liu et al., 2016b).

While these results show a quantitative dependence of the generation of free polarons and the PP precursor states at the HJ, there remains the question of how the CT → CS transition occurs, which can often require an increase in energy of a few hundred meV. It is likely that this excess energy is supplied by energy level bending at the heterointerfaces that segregates the electron and hole in the PP, reducing the recombination probability as charges migrate away from the HJ (Peumans and Forrest, 2004). Asymmetries in the electron and hole mobilities in their respective layers encourages dissociation, further reducing  $k_{\text{PPr}}$ , as shown in Fig. 4.105. Morphology also plays an important role, whereby the electron mobility in fullerene blended HJs is increased with increasing

domain size, thereby promoting the CT → CS transition (Bernardo et al., 2014, Liu et al., 2016b).

Returning to Eq. 4.301 and solving for the open-circuit voltage by setting  $j = 0$  gives

$$qV_{\text{OC}} = \Delta E_{\text{HL}} - k_{\text{B}}T \ln \left[ \left( \frac{k_{\text{PPr}}}{k_{\text{PPd}}} \right) \frac{a_0 k_{\text{rec}} N_{\text{HOMO}} N_{\text{LUMO}}}{j_{\text{X}}} \right], \quad (4.307\text{a})$$

or

$$qV_{\text{OC}} = \Delta E_{\text{HL}} - k_{\text{B}}T \ln \left[ \left( \frac{k_{\text{rec}} k_{\text{PPr}}}{k_{\text{PPd}} + k_{\text{PPr}}} \right) \frac{q a_0 N_{\text{HOMO}} N_{\text{LUMO}}}{j_{\text{ph}}} \right]. \quad (4.307\text{b})$$

Equation 4.307 predicts that  $V_{\text{OC}}$  should increase with decreasing temperature, and with the logarithm of  $j_{\text{X}}$  (proportional to the illumination intensity) with slope  $k_{\text{B}}T/q$ . When polaron pairs are strongly coupled to the ground state,  $k_{\text{PPr}}$  is large and  $V_{\text{OC}}$  decreases, that is, this analysis predicts a decrease in open circuit voltage with increased PP recombination. At  $V_{\text{OC}}$ , the electric field,  $F_{\text{HJ}}$ , is small or even reverses direction (i.e. aiding recombination), such that  $k_{\text{PPd}}$  takes on its zero-field value,  $k_{\text{PPd}}(F_{\text{HJ}} = 0) \approx k_{\text{PPd}} = \frac{3}{4\pi a_0^3} k_{\text{rec}} \exp(-E_{\text{B}}/k_{\text{B}}T)$ . Since  $4\pi a_0^3/3$  is the volume occupied by a polaron pair, this relationship is inserted into Eq. 4.307 to give

$$qV_{\text{OC}} = (\Delta E_{\text{HL}} - E_{\text{B}}) - k_{\text{B}}T \ln \left[ \frac{a_0 k_{\text{PPr}} N_{\text{HOMO}} N_{\text{LUMO}}}{j_{\text{X}} \zeta_{\text{max}}} \right], \quad (4.308)$$

where  $\zeta_{max}$  is the maximum PP density that is sustained at the interface (i.e. all states are occupied).

At  $T = 0$  or at very high illumination intensities,  $\zeta_{max} \rightarrow N_{HOMO}$ ,  $N_{LUMO}$ . Under these conditions, all available molecular sites are occupied by a polaron or an exciton. Furthermore, the maximum exciton current is  $j_X = k_{PP} a_0 N_{HOMO}$ ; at higher intensities there are no further HOMO states to excite and the material becomes transparent. Thus, the argument of the logarithm in Eq. 4.308 approaches unity, giving the maximum possible open circuit voltage:

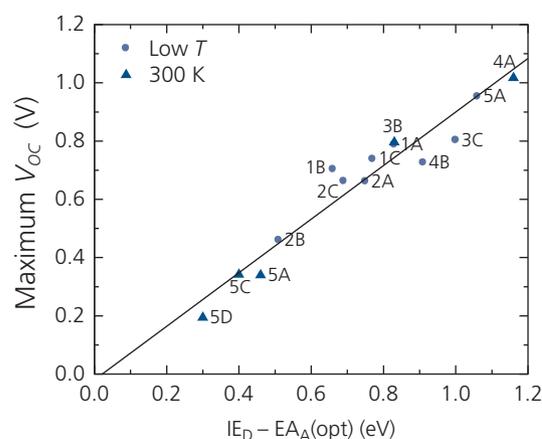

$$qV_{OC}^{max} = \Delta E_{HL} - E_B. \quad (4.309)$$

This expression is a direct result of the foregoing analysis, and is analogous to expressions previously suggested from experimental observation, but never rigorously proven (Rand et al., 2007, Cheyns et al., 2008, Vandewal et al., 2010).

The linear dependence of Eq. 4.309 for a selection of small molecular weight HJs listed in Table 4.7 is shown in Fig. 4.110, which is a plot of  $V_{OC}^{max}$  vs. the difference between the ionization energy of the donor ( $IE_D$ ) and the optical electron affinity of the acceptor ( $EA_A(opt)$ ). Here,  $EA_A(opt)$  is the sum of the energy determined from the long wavelength cut-off of the exciton absorption spectrum, that is, the optical energy gap, and the  $IP$ . The maximum open circuit voltage is measured at  $T = 300$  K or at low temperature ( $\sim 77$  K). It is striking that the best fit to the data is a straight line with a unity slope and an intercept of approximately zero. To relate these data to Eq. 4.309, we note that Rand et al. (2007) postulated that  $EA_A(opt) \approx E_{LUMO,A} - \frac{1}{2}E_{BA} - \frac{1}{2}E_{BD} \approx E_{LUMO,A} - E_{BD}$ .

That is,  $EA_A(opt)$  is equal to the difference between the  $E_{LUMO,A} = EA_A$ , and approximately half the polaron pair binding energy due to the electron on the acceptor ( $E_{BA}$ ), and the other half of the PP energy due to the hole on the donor ( $E_{BD}$ ). With this reasonable approximation, the abscissa in Fig. 4.110 is  $IE_D - EA_A(opt) = E_{LUMO,A} - E_{HOMO,D} - E_B = \Delta E_{HJ} - E_B$ . Thus, the linear fit directly follows from Eq. 4.309.

A similar linear correspondence between  $V_{OC}^{max}$  and  $E_{HOMO,D}$  of a series of polymer donor molecules combined with PC<sub>61</sub>BM is shown in Fig. 4.111. In that study, both  $E_{HOMO,D}$  and  $E_{LUMO,A}$  were measured using cyclic voltammetry (CV, see Appendix C). A linear fit with a unity slope to the data

**Figure 4.110** Maximum  $V_{OC}$  measured at two different temperatures vs. the difference of the ionization energy of the donor ( $IE_D$ ) and the optically determined electron affinity of the acceptor ( $EA_A(opt)$ ) for a number of Type II HJ donor-acceptor pairs listed in Table 4.7. Adapted from Rand et al. (2007).

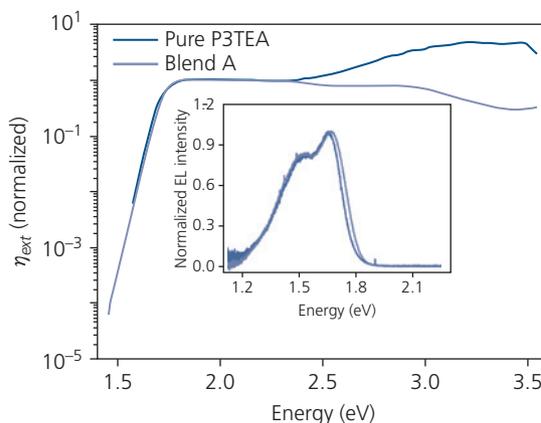

**Figure 4.111** Maximum open circuit voltage vs. oxidation potential measured by cyclic voltammetry and the HOMO energies of a series of donor/PC<sub>61</sub>BM junctions. The straight line is a fit to the data with unity slope and an offset of  $-0.3$  V (Sharber et al., 2006).

following,  $qV_{OC}^{max} = \Delta E_{HL} - 0.3$  eV was found. The offset energy of 0.3 eV was attributed to losses from diode non-idealities and internal fields within the device. Yet, in the context of Eq. 4.309, this offset again can be attributed to the PP binding energy.

Finally, we note that Eq. 4.309 is the organic analog to the band-gap limitation of  $V_{OC}^{max}$  in inorganic solar cells established by Shockley and Queisser (1961), of which we will have more to say in Chapter 7. Indeed, the PP binding energy,  $E_B$ , represents a significant source of energy loss in the photogeneration process. This is readily apparent in Fig. 4.108, where the energies of CT<sub>1</sub> and CT<sub>2</sub> are greater than 0.4 eV below the singlet state energies of the organics comprising the HJ. As we will show in Section 7.4.3, this is the energy needed to drive charge separation. Considerable research has, therefore, been devoted to designing molecules and active region morphologies that minimize the PP binding energy.

An example system where the driving energy is nearly eliminated and yet there is a high  $\eta_{ext} = 66\%$  for charge separation, comprises the P3TEA donor combined with the spiro-fluorene bridged bis-perylenediimide acceptor, SF-PDI<sub>2</sub> (see Section 7.4.3, Yan et al., 2013). The normalized  $\eta_{ext}$  for both the pure donor and the P3TEA:SF-PDI<sub>2</sub> blend are shown in Fig. 4.112, and their electroluminescence spectra are shown in the inset. Unlike the  $\eta_{ext}$  spectra for the fullerene-based devices in Fig. 4.108, here we see complete overlap between the spectra of the blend and the pure donor. Furthermore, the CT electroluminescence spectrum is only slightly shifted from that of the pure donor. There is apparently no difference between the energies of the singlet exciton of the donor and the PP state, implying that  $E_B \approx 0$ . Furthermore, the CT state transfer rate,  $k_{relax} = 0.3 \times 10^{12} \text{ s}^{-1}$ , is 10 times larger than  $k_f$ , which leads to the high external efficiency observed.

**Figure 4.112** Fourier transform photocurrent spectroscopy is used to obtain the  $\eta_{ext}$  spectra of pure P3TEA and a 1:1.5 P3TEA:SF-PDI<sub>2</sub> blend (Blend A). Inset: Electroluminescence spectra of these two devices (Liu et al., 2016a).

The high dissociation efficiency is attributed to several factors. The large volume occupied by SF-PDI<sub>2</sub> results in intramolecular charge delocalization, which greatly reduces the exciton binding energy (Liu et al., 2016a). Thus, the transfer between the exciton and CT state is greatly facilitated, resulting in  $k_{relax} \gg k_f$ . The reduction in exciton binding energy has led to reduction of the energy losses in OPVs that employ large, non-fullerene acceptor molecules such as SF-PDI<sub>2</sub>. The quantitative relationship between molecular size and  $E_B$  is treated in greater detail Chapter 7. Details of the morphology of the donor–acceptor blend may also lead to rapid CT dissociation, even for small  $E_B$ . Morphology is yet another factor controlled by molecular size and shape. Finally, disorder within the domains of the blends may also reduce the CT binding energies.

#### 4.7.2.3 Current–voltage characteristics in the presence of traps

The DOS centered at the HOMO and LUMO energies is broadened by ground state interactions between the donor and acceptor molecules at the heterointerfaces (Sreearunothai et al., 2006, Groves et al., 2010). Here, we extend our calculation of the  $j$ - $V$  characteristics to include an exponential distribution of traps or other sources of disorder at the heterointerface. Their presence changes the kinetics of recombination, and introduces a temperature dependent ideality factor  $n > 1$  into the diode equation.

Assuming trapped ( $n_T$ ) and free ( $n$ ) electron densities in the acceptor along with the trap distribution of Eq. 4.140, and using similar relationships for the trapped hole density,  $p_T$ , in the donor, then Eq. 4.299 becomes

$$j = qa_0 \left( \frac{k_{PPr}}{k_{PPd} + k_{PPr}} \right) \times \left\{ \begin{array}{l} k_{rec,n} \left( n_{HJ} p_{HJT} - \frac{k_{PPd}}{k_{PPd0}} n_{HJ0} p_{HJT0} \right) \\ + k_{rec,p} \left( p_{HJ} n_{HJT} - \frac{k_{PPd}}{k_{PPd0}} p_{HJ0} n_{HJT0} \right) \end{array} \right\} - qj_X \left( \frac{k_{PPd}}{k_{PPd} + k_{PPr}} \right). \quad (4.310)$$

Hence,  $k_{rec,n}$  and  $k_{rec,p}$  are the rate constants due to recombination at the HJ between a free electron in the acceptor ( $n_{HJ}$ ) with a trapped hole in the donor ( $p_{HJT}$ ), and vice versa. Referring to our treatment of trap-free diodes, then,

$$j = qa_0(1 - \eta_{PPd}) \times \left[ k_{rec,n} N_{LUMO} H_{TD} \exp(-\alpha_D/k_B T) \left( \exp(qV/k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right) + k_{rec,p} N_{HOMO} H_{TA} \exp(-\alpha_A/k_B T) \left( \exp(qV/k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right) \right] - j_{ph}, \quad (4.311)$$

where

$$\alpha_D = \frac{\Delta E_{HL}}{n_D} + \frac{m_D - 1}{m_D} (\delta_D \phi_C - \delta_A \phi_A) \quad (4.312a)$$

and

$$\alpha_A = \frac{\Delta E_{HL}}{n_A} - \frac{m_A - 1}{m_A} (\delta_D \phi_C - \delta_A \phi_A). \quad (4.312b)$$

Here,  $m_D = T_{OD}/T$  and  $m_A = T_{OA}/T$  are the trap distribution exponents similar to Eq. 4.143 with the characteristic temperatures,  $T_{OD}$  and  $T_{OA}$ , on the donor and acceptor sides of the HJ, respectively. Also,  $H_{TD}$  and  $H_{TA}$  are the total trap densities on the donor and acceptor sides of the junction, and the respective ideality factors,  $n_D$  and  $n_A$  are given by

$$n_D = \frac{m_D}{\delta_A(m_D - 1) + 1} \quad (4.313a)$$

and

$$n_A = \frac{m_A}{\delta_D(m_A - 1) + 1}. \quad (4.313b)$$

Note that, in a striking difference with conventional Shockley theory, the ideality factors now have an implicit temperature dependence since  $m \sim 1/T$ .

More compactly, Eq. 4.311 becomes the ideal diode equation in the presence of traps (Giebink et al., 2010b):

$$j = j_{0D} \left( \exp(qV/n_D k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right) + j_{0A} \left( \exp(qV/n_A k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right) - j_{ph}, \quad (4.314)$$

which simplifies to

$$j = j_{0D} (\exp(qV/n_D k_B T) - 1) + j_{0A} (\exp(qV/n_A k_B T) - 1) - j_{ph} \quad (4.315)$$

when  $k_{PPd} \leq k_{PPd,eq}$  under forward bias. Here  $J_{0D}$  and  $J_{0A}$  are the dark saturation currents given by the pre-factors in Eq. 4.311, and  $j_{ph}$  is the photocurrent defined in Eq. 4.304.

Thus, in general, the sources of dark current stem from the recombination of free electrons with trapped holes, and vice versa. Each pathway produces its own temperature-dependent ideality factor ( $n_D$  and  $n_A$ , respectively) and dark saturation current, both of which depend on the balance of the voltage drop across the two contacting layers, as well as their characteristic trap temperatures.

It is instructive to consider the important case of a perfectly symmetric device, that is, one with identical transport properties and injection barriers for electrons and holes. Then Eq. 4.311 simplifies to

$$j = 2qa_0(1 - \eta_{PPd}) k_{rec} N_S H_{TS} \exp(-\Delta E_{HL}/n_S k_B T) \times \left( \exp(qV/n_S k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right) - q\eta_{PPd} j_X \quad (4.316a)$$

or, in our usual form,

$$j = j_{0S} \left( \exp(qV/n_S k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right) - q\eta_{PPd} j_X, \quad (4.316b)$$

where the saturation current  $j_{0S}$  is obtained via comparison with Eq. 4.316a, and we have allowed  $N_S = N_{LUMO} = N_{HOMO}$ , and  $H_{TS} = H_{TD} = H_{TA}$ . The symmetric HJ ideality factor is

$$n_S = \frac{2m_S}{m_S + 1}, \quad (4.317)$$

where  $m_S$  has the same definition that relates it to the characteristic trap temperature, viz.  $m_S = T_{TS}/T$  and  $T_{TS} = T_{TA} = T_{TD}$ . Comparing Eq. 4.317 to Eq. 4.313 implies that the voltage is now equally divided between the donor and acceptor sides of the junction. One approximation made is that the HOMO and LUMO densities of states are equal. Although this is reasonable, it would be more precise to allow  $N_S = \sqrt{N_{LUMO} N_{HOMO}}$ . Then, solving Eq. 4.316 for  $V_{OC}$  leads to

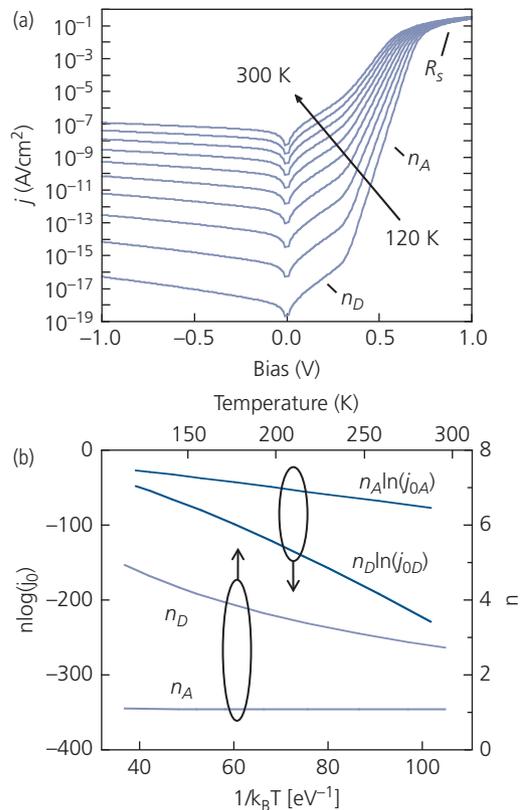

$$qV_{OC} = \Delta E_{HL} - n_S k_B T \ln \left[ \left( \frac{k_{PPr}}{k_{PPd}} \right) \frac{a_0 k_{rec} N_S^2}{j_X} \right]. \quad (4.318)$$

The maximum open circuit voltage,  $V_{OC}^{max}$ , still reduces to  $\Delta E_{HL} - E_B$ , since in the limit of high light intensity, the assumption of  $n_T, p_T, n, p$  used for trap limited transport no longer holds. In this regime all traps are filled and recombination is no longer trap-limited such that Eq. 4.318 reverts to Eq. 4.307b.

The symmetric diode can apply to a p-i-n excitonic homojunction if it too is symmetric, that is, the majority carrier concentrations of both the p- and n-regions are equal. Then the voltage is dropped equally across both sides of the junction. However, the barrier to charge recombination in the p-n junction is  $E_G/n_S$ , which must be substituted into the expression for saturation current. Furthermore, recombination occurs across the depleted i-region, introducing a quadratic voltage dependence to the saturation current as in Eq. 4.286.

A somewhat different expression for the homojunction current is derived in Section 4.7.1. The primary discrepancy arises since the model presented here is based on recombination across the depletion region, in contrast to tunneling across the junction. Recombination is ultimately a thermally activated process, although the Gaussian or exponential DOS results in a temperature dependent ideality factor that counters the thermal energy in such a way that the product,  $n_S(T)k_B T$  is approximately temperature independent, as observed in the devices in Figs. 4.93 and 4.95. Since both models assume a broad density of transport states (one whose alignment allows for tunneling, and the other that factors into the recombination statistics that are reflected in the ideality factor), it is not entirely surprising that both models predict approximately the same functional behavior in the  $j$ - $V$ - $T$  characteristics, although the various constants for  $j_0$  may differ due to the differing physical models employed.

Figure 4.113a shows the dark  $j$ - $V$  characteristics calculated using Eq. 4.314 over the temperature range from 120 K to 296 K for a device using the parameters typical of organic photovoltaic cells listed in Table 4.8. The series resistance is  $R_s = 1 \Omega \text{ cm}^2$  (in which case,  $V$  in the exponential argument is replaced by  $V - jR_s$ ) and it is assumed that most of the potential is dropped across the donor layer (i.e.  $\delta_A = 0.1$ ,  $\delta_D = 0.9$ ), resulting in different ideality factors,  $n_A$  and  $n_D$ , plotted in Fig. 4.113b. Both ideality factors increase with decreasing temperature due to the corresponding increases in  $m_A$  and  $m_D$ . Also,  $n \ln(j_0)$  is nonlinear when plotted vs.  $1/k_B T$ . This contrasts with previous analyses based on the Shockley equation (Rand et al., 2007, Perez et al., 2009), which predicts

**Figure 4.113** Simulated (a) dark  $j$ - $V$  characteristics and (b) ideality factors ( $n_A, n_D$ ) and  $n \ln(j_0)$  (where  $j_0$  is the saturation current density normalized to  $1 \text{ A/cm}^2$ ) vs. temperature for an excitonic Type II HJ with an exponential trap distribution in both the donor and acceptor layers. Parameters used in the simulations are given in Table 4.8 (Giebink et al., 2010b).

a linear relationship for  $n \ln(j_0)$  with a slope of  $-\Delta E_{HL}/2$ .

In the generalized Shockley equation, increasing dark current with reverse bias is phenomenologically accounted for by recombination and generation in the depletion region, whereas in Fig. 4.113 it is due to the field dependent dissociation of thermally generated PPs. The two slopes often observed in semi-log plots under forward bias (Rand et al., 2007, Potsavage et al., 2008, Li et al., 2009) result from the two ideality factors that reflect recombination with trapped carriers at each side of the HJ.

The asymmetry in voltage dropped across the donor and acceptor layers is due to the sheet of trapped interface charge, which is the primary cause of the difference in ideality factors. At low

**Table 4.8** Parameters used in calculating  $j$ - $V$  characteristics in Fig. 4.113

Parameter	Value
donor, acceptor thicknesses	40 nm
$\Delta E_{HL}$	1.2 eV
$V_{bi}$	0.5 V
$T_{0A} = T_{0D}$	1000 K
$H_{TA} = H_{TD}$	$10^{18} \text{ cm}^{-3}$
$N_{HOMO} = N_{LUMO}$	$10^{21} \text{ cm}^{-3}$
$\delta_A$	0.1
$a_0$	1.5 nm
$k_{PPR}$	$1 \mu\text{s}^{-1}$

$R_s$	$1 \Omega \text{ cm}^2$

bias, the current is predominantly mediated by PPs formed from the recombination of free holes in the donor with trapped electrons in the acceptor, such that the current is limited by  $n_D$ . At higher bias ( $0.4 < V_a < 0.7$ ), the reverse process dominates, and the slope is determined by  $n_A$ . As temperature decreases, carriers freeze into the trap states in the tail of the DOS, and recombination becomes further trap-limited, leading to the increase of both ideality factors at low temperature. In forward bias  $V > 0.7$  V, series resistance from contacts and the layer bulk limits the current.

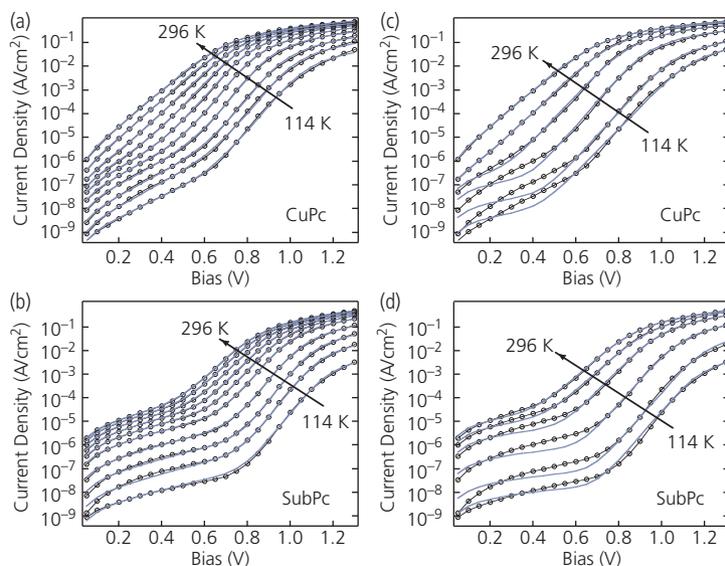

The excitonic diode theory has been applied to 20 nm CuPc/40 nm C<sub>60</sub> and 11 nm SubPc/40 nm C<sub>60</sub> HJs sandwiched between a 10 nm thick BCP buffer layer beneath an Al cathode, and an ITO anode. The  $j$ - $V$ - $T$  characteristics and fits to Eq. 4.314 are shown in Fig. 4.114a and b. The fits are considerably improved compared to those obtained from the Shockley equation in Fig. 4.114c and d, particularly at low temperature. Series resistance (Table 4.8) accounts for the roll-off in  $j$  at high forward bias. The inflection in the slopes at  $V \sim 0.5$ – $0.7$  V results from the different values of ideality factors,  $n_A$  and  $n_D$ .

The ideality factors follow the trends predicted in Fig. 4.113b, providing additional validation to the excitonic diode theory (Giebink et al., 2010b). Since the acceptor layers are identical in both the CuPc and SubPc devices,  $n_A$  is also identical for both junctions, and varies from 4 at low temperature, to 2 at  $T = 300$  K. In contrast, the  $n_D$  for CuPc- and SubPc-based junctions are larger than  $n_A$ , and have a more pronounced temperature dependence. Since  $\delta_D$  and  $\delta_A$

do not cancel as in the trap-free case, changes in the potential distribution across the  $D$  and  $A$  layers with bias and/or temperature influences the values of the ideality factors. For example, an increase in the potential dropped across the acceptor with decreasing temperature leads to a correspondingly greater increase in  $n_A$  over the same interval. This leads to ambiguities in uniquely determining  $\delta$  and  $n_{A,D}$  from fits to the exponential trap distribution model. Thus, an important feature of the model is the existence of two ideality factors that increase super-linearly with decreasing temperature.

We have seen that the trap-free and trap-limited excitonic diode equations are similar in form to the Shockley equation, but the interpretation of the fitting parameters (ideality factors, saturation current densities) is considerably different, reflecting the different excited states and transport dynamics in organic versus inorganic semiconductors. In inorganic semiconductors, excitation directly results in unbound, free carriers, whereas in organic semiconductors, tightly bound excitons are generated. The exciton has a low probability of dissociating unless charge transfer occurs at a DA HJ to separate the electron and hole to a more loosely bound polaron pair. Thus, in contrast to inorganic p-n junctions where current is due to drift diffusion and/or recombination within the depletion region, the current in organic HJs depends on polaron pair recombination and dissociation that occur within a small volume (only a few monolayers at most) at the HJ interface. In the absence of shunt paths or other junction defects, generation and recombination via interfacial polaron pairs is the sole source of dark current. This assumption is reasonable at low bias since PPs (or their eponymously named CT state) provide the lowest energy recombination pathway in DA HJs with Type II (i.e. staggered) HJ energy level offsets. They are, therefore, the most heavily populated state at small quasi-Fermi level separations at low voltage or illumination intensities. Disorder or other defects complicate the trap-free picture, as the recombination kinetics depend on the particular trap distribution chosen. Regardless of the choice, however, the double exponential form of the  $j$ - $V$  relationship given by Eq. 4.314 is a general result, as it stems from the two possible recombination pathways of free electrons with trapped holes at the HJ, and vice versa.

The fundamental treatment of current in this section provides a basis for analyzing the often complex  $j$ - $V$  characteristics of excitonic junctions both as a function of time (Giebink et al., 2010a) and in steady

**Figure 4.114** Measured (data points) and simulated (lines) forward biased dark  $j$ - $V$ - $T$  characteristics under forward bias for (a) CuPc/C<sub>60</sub> and (b) SubPc/C<sub>60</sub> excitonic HJs. The intermediate temperature data were obtained at 128, 145, 155, 171, 193, 218, 247, and 275 K. Simulations to the excitonic diode equation include an exponential trap distribution employing parameters in Table 4.8. (c) and (d) plot the same data using the conventional Shockley equation generalized to include series resistance (Giebink et al., 2010b).

state, as described by Eqs. 4.297 and 4.298. More importantly, this analysis provides predictions for charge generation when used in solar cells and photodetectors. These predictions have been directly tested and confirmed, leading to improved device performance, as discussed further in Chapter 7.

### 4.7.3 Organic–inorganic heterojunctions

Intermediate between pure excitonic and inorganic HJs is the combination of these two materials, forming a hybrid organic/inorganic heterojunction (OI-HJ) at their point of contact. The first OI-HJs consisted of a polyacetylene,  $p$ -(CH) <sub>$x$</sub> , on CdS (Ozaki et al., 1980), and a PTCDA layer deposited onto a Si surface (Forrest et al., 1982). The OI-HJs exhibited remarkable rectifying properties that, prior their discovery, had not been observed in any organic-based device. Since then, many promising technologies have employed OI-HJs as their charge-separating interface, including OI photodiodes (So and Forrest, 1989) and solar cells (Li et al., 2011, Brus et al., 2013), dye-sensitized solar cells (Vlachopoulos et al., 1988, Hagfeldt et al., 2010), and colloidal quantum dot solar cells and light-emitting devices (Coe-Sullivan et al., 2003, Sargent, 2012, Wright and Uddin, 2012).

While there have been many examples of devices that exploit OI-HJs, a comprehensive understanding

of their influence on charge generation, recombination and extraction has only recently been developed. Like excitonic HJs, early models have relied on the properties of inorganic HJs to describe their  $j$ - $V$  characteristics (Forrest et al., 1984a, 1984b). While those models provide a reasonable phenomenological description of the observed characteristics, they fail to provide an accurate physical framework of the dynamics of hybrid state formation and dissociation at the OI-HJ.

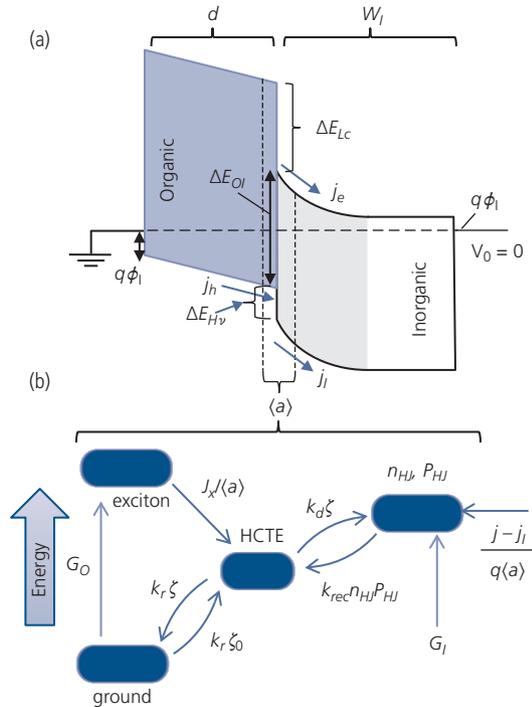

More recently, a comprehensive model based on the injection and generation of charge in the inorganic semiconductor and Frenkel excitons in the organic layer that migrate to the interface to form a *hybrid charge transfer exciton* (HCTE) has been introduced (Panda et al., 2014, Renshaw and Forrest, 2014). The HCTE is analogous to a polaron pair state at an excitonic junction, in that the PP and the HCTE are both Coulombically bound charge pairs across a heterointerface. Unlike the polaron pair where both charge species are localized due to disorder, in the HCTE the charge in the inorganic is spread over several lattice sites, while the polaron is localized on one or only a few molecules.

In this section, we derive the  $j$ - $V$  characteristics of OI-HJs both in the presence and absence of interface traps. The model is developed for the specific example of an n-P anisotype Type II staggered OI-HJ, but

is easily generalized to both isotype and Type I junctions (Renshaw and Forrest, 2014). We use the convention where the lower case “n” refers to the majority carrier type of the inorganic semiconductor, while the upper case “P” refers to the organic layer whose Fermi energy is below the center of the energy gap, and hence is closer to the HOMO.

#### 4.7.3.1 Conduction in organic–inorganic heterojunctions

In Fig. 4.115a depicts an ideal n–P OI-HJ in the absence of interface defects or traps, analogous to that for excitonic junctions in Fig. 4.103. Figure 4.115b shows the interface state energy diagram for the processes leading to charge generation. Unlike excitonic junctions, there is substantial band bending on the inorganic side of the HJ. Photocurrent generation can occur via three mechanisms: (i) direct band-to-band absorption of a photon in the doped inorganic semiconductor that results in minority carrier diffusion to the OI-HJ (Forrest et al., 1984a, So and Forrest, 1989, Li et al., 2011); (ii) photon absorption in the organic

**Figure 4.115** (a) Equilibrium energy diagram of an anisotype, Type II n–P OI-HJ. Band bending on the inorganic side of the HJ gives a depletion region width  $W_I$ . A uniform field develops across a depleted organic layer of thickness,  $d$ . (b) Processes leading to dark and photocurrent generation. The rates ( $k$ ), contact potentials ( $\phi_0, \phi_1$ ) and polaron,  $\zeta$ , and charge ( $n_{HI}, P_{HI}$ ) concentrations are defined in text (Renshaw and Forrest, 2014).

leading to exciton generation and diffusion to the junction, with an exciton current of  $j_X$  (Panda et al., 2014); or (iii) direct absorption by the HCTE at the OI-HJ (Haeldermans et al., 2008, Vaynzof et al., 2012, Panda et al., 2016).

Bound HCTE states have been experimentally detected at ZnO/organic (Vaynzof et al., 2012, Panda et al., 2016) and CdTe/polymer (Bansal et al., 2013) interfaces. However, the high dielectric constant and delocalized nature of carriers in the inorganic semiconductor leads to an HCTE binding energy ( $E_B$ ) much smaller than for polaron pairs at excitonic HJs. In some cases  $E_B/k_B T \leq 1$  at room temperature, such that the interface exciton may be unstable, or at best metastable (i.e. characterized by a very short lifetime  $\sim$  picoseconds) at room temperature.

To estimate  $E_B$ , the HCTE can be thought of as a hybrid between a Frenkel and Wannier–Mott exciton bound at the HJ, as illustrated in Fig. 4.116a. The hole is localized to within  $\sim 1$  nm of the interface; while the electron tunnels into the inorganic forming a delocalized negative charge density extending 5–10 nm over many lattice constants. The charge comprising the exciton rapidly dissociates into an electron on the inorganic semiconductor conduction band that is bound to the hole polaron localized at the OI-HJ, thereby forming the HCTE. The hybrid quasi-particle is then dissociated by either thermal excitation or by the built-in junction field that forces the electron to drift toward the bulk, freeing the hole polaron from the interface. The dynamical properties of the HCTE are also dependent on whether the transfer is between energetically resonant or non-resonant states at the two sides of the interface (Agranovich et al., 2011).

The electron spatial distribution of an untrapped, or free HCTE at the CBP/ZnO interface has been calculated by solving Schrödinger’s equation with the following Hamiltonian (Panda et al., 2016):

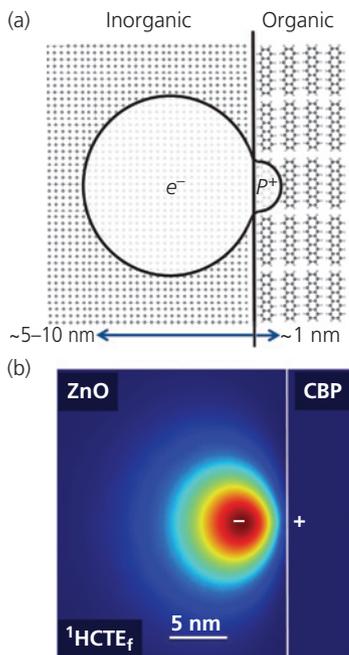

$$H = -\frac{\hbar^2}{2m_r^*(z)} \nabla^2 - \sum_{i=1}^k \frac{\alpha(z)q^2/k}{4\pi\langle\epsilon_r\rangle\epsilon_0|\mathbf{r}_e - \mathbf{r}_i|} - \frac{\beta(z)q^2}{16\pi\langle\epsilon_r\rangle\epsilon_0 z} + \Delta E_{OI} \quad (4.319)$$

The first term is the kinetic energy of the electron, the second is the Coulomb energy due to the hole screened by the dielectric polarization of CBP, and the third is the image potential energy from the induced charge at the interface. Here,  $z$  is the direction perpendicular to the interface, and the reduced effective mass is  $m_r^* = (1/m_I + 1/m_O)^{-1}$ . Also,  $m_I$  ( $m_O$ ) is the effective mass of the inorganic (organic) layer,  $\langle\epsilon_r\rangle$  is the effective dielectric permittivity given by

$\langle \epsilon_r \rangle = (a_I \epsilon_I + a_O \epsilon_O) / (a_I + a_O)$ , where  $\epsilon_I$  ( $\epsilon_O$ ) is the dielectric constant of the inorganic (organic) layer,  $\mathbf{r}_e$  is the position of the electron, and  $\Delta E_{OI}$  is the difference between the ZnO CBM and the CBP LUMO energies. Also,  $a_I$  and  $a_O$  are the extents of the exciton on the inorganic and organic sides of the HJ, respectively. For simplicity, the hole distribution on the HOMO of CBP is replaced with a summation over  $k$  discrete, fractional point charges at position,  $\mathbf{r}_i$ . For this calculation, it is adequate to let  $k = 2$ , accounting for two half-charges located at the symmetry points on the two halves of the CBP molecule. The screening factor for the hole is  $\alpha(z) = 2\epsilon_I / (\epsilon_I + \epsilon_O)$  in ZnO, and  $\alpha(z) = 1$  in CBP, and  $\beta(z)$  is the image charge factor with  $\beta(z) = \pm(\epsilon_I - \epsilon_O) / (\epsilon_I + \epsilon_O)$  where the plus sign is for CBP, and the minus for ZnO. Results of this calculation are shown in Fig. 4.116b, illustrating the highly asymmetric charge distribution across the heterointerface.

The Bohr model is used to estimate the radius of the HCTE as (Agranovich et al., 1998)

$$\langle a \rangle = a_I + a_O = \frac{8\pi(\epsilon_r)\hbar^2}{m_r^*q^2}, \quad (4.320)$$

**Figure 4.116** (a) Conceptualization of a hybrid charge transfer exciton illustrating its loosely bound, Wannier–Mott character on the inorganic side, and more tightly bound, Frenkel-like nature on the organic side of the HJ (Renshaw and Forrest, 2014). (b) Calculated electron density of the singlet, free  ${}^1\text{HCTE}_f$  observed at CBP/ZnO OI HJs. The “+” and “-” indicate the approximate centers of the hole polaron and electron densities. The red color indicates higher electron density (Panda et al., 2016).

Adapted with permission from Panda, A., Ding, K. & Forrest, S. R. 2016. Free and trapped charge transfer excitons at a ZnO/small molecule heterojunction. Phys. Rev. B, 94, 125429. Copyright 2016 by the American Physical Society.

This radius approximately defines the “interaction volume” over which recombination or dissociation of the HCTE occurs. It follows that the HCTE binding energy is:

$$E_B = \frac{q^2}{8\pi\epsilon_0\langle\epsilon_r\rangle\langle a \rangle}. \quad (4.321)$$

Figure 4.117 shows the exciton binding energy and characteristic exciton radius as functions of the effective dielectric constant for electron effective masses of  $m_r^* = 1m_0, 0.2m_0$ , and  $0.05m_0$ , which are consistent with the electron masses for many inorganics (Sze, 1981).

#### 4.7.3.2 Current–voltage characteristics of an ideal OI-HJ

From the preceding discussion, we conclude that at room temperature, the HCTE is a generally unstable precursor to dissociation via the generation of free charges at the OI-HJ (with densities  $n_{\text{HJ}}$ ,  $P_{\text{HJ}}$  in the inorganic and organic layers, respectively). The free carriers are captured at a rate of  $k_{\text{rec}}n_{\text{HJ}}P_{\text{HJ}}$  to form HCTEs with a density of  $\zeta$  and with a characteristic separation between the electron and polaron,  $\langle a \rangle$ , across the interface.

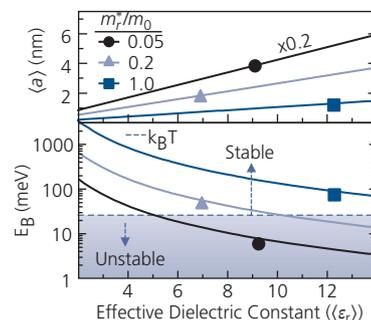

Using similar notation and approaches as in Section 4.7.2, the corresponding rate equations for  $\zeta$ ,  $n_{\text{HJ}}$ , and  $P_{\text{HJ}}$  as functions of time,  $t$ , are given by:

$$\frac{d\zeta}{dt} = -k_r(\zeta - \zeta_0) - k_d\zeta + k_{\text{rec}}n_{\text{HJ}}P_{\text{HJ}} + \frac{j_X}{\langle a \rangle} = 0, \quad (4.322)$$

$$\frac{dn_{\text{HJ}}}{dt} = -k_{\text{rec}}n_{\text{HJ}}P_{\text{HJ}} + k_d\zeta + \frac{j_e}{q\langle a \rangle} = 0, \quad (4.323)$$

$$\frac{dP_{\text{HJ}}}{dt} = -k_{\text{rec}}n_{\text{HJ}}P_{\text{HJ}} + k_d\zeta + \frac{j_h - j_l}{q\langle a \rangle} = 0, \quad (4.324)$$

where the final equality holds for steady-state conditions. Here,  $k_r$  and  $k_d$  are the rates that HCTEs

**Figure 4.117** Radius,  $\langle a \rangle$  and binding energy,  $E_B$  of the HCTE as functions of the spatially averaged dielectric constant,  $\langle \epsilon_r \rangle$ . Zones of stability at room temperature are indicated for several different reduced effective masses,  $m_r^*$ . Adapted from Renshaw and Forrest (2014).

recombine to the ground state and dissociate into free carriers, respectively. The thermal generation rate of an HCTE is  $k_r \zeta_0$ , where  $\zeta_0$  is its equilibrium density given by  $\zeta_0 = k_{rec} n_{HJ,0} P_{HJ,0} / k_d$ .

Minority carriers photogenerated in the inorganic must be extracted through the organic layer and populate  $P_{HJ}$  at a rate determined by the photocurrent density sourced from the inorganic layer,  $j_i$ . Also,  $j_e$  and  $j_h$  are the electron current in the inorganic and the hole current in the organic, respectively. It is assumed that the hole density and mobility are greater than the electron density and mobility in the organic, and hence  $j_h = j$ . Continuity demands that  $\nabla \cdot j = 0$  everywhere in steady-state. At the interface, this implies that  $j_e + j_i = j_h = j$ . Hence, Eqs. 4.323 and 4.324 are identical, resulting in lossless coupling between  $n_{HJ}$  and  $P_{HJ}$ .

In steady-state, the rate equations near equilibrium are solved to eliminate  $\zeta$ , yielding

$$j = q \langle a \rangle k_{rec} (1 - \eta_d) \left( n_{HJ} P_{HJ} - \frac{k_d}{k_{d,eq}} n_{HJ,0} P_{HJ,0} \right) - j_{ph}, \quad (4.325)$$

where  $j_{ph} = q j_X \eta_d - j_i$  is the total photocurrent, which is the sum of the exciton current generated in the organic and the direct carrier generation current in the inorganic. Also,  $j_i < 0$  and  $j_X > 0$ , resulting in  $j_{ph} > 0$ , by convention. Here,  $\eta_d = k_d / (k_d + k_r)$  is the HCTE dissociation efficiency. Equilibrium corresponds to  $V = 0$  in the absence of illumination.

Recall for excitonic junctions we used Onsager–Braun theory (Braun, 1984) to determine  $k_{ppd}$  (see Section 4.7.2, Eq. 4.305), where

$$k_d = A_{OB} k_{rec} \exp\left(-\frac{E_B}{k_B T}\right) \frac{J_1[2\sqrt{-2b}]}{\sqrt{-2b}}. \quad (4.326)$$

This model can also be adapted to describe the field dependence of the HCTE. The prefactor,  $A_{OB}^{-1}$ , is the volume of an ion pair of radius,  $\langle a \rangle$ , that is,  $A_{OB} = 3/4\pi \langle a \rangle^3$ . In the case where the HCTE is expected to have a partial Wannier–Mott character, we use  $A_{OB} = (m^* k_B T / 3\pi \hbar^2)^{3/2}$  where  $m^*$  is the effective mass of the electron in the inorganic semiconductor.

The bimolecular recombination rate for low mobility solids is diffusion-limited, and therefore follows Langevin recombination statistics where  $k_{rec} = q \langle \mu \rangle / \langle \epsilon_r \rangle$ , with an effective mobility of  $\langle \mu \rangle = \mu_I + \mu_0$  (cf. Section 4.5.4). In the case of a highly mobile electron in the inorganic semiconductor,  $k_{rec} = v_{th} \sigma_X$ , where  $v_{th} = \sqrt{3k_B T / m^*}$  is the thermal velocity of the electron and  $\sigma_X = \pi r_c^2$  is its trap capture cross-section. Electric

field screening in the high-dielectric constant inorganic semiconductor allows for neglect of the effects of the electrostatic potential on the capture rate.

If  $j$  is sufficiently small so that the electron and hole quasi-Fermi levels ( $E_{Fn}$  and  $E_{Fp}$ ) are flat throughout the respective inorganic and organic layers, then the interface carrier densities are given by

$$n_{HJ} = N_c \exp\left(-\frac{q\phi_I}{k_B T}\right) \exp\left(\frac{qV_I}{k_B T}\right) = n_c \exp\left(\frac{qV_I}{k_B T}\right) \quad (4.327)$$

and

$$P_{HJ} = N_{HOMO} \exp\left(-\frac{q\phi_0}{k_B T}\right) \exp\left(\frac{qV_O}{k_B T}\right) = P_c \exp\left(\frac{qV_O}{k_B T}\right). \quad (4.328)$$

Here,  $N_c$  is the effective DOS at the CBM of the inorganic,  $q\phi_0$  and  $q\phi_I$  are the injection barriers into the organic (from the anode) and inorganic (from the cathode) shown in Fig. 4.115a, and  $V_O$  and  $V_I$  are the applied voltages across the organic and inorganic layers, respectively. In the case of a thick inorganic layer where the depletion width does not extend to the contacts, then  $q\phi_I = E_c - E_{Fn}$  in the undepleted equilibrium region, where  $E_c$  is the energy of the CBM. Now,  $n_c$  is the electron density at equilibrium as determined by the ionized dopant density ( $N_D$ ). Also,  $P_c$  is the hole density in the organic at the anode contact.

Using these definitions and following procedures analogous to those of Giebink et al. (2010b), we obtain the ideal OI-HJ diode equation by combining Eqs. 4.325, 4.327, and 4.328:

$$j = q \langle a \rangle k_{rec} N_{HOMO} N_c (1 - \eta_d) \exp\left(-\frac{\Delta E_{OI}}{k_B T}\right) \times \left( \exp\left(\frac{qV}{k_B T}\right) - \frac{k_d}{k_{d,eq}} \right) - j_{ph}. \quad (4.329)$$

Here  $\Delta E_{OI} = qV_{bi} + q\phi_0 + q\phi_I$  as defined in Fig. 4.115a, and  $V_{bi}$  is the built-in voltage determined by the inorganic Fermi level and the anode work function (modified by energy level shifts, such as those due to interface dipoles). The applied voltage is related to the voltage dropped across each layer using:  $V = V_O + V_I + V_{bi}$ .

### 4.7.3.3 Current–voltage characteristics of an OI-HJ in the presence of interface traps

As previously, we consider an organic film with an exponential distribution of trapped interface charge

with a total trap density,  $H_O$ , a characteristic trap temperature,  $T_O$ , and a trap parameter:  $m_O = T_O/T$ . For convenience, a similar trap profile near the *inorganic* CBM is defined by the parameters  $H_I$ ,  $T_I$ , and  $m_I$ . While an exponential might serve as a suitable distribution function for disordered inorganic semiconductors, crystalline inorganics are typically characterized by a discrete trap level where the density of trapped charges is  $n_T = H_I \exp(-(E_c - E_{Fn} - E_T)/k_B T)$  at trap energy,  $E_T$ .

Assuming transport is dominated by free rather than trapped carriers on either side of the junction, we arrive at

$$j = q \langle a \rangle (1 - \eta_d) \times \left[ k_{rec,n} N_c H_O \exp\left(-\frac{a_O}{k_B T}\right) \left( \exp\left(\frac{qV}{n_O k_B T}\right) - \frac{k_d}{k_{d0}} \right) + k_{rec,p} N_{HOMO} H_I \exp\left(-\frac{a_I}{k_B T}\right) \left( \exp\left(\frac{qV}{n_I k_B T}\right) - \frac{k_d}{k_{d0}} \right) \right] - j_{ph}. \quad (4.330)$$

Analogous to Eqs. 4.312 and 4.313, we have

$$a_O = \frac{\Delta E_{OI}}{n_O} + \frac{m_O - 1}{m_O} q(\delta_O \phi_I - \delta_I \phi_O), \quad (4.331a)$$

$$a_I = \frac{\Delta E_{OI}}{n_I} + \frac{m_I - 1}{m_I} q(\delta_I \phi_O - \delta_O \phi_I), \quad (4.331b)$$

and

$$n_O = \frac{m_O}{\delta_I(m_O - 1) + 1}, \quad (4.332a)$$

$$n_I = \frac{m_I}{\delta_O(m_I - 1) + 1}. \quad (4.332b)$$

The latter two expressions are the ideality factors,  $n_O$  and  $n_I$  that arise from recombination at traps on the organic and inorganic sides of the HJ, respectively. These factors provide the ratio of the voltage dropped across the corresponding layers of the device. Also,  $k_{rec,n}$  and  $k_{rec,p}$  are the recombination rates for a free electron with a trapped hole, and a free hole with a trapped electron, respectively. Finally,  $\delta_O = V_O/(V - V_{bi})$  and  $\delta_I = V_I/(V - V_{bi})$  are the fractions of the applied voltage dropped across the respective organic and inorganic layers. Contrary to the trap-free case, the voltage distribution across the layers affects the current even in the near-equilibrium approximation used here. This is due to the asymmetry of the electronic properties of the organic and inorganic layers. For discrete traps in the inorganic semiconductor, Eqs. 4.331b must be modified such that  $a_I = E_T$ .

Following the conventions and simplifications in Section 4.7.2 for the trap-free case, we obtain:

$$j = q \langle a \rangle k_{rec} N_{HOMO} N_c \exp\left(-\frac{\Delta E_{OI}}{k_B T}\right) \left( \exp\left(\frac{qV}{k_B T}\right) - 1 \right) - j_{ph}, \quad (4.333)$$

and for an exponential trap distribution,

$$j = q \langle a \rangle \left[ k_{rec,n} N_c H_O \exp\left(-\frac{a_O}{k_B T}\right) \left( \exp\left(\frac{qV}{n_O k_B T}\right) - 1 \right) + k_{rec,p} N_{HOMO} H_I \exp\left(-\frac{a_I}{k_B T}\right) \left( \exp\left(\frac{qV}{n_I k_B T}\right) - 1 \right) \right] - j_{ph}. \quad (4.334)$$

These expressions are nearly identical to Eqs. 4.329 and 4.330, although they are independent of HCTE dissociation dynamics by letting  $k_d/k_{d0} \rightarrow 1$ . Thus, they are the limiting case where HCTEs dissociate with an efficiency  $\eta_d \rightarrow 1$ . Note that  $k_{rec}(1 - \eta_d)$  reduces to  $A_{OB} k_r$  in the limit that  $k_d = k_{rec}/A_{OB} \gg k_r$ .

Now, defining the saturation current density:

$$j_0 = q \langle a \rangle k_{rec} N_{HOMO} N_c \exp(-\Delta E_{OI}/k_B T) \quad (4.335)$$

then Eq. 4.333 simplifies to the familiar form of the ideal diode equation, Eq. 4.236. In a similar fashion, an interface with traps yields the current (cf. Eq. 4.314):

$$j = \left[ j_{SO} \left( \exp\left(\frac{qV}{n_O k_B T}\right) - 1 \right) + j_{SI} \left( \exp\left(\frac{qV}{n_I k_B T}\right) - 1 \right) \right] - j_{ph}, \quad (4.336)$$

making the appropriate substitutions for the saturation currents for the organic,  $j_{SO}$ , and inorganic,  $j_{SI}$ , semiconductors.

The treatment of the ideal diode relationships leading to Eqs. 4.333 and 4.334 assumes that the diode is operating near equilibrium. However, as the current density increases, the asymmetric voltage distribution across the organic and inorganic layers can change dramatically, particularly when there is a high density of interface traps. For example, at high forward voltages, the OI-HJ current is limited by space charge effects in the organic. In this case, the high current regime is reached at the voltage where the space charge current is equal to that of Eq. 4.333. Thus, in the high current regime, the voltage distribution ratio,  $\delta_O/\delta_I$ , must be calculated using a self-consistent solution to the drift-diffusion Eq. 4.237:

$$j = q \mu_{pO} P F - q D_p \nabla P, \quad (4.337)$$

with

$$\nabla \cdot F = \frac{q(P - P_O)}{\epsilon_O}. \quad (4.338)$$

Here,  $\mu_{pO}$  is the hole mobility in the organic,  $P_O$  is the background free hole polaron concentration, and  $D_p$  is the hole diffusivity. This system of equations does not offer an analytical solution, and must be solved numerically. The interested reader should refer to the literature for a more comprehensive treatment (Renshaw and Forrest, 2014).

Equation 4.335 indicates that  $\Delta E_{OI}$  determines the saturation current. There are several means for measuring interface energetics, although all methods are subject to the effects of traps and Fermi level pinning. As we showed in Section 4.6.1, the space charge region width for a uniformly doped semiconductor that is not fully depleted is given by  $W(V) =$

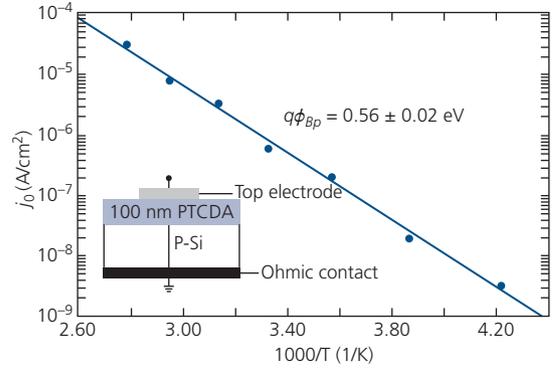

$\sqrt{\frac{2\epsilon_r\epsilon_0}{qN_D}(V_{bi} - V)}$ . Since the capacitance per area of this one-sided junction is  $C(V) = \frac{\epsilon_r\epsilon_0}{W(V)}$ , then,

$$\frac{1}{C^2(V)} = \frac{2}{qN_D\epsilon_r\epsilon_0}(V_{bi} - V). \quad (4.339)$$

Hence, a measurement of  $1/C^2$  vs.  $V$  has a slope determined by the free carrier concentration, and the intercept yields the built-in potential from which the junction energies (e.g.  $\Delta E_{OI}$ ) can be derived. This technique for barrier measurement can lead to errors in the presence of traps, spatial non-uniformities in  $N_D$  over the depletion region width, artifacts arising from fully depleted organic layers (in the case of Schottky diodes or excitonic HJs), and capacitance measurement frequency. At low frequencies the emission of trapped charge can follow the a.c. capacitance measurement voltage (Sharma et al., 2011). While  $C$ - $V$  measurements of barrier heights can lead to errors or difficult to interpret results, this is partially offset by their simplicity.

The interface barrier can also be determined from the activation energy of the  $j$ - $V$  characteristics, extrapolated to  $V = 0$ , which yields  $j_0(T)$ . Plotting the logarithm of the saturation current versus  $1/T$  gives a slope of  $\Delta E_{OI}/k_B$  for an anisotype n-P or p-N OI-HJ.

For an isotype HJ, the measured barrier is the HJ offset energy,  $\Delta E_{Hv}$ . This is the offset measured in p-P junctions between the organic HOMO and the inorganic VBM energy, and  $\Delta E_{Lc}$  is the offset measured at n-N HJs between the organic LUMO and the inorganic CBM energy (see Fig. 4.115). This method has been applied to measuring the offset energy of isotype

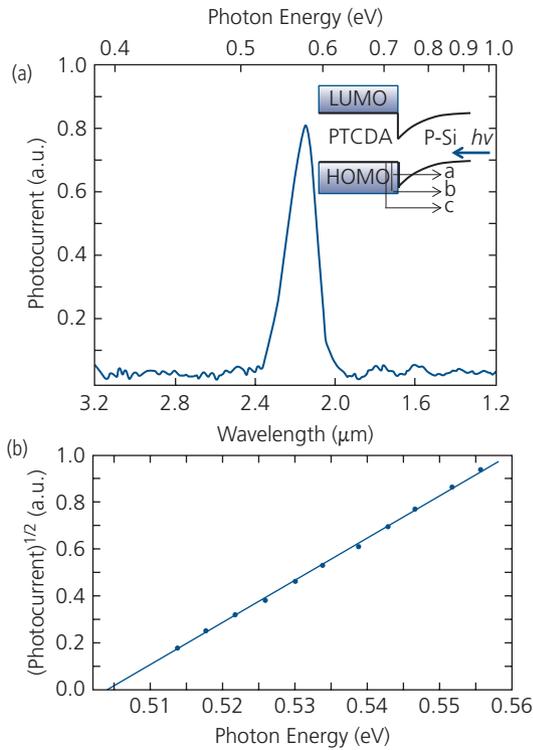

**Figure 4.118** Temperature dependence of the saturation current of a PTCDA/p-Si OI-HJ taken from an extrapolation to  $V = 0$  where  $j \rightarrow j_0$  in the forward-biased characteristics. The activation energy obtained from the slope of the line fit to the data is  $q\phi_{Bp} = 0.56 \pm 0.02$  eV. Inset: Schematic view of the test device. From So and Forrest (1988).

PTCDA/p-Si ( $p_0 = 3 \times 10^{16} \text{ cm}^{-3}$ ) junctions, as shown in Fig. 4.118 (So and Forrest, 1988). The slope of the saturation current data gives the barrier potential,  $q\phi_{Bp} = 0.56 \pm 0.02$  eV. The valence offset energy is found by adjusting for the equilibrium positions of the Fermi levels to the HOMO and VBM,  $E_{FP}$  and  $E_{FP}$ , respectively, such that  $\Delta E_{Hv} = q\phi_{Bp} + E_{FP} - E_{FP} = 0.48 \pm 0.02$  eV.

The energy offset was independently measured using internal photoemission, which was previously shown to be useful for measuring Schottky barrier energies in Section 4.6.2. Photocurrent spectra obtained by illumination of a PTCDA/p-Si OI-HJ with a broad spectral source through the thick Si substrate are shown in Fig. 4.119a. Absorption through the substrate filters out all wavelengths  $< 1.1 \mu\text{m}$ , ensuring only long wavelength light gives rise to the observed photocurrent. The photocurrent has a peak at 0.57 eV, falling off steeply at both lower and higher energies. The spectrum is explained using the inset diagram. At the low energy edge, the photocurrent decreases as the photon energy falls below that of the energy barrier,  $\Delta E_{Hv}$  (Fig. 4.119a, inset, process "a"). It reaches a peak once the photon energy is larger than the barrier (process "b"), and then decreases once more when the energy exceeds that of the relatively narrow width of the PTCDA HOMO (process "c").

As in Eq. 4.256, internal photoemission data should follow  $j_{ph} \propto (E_{ph} - E_{Hv})^2$  (Fowler, 1931, Haase et al., 1987). In Fig. 4.119b, the data on the long wavelength side of the photocurrent spectrum follows the expected quadratic dependence, thus yielding a valence energy offset of  $\Delta E_{Hv} = 0.50 \pm 0.01$  eV. This is

**Figure 4.119** (a) Photocurrent spectra of a PTCDA/p-Si OI-HJ at energies much less than the energy gap of PTCDA (2.2 eV) or Si (1.1 eV) due to emission over the discontinuity at the valence energy edge. Inset: Processes responsible for the photocurrent. The energy level alignment assumes that the PTCDA is adventitiously lightly p-type doped. (b) Plot of the  $j_{ph}^{-1/2}$  vs. photon energy. The intercept with the abscissa gives  $\Delta E_{Hv} = 0.50 \pm 0.01$  eV (So and Forrest, 1988).

consistent with the measurement obtained via the thermal activation of the saturation current in Fig. 4.118. As in transport measurements, it is important to rule out photoemission from unrelated sources such as defects within the organic layer. In this experiment, an In/PTCDA/ITO photoconductor was also illuminated, and no photocurrent was observed, thus ruling out this potential source. However, it remains uncertain from these data whether the energy measured is due to the intrinsic nature of the OI-HJ interface, or whether it is due to Fermi energy pinning at interface traps. In either case, the barrier measured is that which controls the transport, and hence can be used in the analysis of the  $j$ - $V$  characteristics of this OI-HJ.

The OI-HJ open circuit voltage is calculated by setting  $j = 0$  in the presence of a photocurrent. In the case of a stable HCTE (i.e.  $E_B > k_B T$ ), the derivation of the open circuit voltage is analogous to that of an excitonic junction in Section 4.7.2. That is, for the trap-free case of Eq. 4.333, we obtain

$$qV_{OC} = \Delta E_{OI} - k_B T \ln \left( \frac{k_r}{k_r + k_d} \frac{q(a) N_{HOMO} N_c k_{rec}}{j_{ph}} \right). \quad (4.340)$$

The treatment for an unstable exciton ( $E_B < k_B T$ ) is nearly identical, yielding

$$qV_{OC} = \Delta E_{OI} - n_0 k_B T \ln \left( \frac{k_r}{k_r + k_d} \frac{q(a) N_{HOMO} N_c k_{rec}}{j_{ph}} \right). \quad (4.341)$$

Hence,  $V_{OC}$  ultimately depends on the recombination rate,  $k_r$ , of the HCTE. The probability for recombination in OI-HJs, however, is significantly lower than in fully excitonic junctions. That is, in OI-HJs, the internal field at the interface rapidly separates charges following migration to the interface (i.e.  $k_d \gg k_r$ ). Thus, the maximum open circuit voltage as  $T \rightarrow 0$  is

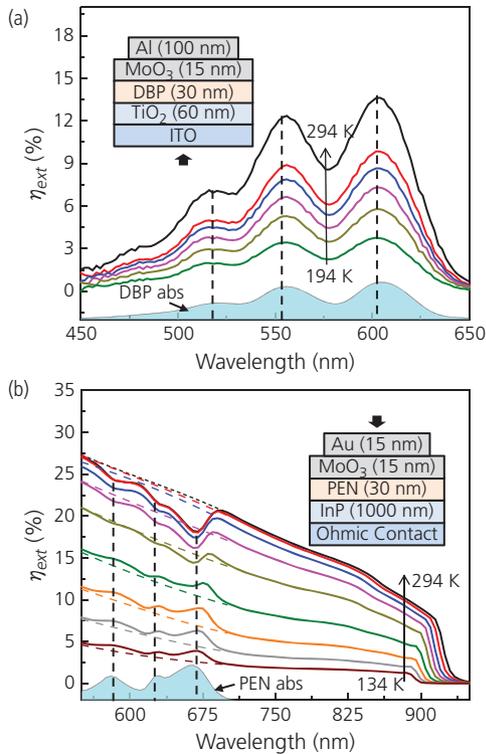

$$qV_{OC}^{max} \approx \Delta E_{OI} - nE_B, \quad (4.342)$$

independent of morphology or other factors that influence  $V_{OC}$  in excitonic junctions.

The foregoing analysis has been applied to several different OI-HJ systems with both free (Li et al., 2011, Panda et al., 2014) and trapped (Panda et al., 2016) HCTEs. Evidence for the generation of HCTEs at DBP/TiO<sub>2</sub> and pentacene/InP interfaces is provided by their external quantum efficiency spectra in Fig. 4.120. The devices employed in these experiments are shown in the insets.

The band gap of TiO<sub>2</sub> is 3.3 eV, which exceeds the energy gap of DBP (2.0 eV); hence the  $\eta_{ext}$  spectrum in Fig. 4.120a is due solely to absorption in DBP resulting in singlet excitons. The excitons subsequently migrate to the OI-HJ where they dissociate into an electron in TiO<sub>2</sub> and a hole in DBP via an intermediate HCTE. The liberated charges migrate to their respective electrodes and are collected.

The spectrum precisely replicates that of the DBP absorption spectrum, hence we conclude that the  $\eta_{ext}$  is initiated by singlet exciton formation in that layer. It can be argued that photoconductivity in the DBP can result in a photocurrent without requiring the generation of an HCTE. However,  $\eta_{ext}$  of an Au/DBP/ITO photoconductor was 100 times smaller than that achieved with the OI-HJ. We note that the  $\eta_{ext}$  increases with increasing temperature, with an exponential activation energy of  $\Delta E_a = 77 \pm 10$  meV. This is due to the thermally activated exciton transport via hopping of excitons to the heterointerface (Panda et al., 2014).

**Figure 4.120** (a) External quantum efficiency vs. wavelength and temperature (in 20 K intervals) for a DBP/TiO<sub>2</sub> OI-HJ diode shown in the inset. Also shown is the room temperature absorption spectrum of DBP (DBP abs). Absorption in the DBP is at lower energies than the band gap of TiO<sub>2</sub> (3.3 eV). (b) As in (a) for a pentacene (PEN)/InP OI-HJ shown in the inset. In this device, the absorption spectra of the organic and inorganic semiconductors overlap. Diagonal dashed lines show the extrapolated InP absorption in the absence of pentacene. Note in both cases the absorption spectral features in the diodes align with those of the neat films (Panda et al., 2014).

The results for the moderate band gap InP (1.35 eV)/pentacene (1.8 eV) OI-HJ are shown in Fig. 4.123b. Here, the absorption spectra of the two semiconductors overlap. At high temperatures, absorption by the top pentacene layer results in a decrease in  $\eta_{\text{ext}}$ . This suggests that excitons generated in the organic recombine prior to reaching the HJ, and hence the addition of this layer results in a net loss in photocurrent. However, as the temperature is reduced, the feature inverts, and loss converts to gain. The temperature at which the pentacene layer becomes transparent is approximately  $T = 200$  K. That is, at sufficiently low temperatures, the excitons can reach the OI-HJ prior to recombination. There, they have an opportunity to form an HCTE that is dissociated into free charge, and thus contributes to  $j_{\text{ph}}$ . This effect is also thermally activated, with  $\Delta E_a = 210 \pm 40$  meV. The opposite temperature dependence of this sample compared to that of the wide gap TiO<sub>2</sub>/DBP junction is attributed to traps at the interface. As

temperature is reduced, the interface traps become occupied, and no longer serve as recombination centers for the arriving excitons.

The photocurrent efficiencies for the devices in Fig. 4.120 of  $\sim 10$ – $15\%$  are remarkably high for OI-HJs, yet they remain comparatively low compared to excitonic detectors with efficiencies ranging from 30% to 90% (see Chapter 7, and Peumans et al., 2003). The low  $\eta_{\text{ext}}$  has frequently been reported in OI-HJ detectors and solar cells (O'Regan and Grätzel, 1991, Olson et al., 2006, Li et al., 2011, Vaynzof et al., 2012). Unlike optimized excitonic OPVs that contain either mixed layers (Uchida et al., 2004) or bulk HJs (Yu et al., 1995) with a very high DA contact surface area and hence a high exciton dissociation efficiency, an OI-HJ has a planar junction. The efficiency is therefore limited by the short diffusion lengths of excitons that must reach the HJ to dissociate into free carriers. The short  $L_D$  necessitates the use of a thin organic layer which cannot absorb much of the incident radiation.

Finally, trap states at the OI-HJ can lead to a bound HCTE that has a higher probability for recombination than dissociation. Indeed, such bound states leading to significant loss in  $\eta_{\text{ext}}$  have been spectroscopically probed at P3HT or F8TBT on ZnO OI-HJs (Vaynzof et al., 2012). It was found that approximately 50% of the excitons that arrived at the ZnO surface formed an HCTE bound to a surface defect, and were likely to recombine rather than generate free charge. When even a monolayer of a “passivating” acceptor, PCBA, is interposed between either F8TBT or P3HT and the inorganic, the number of bound excitons dropped by half, with a concomitant increase in  $\eta_{\text{ext}}$ .

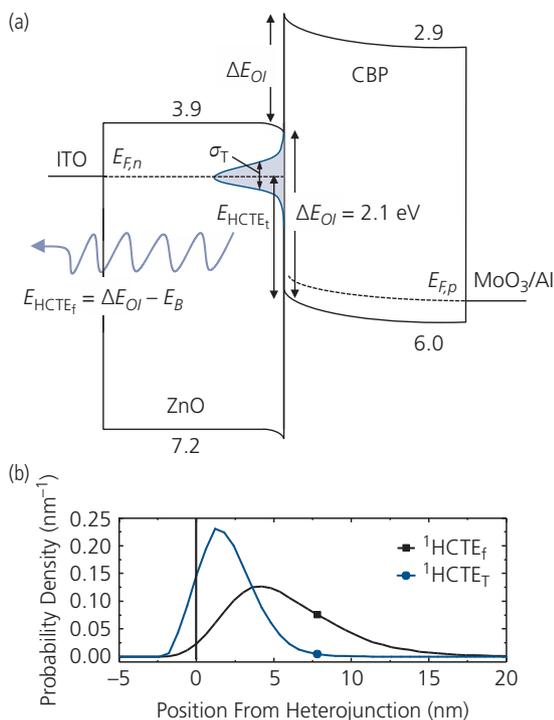

The dynamics of trapped HCTEs have been investigated both theoretically and experimentally in small molecule CBP/ZnO OI-HJs. A free (i.e. unbound to traps) singlet  $^1\text{HCTE}_f$  contributes to the  $\eta_{\text{ext}}$  reaching a maximum efficiency of 6%, which is somewhat lower than observed for DBP/TiO<sub>2</sub>. The free exciton, whose electron density distribution is shown in Fig. 4.116, has a binding energy of only 9 meV. Hence, it is very short lived and has a low oscillator strength, resulting in no detectable photoluminescence. However, under electrical injection, strong electroluminescence is observed from a second, lower energy trapped  $^1\text{HCTE}_T$  state with a relatively high binding energy of 60–430 meV. The electroluminescence from  $^1\text{HCTE}_T$  is attributed to the state bound to defects on the ZnO surface. Spectroscopic analysis indicates that the occupied defects leading to this trapped, high oscillator strength feature are centered approximately 500 meV below the ZnO CBM, with an occupational

DOS width of  $\sigma_T \sim 300$  meV. The energy level scheme describing these various states is shown in Fig. 4.121a (Panda et al., 2016).

The bound state has been modeled by adding the trap potential,

$$V_{\text{trap}} = -Sq^2 / (4\pi\epsilon_r\epsilon_0|\mathbf{r} - \mathbf{r}_{\text{trap}}|), \quad (4.343)$$

to the electron Hamiltonian in Eq. 4.319 that was used in calculating the electron distribution in Fig. 4.116. Here,  $\mathbf{r}_{\text{trap}}$  is the position of the localized defect from the electron at  $\mathbf{r}$ , and  $S$  is the trap dielectric screening factor. The electron density as a function of distance from the OI-HJ along the diameters of both  $^1\text{HCTE}_f$  and  $^1\text{HCTE}_T$  are shown in Fig. 4.121b. The trapped state is much smaller and more tightly bound to the surface than the free state. This accounts for its larger oscillator strength (and hence high electroluminescence intensity) than for the free state that exhibits no measurable electroluminescence. It also clearly demonstrates that trapping at interface defects can decrease  $\eta_{\text{ext}}$  due

**Figure 4.121** (a) Energy level diagram for the CBP/ZnO OI-HJ. The singlet free  $^1\text{HCTE}_f$  has an energy nearly equal to  $\Delta E_{OI}$  due to a binding energy of only 9 meV. The  $^1\text{HCTE}_T$  state is bound at interface traps filling the distribution shown in green with binding energies ranging from 60 to 430 meV and centered  $\sim 500$  meV below the ZnO conduction band minimum. (b) Probability density of the electron in the trapped and free HCTEs as a function of distance from the OI-HJ (Panda et al., 2016).

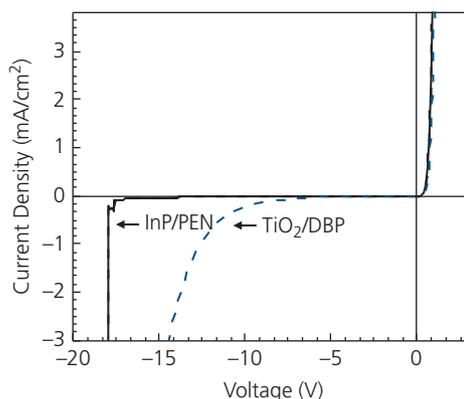

Adapted with permission from Panda, A., Ding, K. & Forrest, S. R. 2016. Free and trapped charge transfer excitons at a ZnO/small molecule heterojunction. Phys. Rev. B, 94, 125429. Copyright 2016 by the American Physical Society.

to enhanced recombination. Passivation of the interface to reduce inorganic semiconductor surface defects is essential to realizing a high detection efficiency.

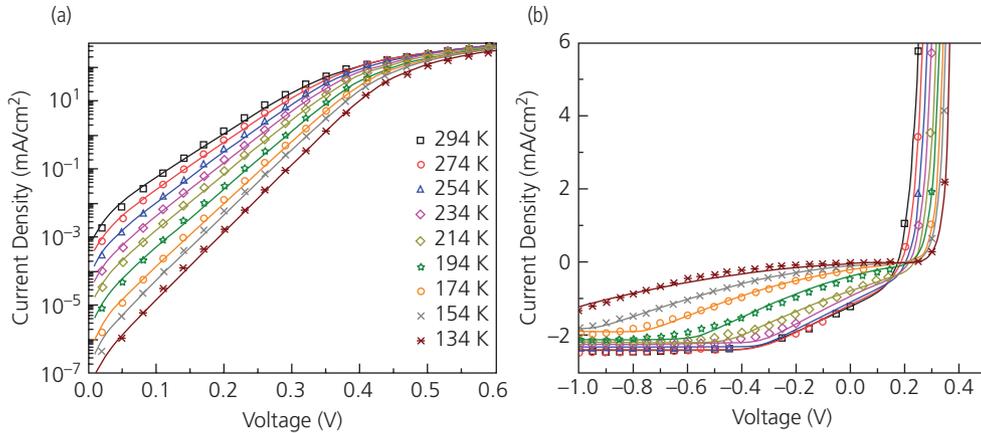

Initial investigations of OI-HJs were encouraged by their very asymmetric and reproducible rectifying characteristics when organics were layered onto a variety of inorganic semiconductors. Particularly the small molecules PTCDA and NTCDA layered onto Si, GaAs and In(GaAs)P show nearly ideal  $j$ - $V$  characteristics of a p-n junction made *only* of the inorganic semiconductor (Forrest et al., 1982, 1984a, 1985a, 1985b). This was particularly remarkable since at that time, no organic diodes showing significant rectification had been reported. It was initially and incorrectly assumed that the organic simply formed a Schottky barrier rather than a HJ barrier with the inorganic material (Forrest et al., 1982). An example of the extraordinary rectifying properties of OI-HJs for the two samples in Fig. 4.120 are illustrated by their bipolar  $j$ - $V$  characteristics in Fig. 4.122.

A more detailed examination of the  $j$ - $V$  characteristics for the PEN/InP junction is shown in Fig. 4.123. Fits to Eq. 4.334 (lines) assume that the junction characteristics are influenced by interface traps, as inferred from its optical properties. The fits replicate all of the details exhibited by the data under both forward and reverse bias. Similarly high quality fits are obtained for DBP/TiO<sub>2</sub> and CBP/ZnO devices (Panda et al., 2014, 2016).

The measured valence band-HOMO offset energy of the PEN/InP OI-HJ inferred from the saturation current in Eq. 4.335 is  $\Delta E_{Hv} = 0.24 \pm 0.04$  eV, which agrees well with UPS measurements. Also, the fits to the forward-biased characteristics yield an ideality

**Figure 4.122** Bipolar  $j$ - $V$  characteristics of the wide- and moderate-energy gap devices in Fig. 4.120. Note the very large reverse breakdown voltages of  $\sim -12$  V for DBP/TiO<sub>2</sub> and  $-18$  V for PEN/InP, as well as the apparent exponential increase in  $j$  with  $V$  under forward bias (Panda et al., 2014).

**Figure 4.123** (a) Forward-biased and (b) bipolar  $j$ - $V$  characteristics of the PEN/InP OI-HJ device in Fig. 4.120b. Solid lines are fits to the data (symbols) as a function of temperature (Panda et al., 2014).

factor ranging from  $n_O = 1.25$  at room temperature to 1.96 at  $T = 134$  K. We have seen in Section 4.7.2 that this temperature dependence for  $n$  is indicative of a distribution of traps within the organic energy gap. Furthermore, the thermally activated mobility  $\mu(T) = \mu_\infty \exp(-E_\mu/k_B T)$  with activation energy  $E_\mu = 71$  meV and prefactor  $\mu_\infty = 10^{-5}$  cm<sup>2</sup>/V s, is consistent with independent measurements from SCL transport of the amorphous pentacene films (Panda et al., 2014).

While the fits validate the diode theory developed for OI-HJJs, we caution that analyses of all diode equations are inherently parametric. This renders their interpretation based on the fitting parameters subject to error, and also can lead to unsupported speculation. Indeed, *the current measured is effectively an integral of all charge generation, recombination, and leakage mechanisms* (including shunts, contact resistances, surface currents, etc.) present. As such, it is often difficult or even impossible to isolate fundamental from parasitic processes, although we have seen that varying temperature and voltage give particularly powerful insights into the various current sources. Thus, it is essential that as many of the parameters used to fit a set of  $j$ - $V$  data be validated via independent measurements to provide confidence in their interpretation. Both the optical and electrical characteristics of the DBP/TiO<sub>2</sub> and PEN/InP samples studied here are consistent with the conclusions that HCTEs do indeed mediate photocurrent generation at these junctions.

#### 4.7.4 Universal ideal diode behavior

We have seen that the ideal diode equations for a variety of junctions, from conventional inorganic p-n

junctions, organic p-n junctions, fully organic (or excitonic) HJs, to hybrid OI-HJ devices all apparently follow the same universal form:

$$j = j_0(\exp(qV/nk_B T) - f(V)) - j_{ph}. \quad (4.344)$$

Here, the saturation current density ( $j_0$ ), the ideality factor ( $n$ ), the bias-dependent reverse-bias factor ( $f(V)$ , where  $f(0) \rightarrow 1$ ), and the photocurrent ( $j_{ph}$ ) have different functional forms in the various material systems due to the different physical processes that govern the junction current. The definition of these parameters for each materials system for one-sided junctions (i.e. where current is controlled by only one of the two contacting materials for simplicity of the comparison) are listed in Table 4.9.

The universal form of the diode equation originates with the commonality of the physics at play in all of these systems. The splitting of quasi-Fermi levels and Boltzmann statistics govern the free carrier distribution and result in an exponential current response to an applied voltage. The non-equilibrium condition imposed by the applied bias is sustained by a balance between carrier generation and recombination. The primary distinguishing feature among these junctions is the specific physics governing the generation and recombination processes, which is embodied in the precise form of the saturation current density,  $j_0$ .

We note that this commonality of form only exists when the dominant mechanism for current transport is recombination. We have shown that for tunneling dominated transport, the current follows a very different, non-thermally activated behavior that depends exponentially on the energy gap and electric field. Tunneling and its associated process of Frenkel-Poole

**Table 4.9** Comparison of diode equations<sup>a</sup>

Equation	$j_0$	$j_{ph}$	$f(V)^b$	$n$
Inorganic (diffusion)	$\frac{D_n n_i^2}{q L_n N_A}$	$j_l$	1	1
Inorganic <sup>c</sup> (generation, recombination)	$\frac{q n_i}{\tau_t} \left( \frac{K_B T}{q} \frac{2\epsilon}{q W N_D} \right)$	$j_l$	$\frac{W}{\left( \frac{K_B T}{q} \frac{2\epsilon}{q W N_D} \right)}$	2
Inorganic Schottky	$\frac{4\pi q m^* k_B^2 T^2}{h^3}$	$j_l$	1	1–2
Organic Schottky	$q \mu_n N_{LUMO} F_m \cdot \exp(-q\phi_{B0}/k_B T)$	$j_0$	1	1–2
Organic HJ (Type II)	$q a_0 k_{rec} N_{HOMO} N_{LUMO} (1 - \eta_{PPd}) \exp\left(-\frac{\Delta E_{HL}}{k_B T}\right)$	$q \eta_{PPd} j_x$	$\frac{k_{PPd}}{k_{PPd0}}$	$\frac{T_A/T}{\delta_D(T_A/T - 1) + 1}$
Organic homojunction <sup>d</sup>	$A(V)(1 - \eta_{PPd}) \cdot \exp\left(-\frac{E_G}{n k_B T}\right)$	$q \eta_{PPd} j_x$	$\frac{k_{PPd}}{k_{PPd0}}$	$\frac{2T_S/T}{(T_S/T + 1)}$
OI-HJ	$q(a) k_{rec} N_{HOMO} N_C (1 - \eta_d) \exp\left(-\frac{\Delta E_{OI}}{k_B T}\right)$	$q \eta_d j_0 + j_l$	$\frac{k_d}{k_{d0}}$	$\frac{T_O/T}{\delta_I(T_O/T - 1) + 1}$

<sup>a</sup> Only one-sided junctions are considered. Definitions of variables given in Sections 4.6 and 4.7. Generalizations of these expressions to more complex situations (e.g. double sided junctions) are found in the literature on inorganic semiconductor diodes.

<sup>b</sup>  $k_{ppd} = k_{ppd0}$  and  $k_d = k_{d0}$  at  $V = 0$ .  $W =$  depletion width on the low-doped side of the junction.

<sup>c</sup> This considers the simplest case of SRH recombination via a single mid-gap trap level in a symmetric p–n homojunction with  $N_C = N_V$ ,  $N_D = N_A$ , and  $|V| \gg k_B T/q$ .

<sup>d</sup> The tunneling based model does not fit the form of Eq. 4.344 which is based only on recombination statistics.  $A(V)$  is a voltage dependent constant.

emission over barriers, and impact ionization (Sze, 1981) are mechanisms that can be found under appropriate conditions (Loi et al., 2007) for all of these various species of junctions. Their presence ultimately leads to phenomena that must be taken into account before applying ideal diode theory to a particular junction. Detailed descriptions of these processes can be found in texts listed in *Further reading*.

## 4.8 Summing up

This chapter concludes Part I, whose purpose has been to lay out the fundamental principles underpinning the field of organic semiconductors. This chapter focused on the transport of charge, which is intimately linked to the physics of molecular excited states and optical properties discussed in Chapter 3. We began by considering the most fundamental of all properties that determines charge transport: the existence of energy bands. Without bands, there can be no charge mobility, and without mobility there is no conductivity. Of course, we learned that the bands in organic semiconductors are, except in a few unusual but important cases, quite narrow (on the order of a few tens of meV) compared with inorganic semiconductors where  $BW > 1$  eV is common. Narrow bands and structural disorder play defining roles in the conductive properties of organics, clearly distinguishing them from ordered inorganic

semiconductors. Importantly, these features result in charge mobility and diffusion governed by hopping through an energetically broad distribution of transport states.

SCL transport in trap-free or trap-dominated solids is found to be the predominant current conduction mechanism in homogeneous, amorphous thin films. Organics can be doped with donors and acceptors that significantly modify their conductive properties, although the doping efficiency (i.e. the number of free charges per impurity molecule or atom) is considerably less than unity since organic solids are electrostatically rather than chemically bonded.

Charge recombination was found to dominate the charge transport characteristics of all organics. The natural outcome of disorder is a high concentration and energetically broadened density of trap states within the HOMO–LUMO gap that promotes recombination. While the precise functional form of the density of traps may be unknown, it is convenient to use an exponential or Gaussian function since they lend themselves to closed-form analytical expressions. Indeed, the effective medium, Gaussian disorder approximation is found to provide reliable descriptions of the mobility, and hence it is reasonable to assume that this functional form can also describe the distribution of disorder-induced traps.

In the final part of the chapter, we explored transport in systems with junctions. Indeed, all organic

electronic devices have contacts, and contacts form junctions. If the contact barrier is large compared to the thermal energy, then the resulting Schottky junction is rectifying, and controls injection into the material. If the barrier is small, then the contact is Ohmic, which is desirable for high current applications such as OLEDs and organic thin film transistors. In all cases, the contact junction properties are determined by disorder resulting in interface dipoles and morphological defects that impact the size and magnitude of the energy barrier.

There are several other types of junctions that play an integral role in transport. Homojunctions consisting of p–n doped regions abutting one another are by far the most fundamental junction in semiconductors, yet are infrequently reported in organics due to the difficulty in efficiently and precisely doping the layers. In contrast, photonic devices contain HJs consisting of two different organic semiconductors in contact with each other. Type I (nested) HJs are found useful for confining charge in the emission zones in OLEDs, whereas Type II (staggered) HJs are used for charge separation in OPVs. Type III (broken junction) HJs can promote charge injection in transistors and photonic devices alike.

We presented semi-classical approaches to describe charge transport across all of these various junction types. The approaches stem from the ideal diode equation of Shockley; an insight that now underpins all modern semiconductor device theory and engineering. Similar considerations lead to descriptions of transport across organic and OI-HJs, providing an understanding of the many rich and varied properties of these important materials systems. The idealized descriptions can be extended in a straightforward manner to consider the many variations that occur in practice. Given the complexities of real junctions consisting of imperfect materials, these so-called ideal diode equations can only go so far in describing actual observations. We continue to caution that although one has at one's fingertips an ideal diode equation, that does not mean that one also has an ideal diode. Such a device, to my knowledge, has never been realized.

While the foundations have been laid, the transport properties of organics represent a topic of immense depth. A truly comprehensive treatment of transport in structures with, or even without a junction, is well beyond the scope of this text. Once again, the interested reader is referred to *Further reading* to continue exploration of this enormously interesting topic.

In spite of our cautions about the effects of materials imperfections, structural and dynamic disorder, and possibly high trap density, the relatively simple theories and analyses described in this and the preceding chapters in Part I provide a remarkably accurate description of the properties of organic semiconductors. While continuously evolving with each new material, measurement and device, this framework has led to advances in optoelectronic applications in recent years that are generating new industries and revolutionary changes in our understanding of what organic semiconductors can achieve. These technological advances are the topic of Part II.

### Problems

1. The band structure of organic molecules can be approximated using the tight binding approximation.
  - (a) Why is this approximation valid in both polymers and small molecules?
  - (b) Assume that the molecules are arranged in a body-centered cubic lattice with lattice constant,  $a$ . Give expressions for the bandwidth, velocity, and effective mass of the solid along the (100) and (111) directions. Plot these functions in the first Brillouin zone.
  - (c) Write an expression for the effective mass and velocity at the zone center.

2. In tight binding theory, one assumption is that the wavefunction is small when the potential perturbation from nearest neighbors is large. In Fig. 4.3 we illustrated such a potential, described by the following function:

$$U(\mathbf{r}) = -U_0 \frac{\sin^2(\pi \mathbf{R}/a)}{(\mathbf{R}/a)^2}$$

where  $\mathbf{R}$  is the lattice translation vector for a simple cubic lattice with side  $a$ .

- Calculate the tight binding parameters  $\alpha$ ,  $\beta$ , and  $J$  assuming that the molecular wavefunction,  $\phi(r)$  is described by a hydrogenic s-state. Hint: Expand  $U(r)$  to second order.
  - Using results in (a), calculate  $BW$  and the electron effective mass along the (100) direction.
  - Plot the dispersion relationship,  $E(k_{(100)})$ .
3. Assume that the electronic states in an organic film are well described by Gaussian disorder with a width,  $\sigma_{GDM}$ .
- Show that the mean thermal equilibrium energy of the distribution is  $\langle E_\infty \rangle = -\frac{\sigma_{GDM}^2}{k_B T} \langle \epsilon_\infty \rangle = -\frac{\sigma^2}{k_B T}$ .
  - Assume that a measurement of mobility proceeds by injecting electrons into a thin film slab of length  $L$ , thickness,  $d$  and then measuring the current at the opposite electrode. Write a suitable expression for mobility in the low temperature, low field regime from time of flight data.
  - Based on the drift-diffusion model in the low field, low temperature regime, calculate an approximate expression for, and plot the shape of the current pulse at the opposite electrode.
4. In Fig. P4.4 is shown the reaction coordinates for parabolic potentials for the reactants ( $V_R(Q)$ ) and products ( $V_P(Q)$ ). If  $\Delta G^0$  is the Gibbs Free Energy of reaction corresponding to the difference between the uncharged and ionized state,
- Show that the activation energy barrier for charge transfer from the reactant (i.e. donor) to the product (acceptor) molecule is given by:

$$\Delta G^* = \frac{\lambda}{4} \left[ 1 + \frac{\Delta G^0}{\lambda} \right]^2$$

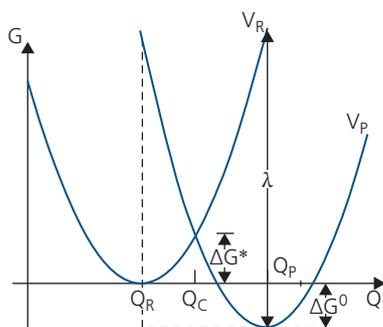

Figure P4.4 Marcus reaction manifolds.

where  $\lambda$  is the reorganization energy for the transfer.

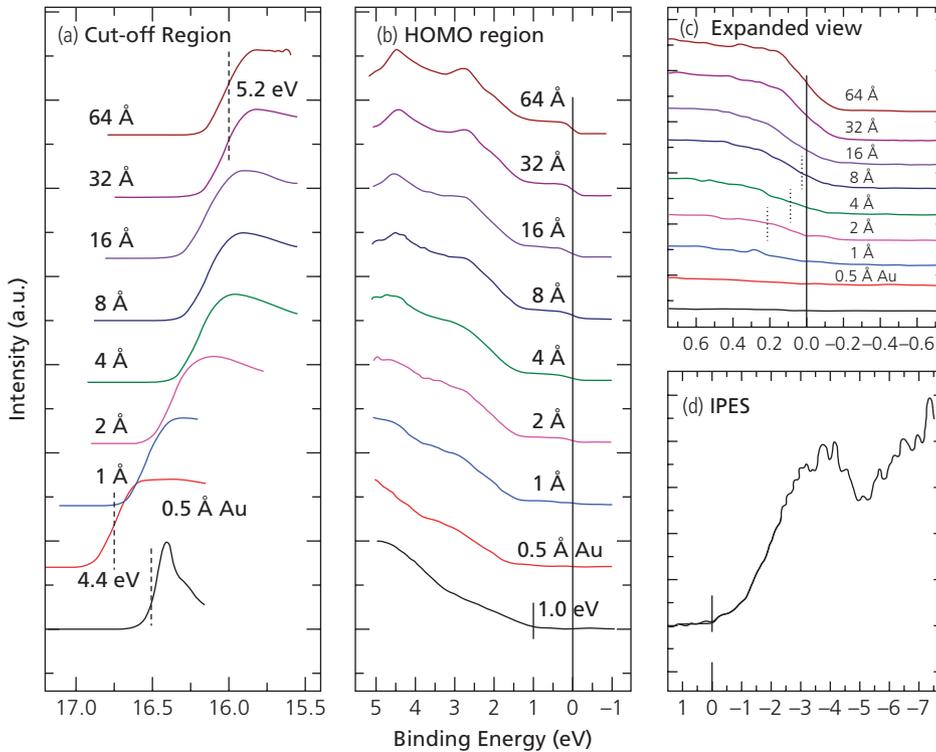

- The diagram is shown for one case of normal Marcus transfer corresponding to  $-\Delta G^0 < \lambda$ . Replot these parabolas for the cases of  $-\Delta G^0 < 0$ ;  $-\Delta G^0 = \lambda$ ; and for the Marcus inverted region where  $-\Delta G^0 > \lambda$ .
  - If we assume that the rate of electron transfer is given by  $k_{ET} = A(\lambda k_B T)^{-1/2} \exp(-\Delta G^*/k_B T)$ , plot  $k_{ET}$  vs.  $\Delta G^*$  and find the value of  $\Delta G^0$  leading to a maximum transfer rate. Plot  $k_{ET}/A$  vs.  $\Delta G^0$  for a given value of  $\lambda$  and  $T$  from below to above the maximum, clearly labeling the regions of normal and inverted electron transfer.
5. Measuring the energetics of organics and their contacts is key to understanding transport. The most common means for measuring ionization potentials and electron affinities is ultraviolet photoelectron spectroscopy (UPS) and inverse photoelectron spectroscopy (IPES, see Appendix C). The spectra of an organic semiconductor with progressively thicker layers of Au on its surface are shown in Fig. P4.5. To gather the UPS spectra, the He I emission line (21.22 eV) was used as the photon source.
- On the spectra, label all the relevant transitions needed to determine the energetic properties of a semiconductor (the vacuum level,  $VL$  or  $E_{VAC}$ , the LUMO ( $E_{LUMO}$ ) and HOMO ( $E_{HOMO}$ ) energies, the deeper energy levels away from the frontier orbitals that can be observed, the energy gap,  $E_G$ , and the Fermi energy,  $E_F$ ), and discuss how these energies are determined.
  - In the data in the figure, the UPS data are shown in varying levels of detail and at different energies. Clearly identify the *all* energies discussed in (a) on the diagrams. The lower black lines in (a) and (b) are the bare organic semiconductor surface, and all other lines correspond to progressively thicker layers of Au.
  - From the data in Fig. P4.5, draw the energy level bending as Au thickness increases, and the organic equilibrium energy level diagram for the  $VL$ ,  $E_{LUMO}$ , and  $E_{HOMO}$  as functions of Au coverage.
6. The space charge limited current in the presence of a Gaussian trap distribution assumes the trap distribution follows:

$$h_T(E) = \frac{H_T}{\sqrt{2\pi}\sigma_T} \exp\left[-(E - E_{Tm})^2/2\sigma_T^2\right]$$

where  $H_T$  is the total density of traps,  $E_{Tm}$  is the mean trap energy, and  $\sigma_T$  is the width.

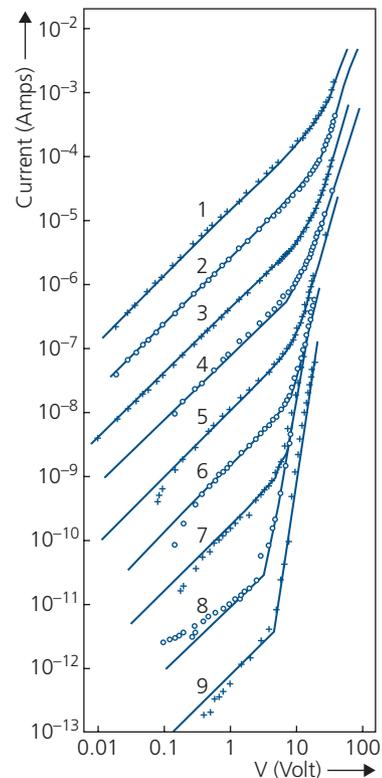

- Show that the trapped charge density is given by:  $p_T = H_T^G \left(\frac{p}{N_{HOMO}}\right)^{1/m}$  where  $H_T^G = \left(\frac{H_T}{2g_p}\right) \exp(E_{Tm}/mk_B T)$  and  $m = (1 + 2\pi\sigma_T^2/16k_B^2 T^2)^{1/2}$ . Here,  $g_p$  is the degeneracy of the trap states.
- Show that the current voltage relationship is given by:

$$j_{SCL} = q\mu_p N_{HOMO} \left(\frac{2m+1}{m+1}\right)^{m+1} \left(\frac{m}{m+1} \frac{\epsilon_r \epsilon_0}{q H_T^G}\right)^m V^{m+1} d^{2m+1}$$

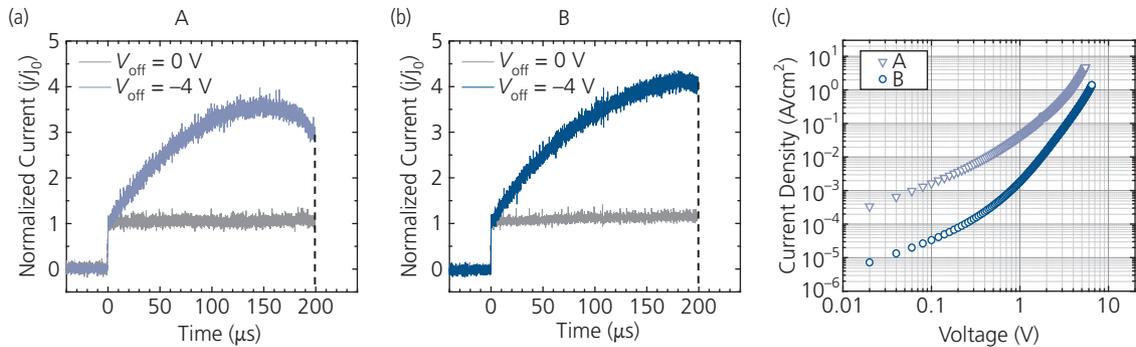

**Figure P4.5** (a, b) UPS spectra of an organic in different energy regions; (c) a detail of (b) near the Fermi energy. (d) IPES data for the same material. (Liu et al., 2015)

- (c) Calculate the cross-over voltage,  $V_x$ , where SCL current equals to the Ohmic current.
  - (d) Plot the  $j$ - $V$  characteristics as a function of temperature and trap density by assuming  $m = 5 E_{TM} = \sigma_T = 10 k_B T$  and  $H_T = 4 \times 10^{19} \text{ cm}^{-3}$  at  $T = 100 \text{ K}, 200 \text{ K},$  and  $300 \text{ K}$ . There is one state per molecule with a density of  $5 \text{ g/cm}^3$  and an atomic weight of  $550 \text{ g/M}$ , the dielectric constant is  $\epsilon_r = 3$ ,  $\mu_p = 0.1 \text{ cm}^2/\text{V s}$ , and the sample thickness is  $d = 100 \text{ nm}$ .
7. In Fig. P4.7 we show the current-voltage-temperature ( $I$ - $V$ - $T$ ) characteristics of an organic sample that is  $9.3 \mu\text{m}$  thick, and has an area of  $1 \text{ cm}^2$ . From these data, and assuming that  $m_n^* = m_p^* = m_0$ , the mass of the electron, and the density of states,  $N_{HOMO} = N_{LUMO}$ , determine the following:
- (a) The physical origins of the currents at low and high  $V$ .
  - (b) Since this is a hole conducting material, what is the hole mobility,  $\mu_p$ ?
  - (c) Plot the conductivity ( $\sigma$ ) as a function of temperature.
  - (d) Calculate the energy gap and  $N_{HOMO}$  of this material. Any guesses as to what the material is? (Hint: it is a common, small molecule organic semiconductor.)
  - (e) What is the trap density and energy depth assuming an exponential trap distribution?
8. Figure P4.8 shows data taken from the  $j$ - $V$  characteristics and by charge extraction by linearly increasing voltage (CELIV) for two regioisomeric donors, A and B. Both CELIV and the  $j$ - $V$  characteristics provide hole mobility measurement of two donors, A and B. The device

**Figure P4.7**  $I$ - $V$  characteristics at several temperatures: 1 = 250; 2 = 215; 3 = 180; 4 = 155; 5 = 125; 6 = 100; 7 = 75; 8 = 55; 9 = 17°C

**Figure P4.8** CELIV data for (a) sample A and (b) sample B. (c) Current–voltage characteristics of samples A and B.

structure is: ITO/ donor (40 nm)/MgF<sub>2</sub> (15 nm)/Al. The ITO contact is Ohmic and hole injecting. For CELIV, a waveform generator shaped triangular voltage pulse increases by 2 V in 200 μs. The transient current is shown in Fig. P4.8a and b for these two materials at two different voltages that were negatively pulsed at  $V_{\text{eff}}$  prior to the triangular pulse.

- (a) What is the mobility extracted from the current transients shown in Fig. P4.8a and b? Why is there no signal at  $V_{\text{eff}} = -4$  V?
  - (b) From the data in Fig. P4.8c calculate the hole mobility, and the background free hole concentration for both donors A and B.
  - (c) Estimate the errors in both measurements from the data presented. Can you explain why there are differences in mobilities measured by CELIV and the  $j$ - $V$  characteristics, and are they significant?
9. The  $j$ - $V$  characteristics for Schottky barrier diodes have a saturation current given by  $j_0 = A^* T^2 \exp(-q\phi_{Bn}/k_B T)$ .
    - (a) Calculate the effective Richardson constant,  $A^*$ , by assuming a Gaussian distribution of LUMO states whose center energy is at  $E_{\text{LUMO}}$ , and whose width is  $\sigma$ .
    - (b) Calculate the ratio of the constant obtained for  $A^*$  to that used for conventional semiconductors. Is there a way to distinguish if the Schottky barrier diode employs an organic or an inorganic semiconductor based on this result?
  10. In calculating the tunneling current in Schottky/organic diodes, we made several claims and assumptions. We need to clarify those assumptions.
    - (a) The total current is equal to the difference of the current from the metal to the semiconductor ( $j_{m \rightarrow s}$ ) and from the semiconductor to the metal ( $j_{s \rightarrow m}$ ), that is,  $j_{\text{tun}} = j_{m \rightarrow s} - j_{s \rightarrow m}$ . Show that the tunneling current can be expressed as:

$$j_{\text{tun}} = \frac{qm^*}{2\pi^2\hbar^3} \int_{E_{\text{min}}}^{E_{\text{max}}} T(E_x) dE_x \int_0^\infty \int_0^\infty (f_m(E) - f_s(E)) dE_r,$$

where  $T(E_x)$  is the tunneling probability of an electron with energy  $E_x > E_{\text{LUMO}}$ ,  $E_{\text{metal}}$  through the

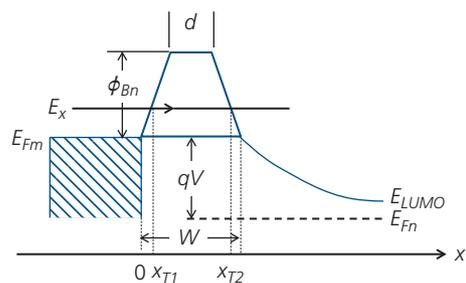

energy barrier along  $\hat{x}$ , and the Fermi–Dirac functions are given for the metal and the organic semiconductor by  $f_m(E)$  and  $f_s(E)$ , respectively. Here,  $E_{\text{LUMO}}$ ,  $E_{\text{metal}}$  are the energies of the organic LUMO and the metal work function, respectively.

- (b) Show that by assuming  $f_m(E) = 1$  for  $E < E_{Fm}$ , and  $f_m(E) = 0$  for  $E > E_{Fm}$ , then:

$$j_{\text{tun}} = \frac{qm^*}{2\pi^2\hbar^3} \left( \int_{-\infty}^{E_{Fn}} T(E_x)(E_{Fm} - E_{Fn}) dE_x + \int_{E_{Fn}}^{E_{Fm}} T(E_x)(E_{Fm} - E_x) dE_x \right).$$

Show that the first integral vanishes when the electron energy is  $E_x < E_{Fn}$ , the Fermi energy of the n-type organic semiconductor. This is known as the Tsu–Esaki model.

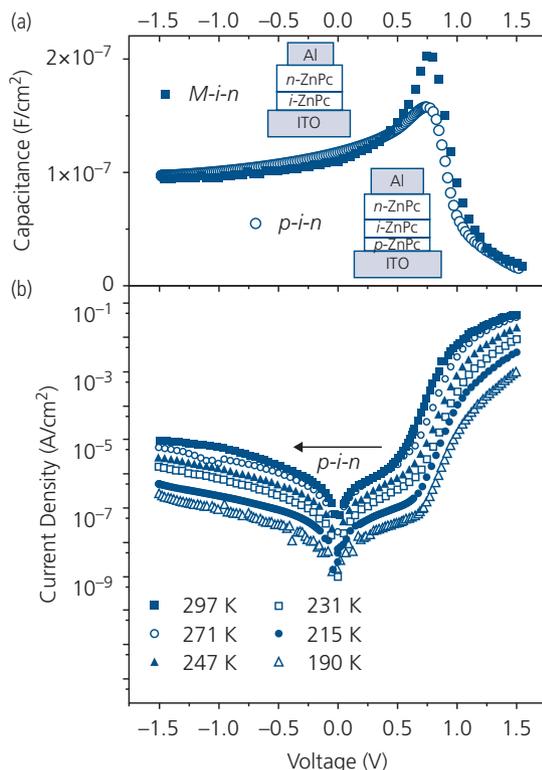

11. An equilateral trapezoidal Schottky barrier with top width,  $d$ , and base width,  $W$ , is shown in Fig. P4.11.
  - (a) For an electron of mass  $m^*$  in an electric field,  $F$ , calculate the tunneling probability using the WKB approximation or other approach.
  - (b) Calculate the tunneling current for the trapezoidal barrier and plot the current vs. applied voltage,  $V$  over 4 decades in  $j_{\text{tun}}$  for  $d/W = 0, 0.5, 1.0$ . Compare

**Figure P4.11** Tunneling Schottky barrier energy diagram.

this to tunneling over a triangular barrier of similar barrier height and width,  $W$ .

12. The data in Fig. P4.12 are for a homojunction Zn phthalocyanine p-i-n diode and a Schottky metal (M)-i-n diode.
  - (a) From the reverse bias  $1/C^2$ - $V$  data, obtain the donor concentrations and the built-in voltage of both devices.
  - (b) Using the built-in voltage from (a), fit the forward bias characteristics of the p-i-n diode to the organic homojunction diode equation 4.290. Assume the device is symmetric (a good assumption in this case), and a normalized Gaussian disorder width of  $\hat{\sigma} = 4$ .
  - (c) Now assuming a recombination model for the p-i-n diode, plot the trap temperature exponent,  $m$  vs.  $1/T$ . What is your physical interpretation of the result?
  - (d) From the voltage and temperature dependence of the reverse biased p-i-n,  $j$ - $V$  characteristics, can you determine the source of the leakage from the following possibilities: generation-recombination from traps (either discrete or a distribution), parasitic junction shunt resistance, series resistance, tunneling, or other source? Justify your answer via analysis of the data.

**Figure P4.12** (a) Capacitance–voltage ( $C$ - $V$ ) characteristics and (b) the room temperature p-i-n forward and reverse diode  $j$ - $V$  characteristics at several temperatures. Data from Harada et al. (2005).

---

# Materials purity, growth, and patterning

---

*"Nature uses only the longest threads to weave her patterns, so that each small piece of her fabric reveals the organization of the entire tapestry."*

**Richard P. Feynman, Physicist**

In Part I, Foundations, we discussed the characteristics of organic semiconductors that determine their structural, optical and electrical properties. We found that almost all differences between organic and inorganic semiconductors arise from their cohesive forces: soft van der Waals bonds dominate in organics, whereas in inorganics, covalent bonds, sometimes with an admixture of ionic bonding, result in comparatively rigid and brittle materials. In Chapter 2, we showed that van der Waals bonds allow for growth of self-assembled crystalline and nanocrystalline structures on virtually any flat substrate. The resulting films, whose morphologies can range from crystalline to highly disordered form the basis for many practical devices, ranging from light emitting diodes to solar cells.

In this first chapter of Part II, Applications, we examine the important role that materials purity plays in determining materials and device properties, and describe several methods used to achieve the highest possible purity. This is followed by a discussion of bulk crystal growth. We note that bulk crystals are not of great interest for device applications, yet they are highly useful for understanding the fundamental optical and electrical characteristics of organic materials. This section relies heavily on the insights gained in Chapter 2 on the bonding forces governing film morphology. The control of both materials purity and film structure can be achieved only if they can be quantitatively evaluated.

Next, we discuss how thin films are deposited, often with monolayer precision, by both vapor and solution phase processes. Integral to achieving the desired film thickness is to also achieve the needed film morphology. This is necessarily varied from single crystalline films, to those with nanocrystalline domains, and to amorphous structures. Further, many devices require precisely controlled blend morphologies comprising two or more constituents. We will discuss many of the growth and post-growth processes used in Sections 5.4 and 5.5. In Section 5.6, we introduce the practical and important topics of patterning of organic films and contacts with nanoscale feature resolution necessary for modern electronic devices. Electronic devices generally require several sequential heterogeneous materials deposition steps that are registered to underlying layers. Patterning of conventional inorganic semiconductor circuits is a highly complex, costly, and sophisticated process that demands the registry of nanometer-scale features from one layer to the next. It is enabled by a photolithographic sequence of addition and removal of materials of widely varying physical and chemical properties. It is not uncommon for a circuit to require 20–50 such precise layering steps in a well-defined sequence to create the end product. Such complexity, however, is well beyond the capabilities of modern organic electronics and may, in fact, not even be desirable. The attraction of organic electronics is its

ability to provide relatively large devices (e.g. displays, lighting, solar cells, biosensors, etc.) at extremely low cost. Hence a large variety of patterning methods have been adapted to the needs specific to organic materials.

This leads to a discussion of manufacturing methods by continuous roll processing, ending with consideration of device packaging to prevent performance degradation due to environmental exposure. One way to view organic electronic device manufacturing is as an exercise in “making small things big.” How do we take the quantum properties of molecules, create films and morphologies at the nano- and microscales, then develop individual devices at the micron to millimeter scales, and to finally realize 77” televisions, large room lighting fixtures, or solar cells that cover entire roof tops? It is these last topics that clearly delineate the “worlds” of organic and inorganic devices. As mentioned in Chapter 1, the ability to print organic devices in batches or even on continuous rolls of lightweight and flexible substrates creates distinct opportunities to generate entirely new classes of applications that conventional semiconductors are unable to address. However, their fragility, and the absence of chemical bonds between molecules also makes organics vulnerable to attack by moisture, oxygen and other environmental contaminants. Hence, a discussion of materials growth and purity would be incomplete without also considering means for protecting the as-grown materials from degradation through environmental exposure.

We intentionally omit a discussion of materials synthesis and chemical structure in this volume. While it is understood that the enormous control of property and structure unique to organic materials arises from the ability to synthesize a staggering variety of complex molecules, we cannot do this field justice by including a necessarily brief overview of the topic. Interested readers will find ample discussion of these topics elsewhere. Here, we will only refer to a small subset of molecules that provide illustrative models for the growth and applications that are currently the most widespread.

## 5.1 The organic semiconductor difference

In Part I, we discussed the foundational principles and properties of organic semiconductors; it was basically about the “how” in how things work. Part II, then is all about the “what.” What do we do with these materials? Can we use their unique physical, electronic and optical properties to create things that can make a difference in our everyday lives, or that can even possibly change the very way we live and interact with the technological world? But before we can address these applications that span the gamut from displays and lighting, to solar cells and many other optical and electronic applications, we first need to understand how to *make* things with organic materials. So, this chapter is all about making things and should give a firm foundation on how to build sophisticated, reliable and high performance devices out of electronic-grade materials deposited in precisely controlled layers.

The ability to synthesize, purify, process, and fabricate high performance organic devices has benefited from over 60 years of research and technology development. Yet, achieving high materials quality, and the ability to fabricate complex devices sometimes requiring processes that can produce nanometer scale features, is still not nearly as straightforward as it is for conventional semiconductors. The principal difference lies in the relative “softness” of

materials: they tend to readily degrade when exposed to many solvents or the ambient, they can be easily damaged by handling, and they are difficult to purify. As in all electronic devices, the starting materials for organic semiconductors must be highly pure to be useful, yet as we will see, this remains a daunting task, and results to date in achieving very high purities have been mixed.

Given the range of materials processing techniques that have been developed, and the extraordinary creativity shown by the engineering communities in their development, a full description of all of the possibilities is impractical. Here, we only provide a sampling of the most important (although in all cases not necessarily the best) methods used. Even so, the discussion in this chapter illustrates many challenges and degrees of freedom in materials deposition and structural control afforded by organic semiconductors. The end product of any electronic application is a tapestry, woven from many threads that together create a whole that is unquestionably greater than the sum of its parts. So, too, does this chapter attempt to weave together the threads that form a high performance organic electronic device.

Before we go further, it is useful to remind ourselves of that which makes organic electronics unique. It is these properties that serve as a guide when we consider the efficacy of a particular growth, patterning or manufacturing method. In Chapter 1, we noted

that organic electronics are useful when the application demands a large area, low cost, lightweight, conformable or flexible form factor. Furthermore, the most interesting applications for organics are often those that have a photonic property, such as light emitters or detectors. In these cases, at least one surface of the device must be transparent to the wavelength band in which it operates. This broad application space, and the weak bonds of organic thin films, requires fabrication processes near room temperature. So too, organics are vulnerable to exposure to liquids and other processing agents commonly employed in electronic device processing. Taken together, these constraints limit the types of processes that are suitable for the fabrication of thin film organic devices. Nevertheless, techniques have been adapted to overcome many of the apparent limitations set by the varied substrates and materials employed. Throughout the following discussion, we need to keep these constraints in mind to focus our attention on methods most likely to lead to high performance devices.

## 5.2 Effects of impurities on materials properties

A fundamental property of all high performance electronic devices that exhibit a long operational lifetime and can be produced at high yield, is that the materials of which they are comprised are of high purity. To access their intrinsic properties, the materials must be as free as possible from extrinsic defects that result from the unintentional incorporation of foreign species. As in real estate where value is claimed to be all about “location, location, location,” in electronics it is all about “purity, purity, purity.” Unfortunately, the literature on organic materials and devices is replete with studies that report what are assumed to be intrinsic materials characteristics, but are instead features of contaminants adventitiously included during growth or processing. Hence, considerable care must be taken to remove impurities from the source materials if reproducible, stable and comprehensible characteristics are to be achieved.

The different cohesive forces binding inorganic and organic semiconductors lead to different outcomes in their properties in the presence of impurities. As we have seen in Part I, a high concentration of impurities, or defect density leads to significant variations in the conductivities and optical properties compared to pristine material. Furthermore, the operational stability of devices comprised of materials unintentionally

doped with impurities can be adversely affected. That is, the various device performance characteristics can change over time, depending on the concentration, reactivity, diffusivity and other properties of the contaminants.

As discussed in Chapter 4, impurities that take the place of a lattice atom in a covalently bonded material can either give up an extra electron to the lattice (if it has one more outer shell electron than the lattice atom itself). Alternatively, if it has one fewer valence electron, it can accept an electron and become negatively charged. In the first case, the impurity is known as an *electron donor*, and in the second it is an *electron acceptor*. These types of impurities are known as *substitutional dopants*. Substitution can result in an increase in the conductivity of covalently bound semiconductors (e.g. Si or Ge) by as much as  $10^9$  from its intrinsic value at room temperature. As a result, controlled doping is a common strategy for modifying the conductivity in almost all semiconductor devices.

The introduction of extrinsic impurities can create lattice strain: that is the “fit” of an impurity atom into a lattice is never perfect. Hence, the lattice must locally conform to the size and valence electron distribution of the impurity. This creates an additional energy associated with the defect that influences the conductivity of the host material.

Another type of impurity is that which is located at unoccupied lattice sites; these are called *interstitial dopants*. Like substitutional dopants, interstitials can also lead to significant changes in the lattice conductivity even though they do not share a bond with the lattice atoms. Under the right circumstances, alkali atoms and the halogens with their partially filled outer valences can serve as electron donors or acceptors, respectively. Interstitial defects are more difficult to control than substitutional impurities, making the latter more desirable for doping.

A third and final type of defect is the *vacancy*, where an atom is missing from a particular position in the lattice. In Si, this results in four unfulfilled, or dangling bonds from the atoms neighboring the vacant site, thereby potentially donating as many as four electrons to the conduction band of the semiconductor. Unlike impurities which, in principle (but never in practice), can be completely eliminated, the density of lattice vacancies is determined by thermodynamics, and hence can never be avoided. If the enthalpy of formation of a vacancy is  $\Delta H^{vac}$ , then the density of vacancies in the solid is

$$N_{vac} = N \exp(-\Delta H^{vac}/RT), \quad (5.1)$$

where  $N$  is the total number of lattice sites, and  $R$  is the universal gas constant. An associated site is the *self-interstitial* where an extra lattice atom locates in a region between filled lattice sites. The probability of formation of a self-interstitial is also given by Eq. 5.1, although the energy of formation is far higher than for a vacancy, since squeezing an extra atom into the lattice is accompanied by significant local lattice distortion.

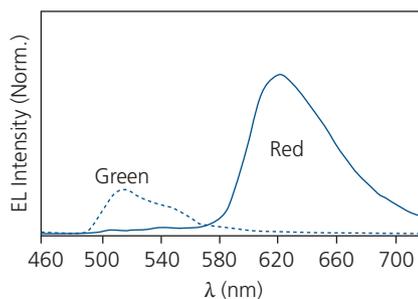

Unlike inorganic semiconductors, impurities in most organic materials do not share valences within the lattice since there are no bonds to make or break in these electrostatically bonded materials. The defects, therefore, typically occupy interstitial sites where charges remain tightly bound to the impurity itself. Nevertheless, if the impurity species is readily ionized (e.g. alkalis such as  $\text{Na}^+$  and  $\text{Li}^+$ , or halogens  $\text{Cl}^-$  and  $\text{F}^-$ ), the interstitial defects can also contribute free charge and hence, unintentionally lead to a dramatic change in conductivity. One common example impurity is the oxygen molecule, which readily accepts electrons to form an  $\text{O}_2^-$  complex with the copper atom in CuPc, increasing the background density of holes (Simon and André, 1985). Also, depending on the position of their frontier orbitals relative to that of the host lattice, larger molecular impurities can also contribute charges to the host. For example, in Section 4.4.1 we showed that  $\text{F}_4\text{TCNQ}$  is an acceptor in such hosts as ZnPc (Maennig et al., 2001). That is, introduction of impurities can result in the reduction or oxidation of the host species, thereby contributing free charge. This strategy has been used to modify the conductivity of a wide range of organic materials.

As noted above, impurities in organic thin films can disrupt the crystalline order in molecular solids. That is, the foreign species can intercalate into the lattice, creating a stacking fault or dislocation. The resulting disorder results in a reduced charge mobility, where the carriers are forced to surmount energy barriers formed at grain boundaries between individual crystallites comprising the solid (Forrest et al., 1984). The size of the impurity species determines the significance of the defect that results: individual atomic or ionic impurities may not be sufficiently large to induce stacking faults due to the large gaps between neighboring molecules, whereas molecular impurities or molecular fractions left over from synthesis or that result from decomposition during processing are more likely to disrupt the lattice.

The presence of impurities also can have a dramatic impact on the luminescent properties of materials.

Intentionally doping a conductive host material with luminescent impurity molecules is a well-established means for obtaining high efficiency light emission in OLEDs (Tang et al., 1989, Baldo et al., 1998b). However, unintentional incorporation of molecular species at even trace levels can lead to luminescence quenching due to exciton trapping and non-radiative recombination, parasitic luminescence at undesired wavelengths, and even a reduction in device operational lifetime and stability. A dramatic example that illustrates the sensitivity of the luminescent properties to impurities is illustrated in Fig. 5.1. The emission zones of two OLEDs containing a 20 nm thick CBP host are doped with only a 0.2 Å layer of a highly emissive phosphor. One is doped with the green emitting  $\text{Ir}(\text{ppy})_3$ , and the other with the commercial red-emitting dopant, RD-15 (Universal Display, Inc., Ewing, NJ, USA). Emission from both structures is easily detectable, although that of the lower energy red emitting phosphor is 3–4 times higher than for the green. It is striking that the red dopant concentration constitutes only  $10^{-4}$  of that of the host. The instrumental resolution of this experiment indicates that the red emission is observable at a thickness of 1/500 of a monolayer, or a concentration equivalent to only one part in  $10^6$ .

Impurity quenching of excitons has also been observed in organic photovoltaics. The primary mechanism for photocurrent generation in organics is via the dissociation of optically generated excitons that diffuse to an interface between two dissimilar materials (see Chapter 7). The presence of impurities has been directly linked to a decrease in the exciton diffusion length in CuPc-based organic photovoltaics, thereby preventing their migration to the interface,

**Figure 5.1** Electroluminescence spectra from organic light emitting devices (OLED) whose emission layers contain either a 0.2 Å thick layer of a green or red phosphorescent dopant in a large energy gap host layer. While the green doped device intensity is only ~25% of the red device, the instrumental detection limit of the red emission corresponds to only 1/500 of a monolayer of dopant. After McGraw and Forrest (2013).

and hence reducing their power conversion efficiencies (Salzman et al., 2005).

While there have been relatively few detailed quantitative studies, it is clear that the reliability of almost all electronic devices depends critically on the purity of the materials used in their manufacture. For example, the efficiency of polymer solar cells degrades rapidly over time due to contamination by low molecular weight species, unreacted monomers that comprise the polymer chains, or reaction byproducts that are not completely removed following synthesis (Mateker et al., 2013). These species react with the host polymer to form exciton quenching sites, similar to the effects of extrinsic contaminants in CuPc-based cells. Reaction products that emerge during device operation, such as polymerization of C<sub>60</sub> in fullerene-based organic solar cells have been implicated in a long term decrease in solar cell performance (Wang et al., 2014). Similar molecular dissociation effects are also known to negatively impact the luminescence efficiency of organic light emitting devices over time via the production of exciton quenching sites (Giebink et al., 2008, Jeong et al., 2019).

Whether the defects are induced during device operation, catalyzed by the presence of extrinsic contaminants, or are an intrinsic materials property, impurities play a major if not dominant role in device performance. While the mechanisms leading to impurity effects may differ between organics and inorganics, their impacts can be equally important. The question remains, however: how pure must a material be for it to be useful? The answer is as ambiguous as the question since it is contingent on the particular application and the materials properties (i.e. both the source and the impurity) themselves. Unfortunately, it is often more difficult to measure the impurity concentration in organics with the same precision achieved for inorganics such as Si and Ge. The best means to determine if the material has achieved the appropriate level of purity is the most practical: the residual contamination following purification should not measurably affect the host material or the devices of which they are comprised, including their electrical, morphological or optical properties from batch-to-batch or over extended periods of use.

In the following section we will discuss means for achieving high materials purity, followed by discussions on how to deposit films in a desired morphology while maintaining the purity of the source. We will also discuss several methods for evaluating both purity and morphology of bulk and thin film materials.

## 5.3 Materials purification

Virtually all effective means for purification rely on separating the host from its contaminants based on differences in molecular weight or size. Thus, it is easier to achieve highly refined substances when they are *monodisperse*, that is, they have a single, well-defined molecular weight or isomeric content. Monomers and oligomers provide excellent candidates for this type of purification process. In contrast, the indeterminate chain lengths of polymers result in a similarly indeterminate molecular weight and size, making their purification correspondingly more difficult. In the following, we will focus on the most effective and frequently employed means for purification of both classes of molecules. We note that to achieve high purity, often one or more techniques are sequentially employed, each being chosen due to a combination of effectiveness in removing specific impurities, or efficiency in reducing the processing time (and hence, cost). For this discussion, we assume that the materials have gone through the standard regime of purification during synthesis including distillation, precipitation, filtration, etc. The purity of materials used in organic electronics following synthesis is generally specified to be ~90% to 95%, although far lower purities are typically encountered. Moreover, this level of purity is far too low for mass-produced components whose operating characteristics fall within an acceptably narrow range to produce high yield, long lived, and high quality electronic appliances.

### 5.3.1 Zone refining

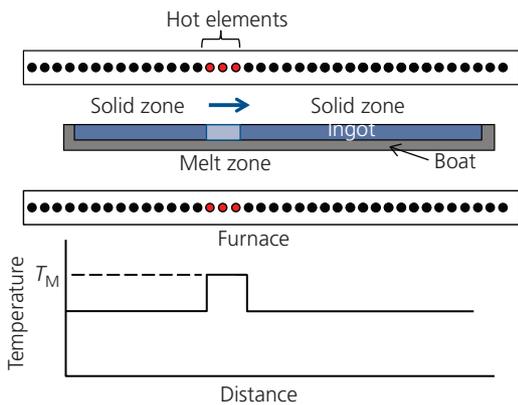

The highest purity organic crystals have been achieved via *zone refining*—a situation that also obtains for inorganic semiconductors (Hoesterey and Letson, 1963, Warta et al., 1985). Zone refining is suitable for materials that undergo a liquid phase when heated. Thus, its application has been limited since a large fraction of the useful organic semiconductors go directly from the solid to the gas phase on heating at atmospheric pressure or below (i.e. they *sublime*). Zone refining takes advantage of the difference in the saturated impurity concentration in the source between its liquid and solid phases. The equilibrium concentration of an impurity at temperature,  $T$ , is given by its *distribution* (or *segregation*) *coefficient*,  $k$ . That is, if  $c_S$  is the mole fraction of the impurity in the solid and  $c_L$  is that in the liquid, then,

$$k = \frac{c_S}{c_L}. \quad (5.2)$$

By melting a local region of a solid ingot of the source material in a thermally resistant boat (consisting of graphite, quartz, alumina, etc.), and then translating the melted zone along its length, impurities either collect in the melted or the solid zone, depending on whether  $k < 1$  or  $k > 1$ , respectively. That is, when  $k < 1$ , the mixed impurity/source phase has a lower melting point (at temperature,  $T_M$ ) than the pure host, and hence the impurities remain in the melted zone as it is slowly, thermally dragged along the length of the ingot, as shown in Fig. 5.2. For an impurity diffusion constant  $D_I$  and a melt interface of width  $w$ , the speed of zone translation must be kept below  $v = D_I/w$  to assure efficient segregation of the impurities from the source. Once the end of the ingot is reached, the zone containing the highest concentration of impurities is removed (Fig. 5.3). The process can be repeated multiple times to continually increase the purity of the source.

This method of isolating impurities can be applied as long as their concentration is low, and that different species do not interact to impact their several distribution coefficients in the host. Furthermore, if the contaminant and host form a *eutectic*, zone refining cannot be employed. Eutectics, however, require a high concentration of both species where zone refining is ineffective.

The impurity concentration in the ingot at zone position,  $x$ , along its length  $L$  after the  $n$ th zone

**Figure 5.2** Schematic of a zone refining apparatus. The solid source material ingot is contained in a thermally resistant boat inserted into a linear furnace. A selected group of heating elements (red circles) is heated to induce local melting at temperature  $T_M$  in the ingot. The hot zone is then slowly translated along the length of the ingot (arrow) until it reaches one end. When  $k < 1$ , the impurity concentration will be highest at the terminus of the ingot. This section of the ingot is removed to eliminate the segregated impurities. The process is repeated until a suitably high purity is achieved. The temperature profile in the furnace at a given time in the process is shown in the lower graph.

refining cycle is  $c_n(x)$ . Here,  $x$  is an integer index of the zone at that position along the furnace. Here,  $x = 0$  indexes the initial zone, and  $N$  is the final zone in a furnace  $N$  zones long. It follows that the length of each melt zone is  $l = L/N$ . If the zone is translated a distance  $x$ , then the change in concentration in the solid zone is

$$dc_n(x) = k[c_{n-1}(x + 1) - c_n(x)]dx, \quad 0 \leq x \leq N - 1. \quad (5.3)$$

That is,  $c_{n-1}(x + 1)$  is the concentration in the next solid zone ( $x + 1$ ) that achieved a concentration,  $c_{n-1}$  in the previous cycle. Then, at the end of the ingot where  $x = L$ , we have in the last increment:

$$\frac{dc_n(x)}{dx} = \frac{1 - k}{N - x} c_n(x), \quad N - 1 \leq x \leq N. \quad (5.4)$$

After a single pass ( $n = 1$ ), solutions to Eqs. 5.3 and 5.4 are, respectively,

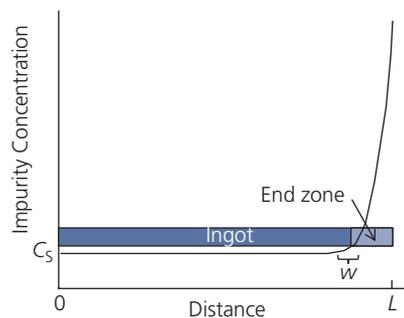

$$c_1(x) = 1 - (1 - k)\exp(-kx), \quad 0 \leq x \leq N - 1, \quad (5.5)$$

and

$$c_1(x) = c_1(N - 1) \cdot (N - x)^{k-1} \quad N - 1 \leq x \leq N \quad (5.6)$$

Since  $N > x$  and  $k < 1$  under the most common circumstance where the melting temperature is lowered by the introduction of impurities, we see that  $c_1(x > N - 1)$  in the end zone (Eq. 5.6) is greater than  $c_1(x)$  along the ingot (Eq. 5.5). A further implication is that, as  $k \rightarrow 1$ , then  $c_1(N) \rightarrow c(x < N)$ , that is, purification is ineffective since there is no means to segregate the impurity by melting the host.

As previously, the zone refining process is iterative, with each additional cycle removing more of the remaining impurities. Hence it is interesting to determine the highest purity that can be attained after an unlimited number of zone refining steps. For this

**Figure 5.3** Impurity concentration profile of an ingot of length  $L$  following zone refining. Here,  $w$  is the approximate width of the liquid-solid interface during zone refining, and  $c_s$  is the concentration of impurities in the solid host following refinement.

calculation, we assume that  $k < 1$ , and the impurity concentration is sufficiently low that  $k$  is unaffected as the material purity is increased. Complications arise since the concentration  $c_n$  depends on the concentration  $c_{n-1}$  following the procedure for a single zone refining cycle (Helfand and Kornegay, 1966). Derivation of the highest purity obtained (at  $n \rightarrow \infty$ ) for a given distribution coefficient can be found elsewhere (see Problem 4.1); here we will simply report the result (Pfann, 1966):

$$c_{n \rightarrow \infty}(x) = k_1 \exp(k_2 x), \quad (5.7)$$

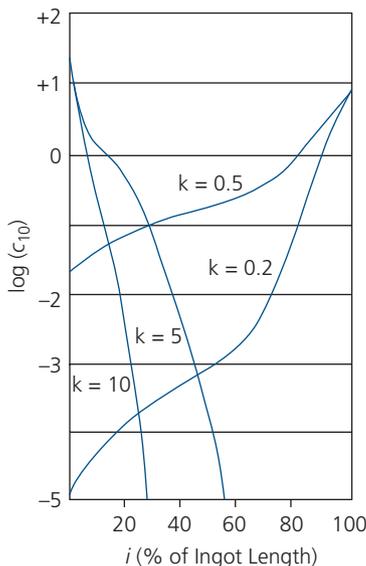

where  $k_1$  and  $k_2$  depend implicitly on  $k$ , viz.:

$$k = \frac{k_2}{(\exp(k_2) - 1)} \quad (5.8)$$

and

$$k_1 = \frac{N k_2}{(\exp(N k_2) - 1)}. \quad (5.9)$$

As  $x \rightarrow N$ , the impurity concentration in the end zone rises exponentially. Since impurities are distributed along the length of the ingot, the ultimate material purity is determined by how much of the source material is discarded. This tradeoff is illustrated in Fig. 5.4 (Karl, 1980). Note that for  $k > 1$ , the impurity *increases* the melting point, and hence is preferentially incorporated into the solid. Then, the impurity concentration is highest at the beginning of the ingot, in

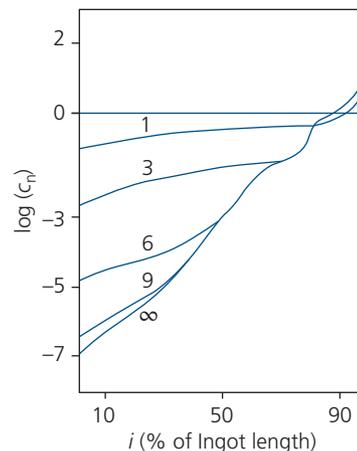

**Figure 5.4** Impurity concentration after ten zone refining cycles (for  $n = 10$ ) vs. distance along the ingot for several different values of distribution coefficient,  $k$  (Karl, 1980).

contrast to  $k < 1$  where impurities concentrate at the end of the ingot.

Finally, it is useful to determine how many zone passes are required to obtain an *acceptable* purity concentration. In Fig. 5.5, therefore, we show the purity for the case of  $k = 0.1$  and the number of zones is  $N = 5$ , and the number of passes varies from  $n = 1$  to  $\infty$  (Karl, 1980). We observe that  $c_1$  is nearly 10 times smaller than  $c_0$ , and that  $c_9 \approx 10^{-6} c_0$ . Clearly, for these conditions there is little reason to proceed beyond nine zone refinement steps, setting a practical limit on the level of purity attainable.

Zone refining can be implemented in both horizontal and vertical furnaces. Typically, the ingot is maintained in an inert atmosphere to prevent contamination of the source material due to environmental exposure at elevated temperatures. For many materials that sublime at atmospheric pressure, the sample can be refined by increasing the pressure such that the source undergoes a solid-liquid transition. To accelerate the refinement rate, many closely spaced zones are used, with several zones simultaneously heated above the melting point, separated by zones that allow the intervening regions to cool and freeze. In this way, multiple zones undergo refinement in a single pass. Very cold regions must be avoided since evaporation of the source and impurities from the heated zones will tend to condense on these cold spots. Then, subsequent passes of the hot zone will re-evaporate the condensate, potentially reintroducing contamination back into previously purified regions of the ingot. Finally, the hot zones must be kept at temperatures well below the decomposition point of the source material.

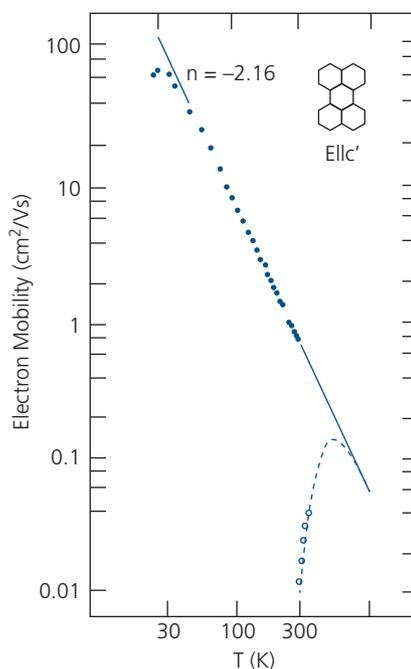

**Figure 5.5** Impurity concentration vs. distance along the length of the ingot as a function of the number of zone refining cycles (for  $n = 1, 3, 6, 9, \infty$ ). For this calculation,  $N = 5$  and  $k = 0.1$  (Karl, 1980).

There are several considerations that must be addressed to achieve the highest possible purities. The most important is the speed of zone movement. As noted, the speed cannot be higher than the rate of diffusion from the melt to the solid phases across the interfacial zone. Since many impurity diffusion coefficients range from  $D \sim 10^{-3}$ – $10^{-6}$  cm<sup>2</sup>/s, and a typical interface width is  $w \sim 0.1$  mm in a precision zone refining apparatus, zone translation velocities of  $v \sim 10^{-5}$ – $10^{-7}$  cm/s are optimal. Thus, a 10 cm long ingot may take as long as 2 years to purify! Furthermore, the rate must be sufficiently slow to avoid accumulation of crystal defects and even bubbles at the melt interface due to thermal expansion, rapid cooling, etc. Such defects can accumulate, or *getter*, impurities, thereby preventing them from following the melted zone. Zone refining is therefore a slow and laborious process requiring an automated furnace consisting of many (10–100) short, and precisely controlled temperature zones. In spite of these shortcomings, zone refining has the potential of achieving the highest materials purity.

Warta and Karl have produced what are arguably the highest purity, electronic grade organic crystals via meticulous zone refining of perylene and naphthalene combined with several pre-purification steps (Warta et al., 1985). In that work, the source material was initially purified by column chromatography and vacuum sublimation, to be discussed below. This was followed by an initial single zone refining step in an apparatus comprised of 100 separate zones that thermally transited the ingot at 1 cm/h. After this, the impurity concentrations of b-methylnaphthalene and thionaphthalene were at 1 ppm. At this concentration,  $k \approx 1$ , making further purification impossible. Thus, the source was subsequently exposed to molten potassium that reacts with the impurities to form products with significantly lower distribution coefficients. The material exposed to this impurity reaction process was then “ultrapurified” in three additional zone refining steps using an apparatus with 500 zones.

The purified materials were grown into single crystals from the melt via the vertical Bridgman process (see Section 5.4.1). The electronic properties of the crystals were characterized to assess their quality. This process, although time consuming, resulted in low temperature hole mobilities of 400 cm<sup>2</sup>/V s at  $T < 30$  K for naphthalene, and 80 cm<sup>2</sup>/V s at  $T = 30$  K for perylene; the highest yet reported for an organic solid (Section 4.4.3). The electron mobility in perylene vs.  $T$  increases monotonically until  $T = 30$  K, where it peaks at  $\mu_e = 80$  cm<sup>2</sup>/V s, as shown in Fig. 5.6. It follows a power law dependence of  $\mu \sim T^{-n}$  clearly indicative of band-like conductivity (Section 4.3). This is in striking

**Figure 5.6** Electron mobility vs. temperature for a zone refined perylene crystal along its  $c'$  crystal axis (closed dots). Also shown are data for the same material that was not zone refined (open dots). The mobility has a temperature dependence of  $\mu \sim T^{-n}$  (Warta et al., 1985).

contrast to a sample that was not as thoroughly purified, with peak of  $\mu_e \sim 0.08$  cm<sup>2</sup>/V s at room temperature (Maruyama et al., 1973).

The effect of traps of density  $N_T$  in a host of density  $N_H$  on the mobility can be derived using Shockley-Reed-Hall recombination statistics to yield (Hoesterey and Letson, 1963, Sze, 1981)

$$\mu(T) = \mu_0(T)[1 + N_T/N_H \exp(\Delta E/k_B T)]^{-1}, \quad (5.10)$$

where  $\mu_0$  is the trap-free mobility,  $\Delta E = |E_T - E_{FO}|$  is the difference in the trap ( $E_T$ ) and the frontier orbital ( $E_{FO}$ ) energies (i.e. the LUMO for electrons, or the HOMO for holes), and  $k_B$  is the Boltzmann constant. Fits to the data in Fig. 5.6 using this relation are indicated by the solid and dashed lines. The analysis yields  $\Delta E = 270$  meV and  $N_T/N_H = 5 \times 10^{-4}$  mol/mol for the ultrapurified crystal, and 17.5 meV and  $1.7 \times 10^{-3}$  mol/mol for the lightly purified film. Hence, the trap density is not only lower in the ultrapurified sample, but it lies deeper in the energy gap. Hence, the traps are frozen out at low temperatures, leading to a significant thermal activation and an increase in  $\mu_e$ . The source of the traps may be due to impurities or structural defects;

two factors that can be related. That is, interstitial defects can result in stacking faults, leading to trap energies lying deep within the energy gap that determines the temperature dependence of the mobility in Fig. 5.6. In any case, it is clear that zone refining can result in high purity crystals whose properties are largely determined by the *intrinsic* characteristics of the host rather than by extrinsic, impurity-related effects.

### 5.3.2 Thermal gradient sublimation

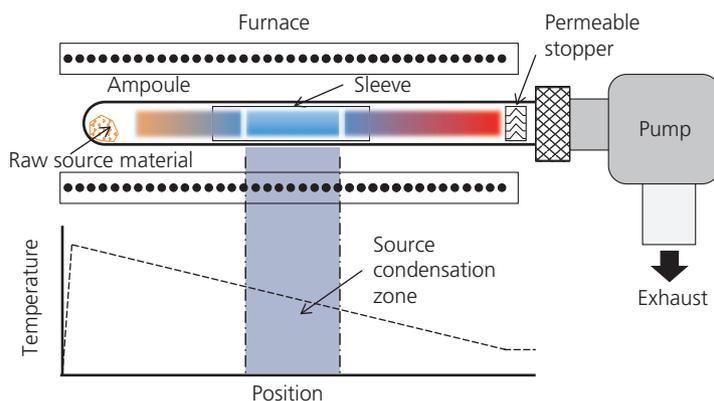

Since a significant number of materials used in organic electronic applications sublime rather than melt at atmospheric pressure or below, the most commonly used means for purification is *thermal gradient sublimation* (Gutmann and Lyons, 1981, Forrest, 1997). Thermal gradient sublimation is a variant of zone refining based on different distribution coefficients of the impurity and host during a solid-gas phase transition. A schematic of a gradient sublimation apparatus is shown in Fig. 5.7.

The purification process typically proceeds as follows. Several grams of the unpurified source material are loaded into the end of a long glass ampoule closed at one end, with the open end connected to a vacuum pump. A glass sleeve is placed inside the tube to capture the sublimed material, and a wad of glass wool or other semi-permeable membrane (e.g. an alumina plug) is positioned adjacent to the vacuum port to prevent the solid (powder) source material from blowing into, and contaminating the pump. The tube is evacuated to  $< 1 \times 10^{-6}$  torr using a turbomolecular or another dry pump. Conventional organic pump oils used in rotary or diffusion pumps are avoided since they can back-stream into the ampoule and

contaminate and/or react with the source material. The end containing the source material is inserted into a tube furnace that consists of several separately controlled zone heaters (typically between 3 and 5) that are adjusted to impose an approximately linear temperature gradient along the tube longitudinal axis. The source material lies in the hottest zone whose temperature should be lower than the source decomposition temperature.

To begin the process, the maximum temperature is adjusted until the pressure within the tube shows a slight increase, indicating that the evaporation of the most volatile impurities has commenced. Once the pressure returns to the base pressure of the cold system (often taking several hours or more), the temperature is incrementally increased across the gradient once again, and the process of waiting for the pressure to return to its base value is repeated. This cycle is iterated until the purified source material is condensed along a band within the sleeve in the glass tube, and the pressure no longer rises significantly when the temperature is incrementally raised one last time. At this point, most volatile impurities are either condensed in the tube cold zones, or have been extracted by the vacuum pump. The less volatile impurities remain in the hottest zones, or at the position where the source material was originally placed at the closed end of the tube.

The sleeve insert is then removed, and the deposit is extracted and used as the source material by placing it in a freshly cleaned ampoule for a subsequent purification cycle carried out in the same way. The purest organic compounds are obtained after multiple cycles, when there is no significant pressure increase after incrementally raising the furnace temperature. After

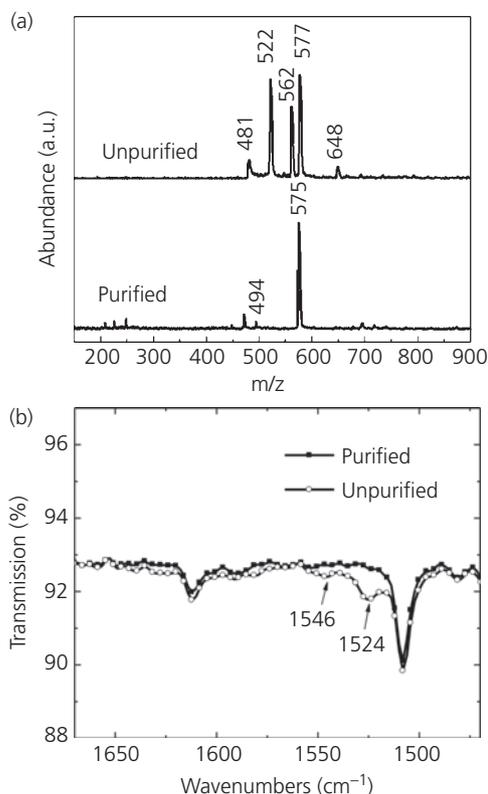

**Figure 5.7** Schematic of a vacuum thermal gradient sublimation apparatus. The furnace consists of several (typically 3–5) independently controlled thermal zones to create a temperature gradient. The purified material condensate is captured in a glass or quartz sleeve inserted into the appropriate zone within the furnace. The purified source is shown in blue; other colors along the tube length suggest condensation of impurity-rich fractions.

concluding the process, typically  $\sim 50\%$  of the original source material has been removed, and the background pressure of the sublimation system approaches  $\sim 10^{-7}$  torr. Often there are losses of the source along with the impurities, making this process somewhat inefficient.

The success of sublimation purification requires that there is a significant difference between the sublimation temperatures of the source and its impurities. This is analogous to requiring a difference in distribution coefficients for zone refining. Furthermore, the sublimation and decomposition temperatures of the host must also be substantially different to avoid degradation of the source. Given the poorly defined width of the source condensation zone (see Fig. 5.7), impurities and host are often intermingled, particularly at the zone edges. This problem can be somewhat reduced although not eliminated by increasing the temperature gradient on each purification cycle. If the process is done quickly, the host condensate will be amorphous. If it proceeds more slowly, single crystalline flakes can deposit within the sleeve. Finally, it is important that the temperature gradient, particularly in the region both in front of, and behind the starting source material, monotonically decrease toward the cold end of the ampoule. This ensures that condensation at a cold, closed end of the tube does not scavenge material that would otherwise be deposited within the capture sleeve.

The differences between single cycle vacuum gradient sublimed and unpurified CuPc materials used in organic photovoltaics are shown in Fig. 5.8. Using a combination of mass spectrometry and Fourier transform infrared (FTIR) spectroscopy, it is apparent that the unpurified source material (labeled as 98% pure by mass, by the manufacturer) has a high concentration of the metal free phthalocyanine ( $H_2Pc$ ) along with some CuPc fractions that are completely absent in the purified material (Salzman et al., 2005).

Interestingly, film deposition by *vacuum thermal evaporation* (VTE, see Section 5.4.2) can also be used for thermal gradient purification, although this is inefficient. When unpurified or partially purified material is evaporated in vacuum prior to, or even during thin film deposition, the first deposit will have a higher concentration of volatile impurities than in subsequently deposited films since the source is partially purified by the previous deposition cycles. Purification during thermal evaporation results in an increase in the room temperature hole mobilities of a series of CuPc films sequentially deposited in vacuum from the same source, as shown in Fig. 5.9 (Salzman et al., 2005). Between the first and sixth

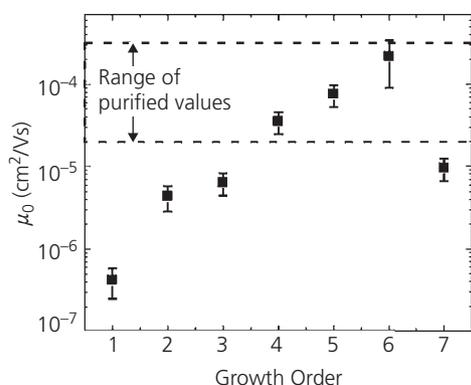

**Figure 5.8** (a) Mass (in atomic number,  $Z$ ) and (b) infrared spectra for CuPc as-purchased, and after a single purification cycle by thermal gradient sublimation of CuPc. The additional peaks in the unpurified samples are associated with  $H_2Pc$  (at  $m = 522$  amu) and other impurity fractions compared to the purified CuPc, with peaks at  $m = 575$  amu in the mass spectra and infrared peaks at  $\sim 1510$   $cm^{-1}$  and  $1615$   $cm^{-1}$  (Salzman et al., 2005).

depositions from an originally unpurified batch of CuPc, the mobility increases by nearly three orders of magnitude, from  $4 \times 10^{-7}$   $cm^2/V$  s for growth #1 to  $3 \times 10^{-4}$   $cm^2/V$  s for growth #6. These data indicate the effectiveness of purification via sublimation even under the poorly controlled conditions of *in situ* VTE.

There are numerous variants to the process described above. For example, sublimation can occur in an inert gas environment as opposed to vacuum (Wagner et al., 1982, Laudise et al., 1998). Sublimation often results in purified single crystal flakes, discussed further in Section 5.4.1. Sublimation in an inert gas has been used to achieve both pristine and doped materials with exceptional electrical properties, suggesting the effectiveness of this method (Laudise et al., 1998, Hiramoto and Sakai, 2008). A particular advantage of using an inert carrier gas is the reduction of condensation behind the source in

**Figure 5.9** Hole mobility (measured via space charge limited current–voltage characteristics, Section 4.4.2) vs. order of thin film growth by vacuum deposition of an unpurified CuPc source. Also shown is the range of mobility obtained for CuPc purified by a conventional single thermal gradient sublimation step (Salzman et al., 2005).

the cold region at the furnace opening by forcing mass transport along the gas flow direction. Using an inert carrier gas can also increase the rate of material transport, hence leading to a shorter time for purification.

Gradient sublimation can also be achieved by completely filling the ampoule with a plug of source material, and then vaporizing a single zone within the plug. Moving the vaporized region toward one end of the plug is analogous to zone refining. It moves those impurities with different distribution coefficients in the vapor vs. the solid to an extreme end of the plug once the zone has been completely transited by the thermal gradient (Weinberg and Rossi, 1960). Care must be taken to avoid decomposing the source, or in translating the hot zone too rapidly such that there is incomplete segregation of the impurities.

To further improve impurity separation, a series of partitions, or baffles, can replace the inner sleeve along the length of the thermal gradient, as shown in Fig. 5.10. The baffles “digitally” separate the impurity fractions by allowing condensation to occur in discretely defined temperature zones along the thermal gradient. Since there is condensation both on the partitions and on the furnace tube walls, a tradeoff must be made between material yield and the level of purity of the refined source material (Jeon et al., 2008).

### 5.3.3 Solution-based purification methods

There are several methods of purifying materials using solvent-based mass selection, distillation and

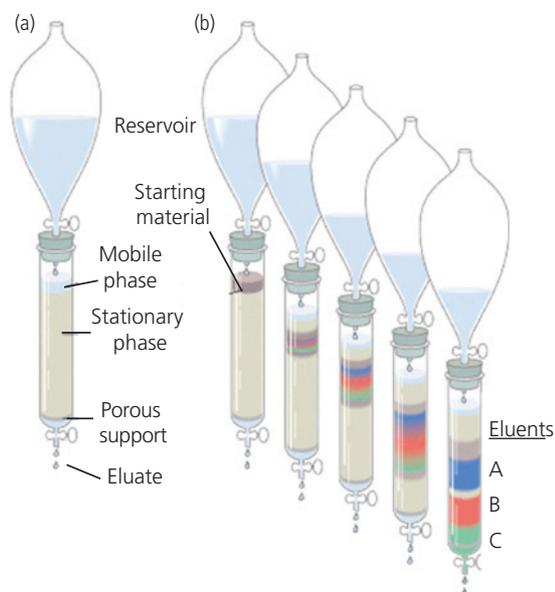

**Figure 5.10** Gradient sublimation apparatus using a five-zone furnace with a series of partitions inserted within the thermal gradient. The various material fractions found in the source selectively deposit on baffles located at their particular condensation temperatures. The baffles located in zones where source condensation is favored contain the purified material (Jeon et al., 2008). Reprinted from *Org. Electron.*, 9, 903, Jeon, H.-G., Inoue, M., Hiramatsu, N., Ichikawa, M. & Taniguchi, Y., A modified sublimation purification system using arrays of partitions, copyright 2008 with permission from Elsevier.

filtration. These techniques have the advantage of being rapid compared to vapor sublimation and zone refining, and are compatible with both small molecules and polymers. Their disadvantage is that the level of purity achieved is not nearly as high as the upper limits attained using zone refining and thermal gradient sublimation. As noted above, solvent purification is often used as a means for preparing crude source materials for subsequent purification by other more rigorous methods.

Solution based purification has many variants. Here we discuss the three most commonly used in the refinement of organic electronic materials: column chromatography (or simply, chromatography), *size exclusion chromatography* (SEC), and *solvent extraction*. It will become apparent that the principles of these methods are not significantly different than those of sublimation and zone refining: the concept relies on spatially segregating unwanted impurities from the host material by leveraging differences in their ability to be dissolved in a particular solvent. Hence, solvent selectivity (versus temperature selectivity) becomes the determining factor that leads to purity of the source.

Column chromatography was introduced in the early twentieth century by M. S. Tswett who was developing techniques for separating chlorophyll from plants (Gehrke et al., 2001). The process relies on introducing a solution containing the impure source in a column packed with a porous material that selectively captures various solute impurities for different durations. A schematic of the process is shown in Fig. 5.11. The unpurified source is dissolved in a solvent, called the *mobile phase*. This solution is

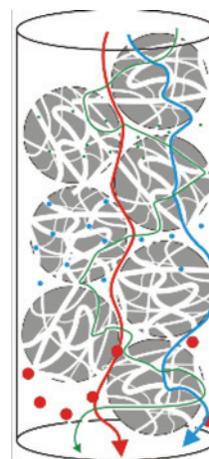

**Figure 5.11** Schematic of column chromatography distillation. (a) Initial set up; (b) time progression of eluents as they move along the column, resulting in separate bands (labelled A, B, C) moving at different velocities that are collected at the exit of the column (Ebioe, 2010).

placed on top of a column packed with a solid absorbent called the *stationary phase*. Typically, the absorbent is comprised of silica ( $\text{SiO}_2$ ) or alumina ( $\text{Al}_2\text{O}_3$ ) beads only a few tens of microns in diameter. The molecular species and their solvents are trapped for differing lengths of time on the particles in the column, depending on their polarizability. Hence, highly “sticky” dipolar fractions, known as *eluents*, will take longer to travel along the column to its exit than will the less polar eluents. By capturing the eluate at different times following their introduction into the column, different materials are collected, thus allowing for separation of the purified source (McGhie, 1974).

When gravity is relied upon to move the solution along the column, the process is known as *gravity column chromatography*. This method tends to be slow, although multiple large diameter columns operating in parallel can be used to significantly expedite the purification of large volumes of the source. Applying pressure with an inert gas can significantly accelerate the process. This is known variously as *flash chromatography*, or *high performance (or high pressure) liquid chromatography* (HPLC).

The effectiveness of column chromatography depends on the degree to which impurity and source transit times through the column differ. This in turn depends on the adsorption rates on the beads within the column, and the polarity (or non-polarity) of the

**Figure 5.12** Schematic of the size exclusion chromatography separation process. The column is filled with beads of varying pore sizes. Small particles penetrate the smallest pores (green line) while the largest particles pass between the beads. The length of the path taken determines the duration a given size population spends within the column: smaller particles take the longest, and the largest particles transit at the highest average velocity (Li et al., 2013).

eluent. Indeed, improved selectivity can be obtained by slowly varying the polarity of the solvent introduced from the reservoir as the process evolves. While this process is useful for both polymers and small molecules, the degree of segregation of source from impurity is never high since non-polar impurities are uniformly dispersed along the column, and the distribution of any given species along the column is a rather broad Gaussian determined by its particular retention time.

Size exclusion chromatography is effective for separating polymers according to their hydrodynamic volume (Moore, 1964). Size exclusion (also known as *gel filtration* or *gel permeation chromatography*) is primarily used to narrow a polydisperse distribution of macromolecules, such as polymer chains of varying mass. It is also capable of separating low molecular weight impurities from the source. Like column chromatography, the process sorts molecules based on differences in their transit times through a column of porous beads, as illustrated in Fig. 5.12. For example, a mixture of polymers of varying molecular weights is introduced into the top of the column. Unlike column chromatography, the molecules themselves do not interact with the beads, that is, there is no trapping or sticking on the surface of the stationary phase that retards their transit. Rather, the size of the molecule determines the path length that is sampled: larger

molecules that cannot penetrate into the pores of the spheres transit the column via the interstices between them, whereas smaller molecules can enter the pores within the beads (as well as the interstices) and hence will sample a greater volume of the column before exiting. The largest particles exit first, followed by distributions of successively smaller molecules, thereby effecting their separation. The eluent populations are Gaussian distributions of molecular size, and the pore sizes define the resolution limits of the process. Molecular populations with masses above the exclusion limit are not differentiated by transit times, with a similar situation obtaining for molecules smaller than the smallest pores in the stationary phase. In that case, the molecules are smaller than the permeation limit.

The transit times in SEC are accurately determined using the hydrodynamic volume ( $V_H$ ) of the molecules. Here,  $V_H$  is the volume of the polymer coil in the solvent that is determined by the details of the interactions between the polymer and solvent. The hydrodynamic volume can be written in terms of the Einstein viscosity law, viz. (Grubisic et al., 1967)

$$V_H = K\eta M_w. \quad (5.11)$$

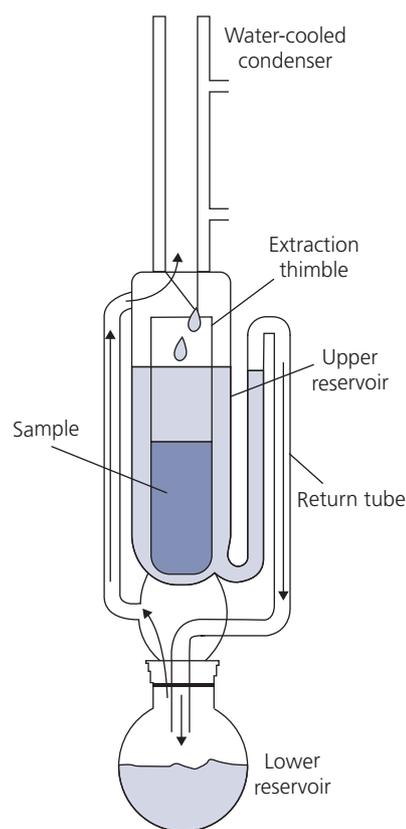

Here,  $\eta$  is the viscosity,  $K$  is a constant, and  $M_w$  is the molecular weight. That is, the viscosity of the material in solution, which determines its transit time through the column, is directly proportional to its hydrodynamic volume. Indeed, this relationship holds for polymers (and even mixtures of polymers and small molecules) independent of their shape, chemical composition or morphology as long as they do not undergo electrostatic or other interactions with the beads in solution, as is typically the case in conventional column chromatography.

The resolution of the process is determined by the differences in particle velocity, which is a function of temperature. Since separation is determined by the elapsed time in the column, care must be taken to introduce the entire population of source and impurity molecules at one time. As with other methods, the best results are obtained when the crude material is first purified by other means before being sorted by SEC. Due to its simplicity and utility in purifying and isolating molecular populations by mass, SEC is frequently employed in the refinement of polymers (Ashraf et al., 2013, Mateker et al., 2013).

Another solution purification technique that is used for both large and small molecules is solvent extraction. Extraction is a means of filtration, or washing of the host materials, and hence is effective when used as a pre-purification step of the crude source material.

A convenient implementation uses a Soxhlet distillation apparatus, shown in Fig. 5.13. The crude source material is placed in a semi-porous extraction thimble consisting of alumina, or filter paper. A high boiling point, pure solvent is placed in the lower reservoir. Extraction can proceed by two paths. If the desired product is insoluble, it remains in the thimble, while the impurities wash through to be collected in the reservoir. Alternatively, if the product itself is soluble, it is dissolved and collects in the reservoir.

Solvent extraction has been used in the purification of PTCDA that is insoluble in xylene (with a boiling point of 140°C). Purification then proceeds as follows: The solvent is heated to its boiling point. The vapors travel up the tube on the left in Fig. 5.13 and are cooled in the condenser. The distilled solvent then flows into the upper reservoir where it dissolves the impurities in the source powder. This solvent/impurity solution flows out of the thimble, and into the upper reservoir. With time, the upper reservoir fills to the top of the return tube, at which point the reservoir siphons into the lower reservoir, and the extraction cycle is repeated. In the case of PTCDA (a red powder), the xylene in the lower

**Figure 5.13** Soxhlet solvent extraction apparatus.

**Table 5.1** Several high boiling point (BP) solvents useful in solvent extraction

Solvent	BP (°C)	Solvent	BP (°C)

Dimethyl formamide	153.0	Xylene	140.0
Dimethyl sulfoxide	189.0		

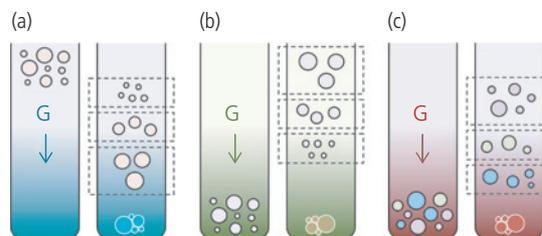

reservoir becomes saturated with impurities after several cycles, turning from clear to an opaque greenish color. Once the solvent becomes excessively contaminated, it is replaced by fresh liquid. This process is continued until there is no more visible contamination of the solvent after several reflux cycles; a procedure that may take hours or days, depending on the level of contamination of the crude material. At the end of the extraction process, the remaining material is dried and prepared for use, or for further purification.

To remove as many soluble impurities as possible, both polar and non-polar solvents may be sequentially used. Table 5.1 lists several common solvents used in extraction purification. This method can only succeed if there is a difference in solubility between the source and the impurities. Hence, high purity materials can only be obtained when solvent extraction is used in conjunction with other, more rigorous processes such as thermal gradient sublimation or zone refining.

### 5.3.4 Ultracentrifugation

*Centrifugation* separates materials having different hydrodynamic volumes or masses suspended in solution by applying a strong, directional force to the suspension by rapid rotary motion. *Ultracentrifugation* is a class of centrifugation where  $>5000g$  (where  $g$  is the acceleration due to gravity) is applied to the sample. Another variant known as *density gradient ultracentrifugation* (DGU) (Miller et al., 2014) is employed in separating semiconductor and metallic nanoparticles useful in colloids, and in separating single from multi-walled carbon nanotubes (CNTs). In principle, centrifugation can separate any sufficiently polydisperse population of materials such as polymers, proteins, and other macromolecules.

An illustration of DGU separation is shown in Fig. 5.14. A vial containing a fluid mixture with a

**Figure 5.14** Density gradient ultracentrifugation. A vial is filled with a solvent whose density is graded upward from its maximum at the bottom.  $G$  is the centrifugal force applied to a polydisperse population that is introduced at the top of the vial. After centrifugation, the volume-disperse population stratifies along the density gradient for particle densities that are: (a) higher, or (b) lower than that of the solvent. (c) Isopycnic DGU for particles of different *densities* (indicated by different color circles) that lie within the density extremes of the solution. The material at the bottom of each vial corresponds to separations of high density impurities (Miller et al., 2014).

density gradient is loaded with the population of particles with a range of hydrodynamic volumes or masses. If the particles are less dense than the liquid, they float to its surface; otherwise they sink (Figs. 5.14a and b, respectively). Ultracentrifugation at  $\sim 20,000$ – $80,000$  rpm results in stratification of the population into regions of different liquid density. If the population itself consists of particles of different densities, they will separate from (starting at the bottom) the most to the least dense species. High density impurities are trapped at the bottom of the vial. A micropipette is inserted at various distances within the container to extract the particles within a given stratum, thereby completing the separation process.

DGU creates a particle flux with terminal velocity  $v\hat{z}$  along the direction of acceleration,  $G\hat{z}$  of (Miller et al., 2014)

$$v = \frac{2GR^2}{9\eta_s}(\rho_c - \rho_s). \quad (5.12)$$

Here, the solution with density  $\rho_s$  and viscosity  $\eta_s$  contains a colloid of density  $\rho_c$  and radius  $R \sim V_H^{1/3}$ . From Eq. 5.12, successful separation depends on a large density “contrast” between solution and colloid, and that volumetric differences within a population will result in large spatial separations. For  $\rho_c > \rho_s$  (Fig. 5.14a), particles with smaller radii move more slowly than larger particles, and collect near the top of the fluid. For the opposite relationship between  $\rho_c$  and  $\rho_s$ , the velocity is negative, and the larger particles drift toward the top (Fig. 5.14b), with the smallest particles moving at the highest terminal velocity. *Isopycnic*

separation in Fig. 5.14c segregates particles of different densities along the solvent gradient independent of size.

The degree of separation between particles of different radii along the length of the vial can be obtained assuming conservation of mass of an incompressible fluid. Then the radius is:

$$R(z) = \sqrt{\frac{9\eta_s z}{2Gt|\rho_c - \rho_s|}}, \quad (5.13)$$

where  $z$  is the position. It is thus important to halt the process at a time,  $t < t_M$ , where the largest (smallest) particles in the solution with  $\rho_c > \rho_s$  ( $\rho_c < \rho_s$ ) have yet to travel the entire length of the vial. Note that since  $R$  depends on the hydrodynamic volume of the particle population, the particle shape also determines its position as a function of centrifugation time. For example, elongated nanowires are expected to distribute differently than would nanospheres. Indeed, in mixed particle shape populations, it has been shown that the increased friction of the wires leads to their collecting more toward the top of the solution as compared to spheres (Bai et al., 2010). Using *analytical centrifugation* where optical or other measurement tools are employed during the rotational separation, the particle size distribution,  $R(z)$  can be determined in real time, adding a degree of control to the process.

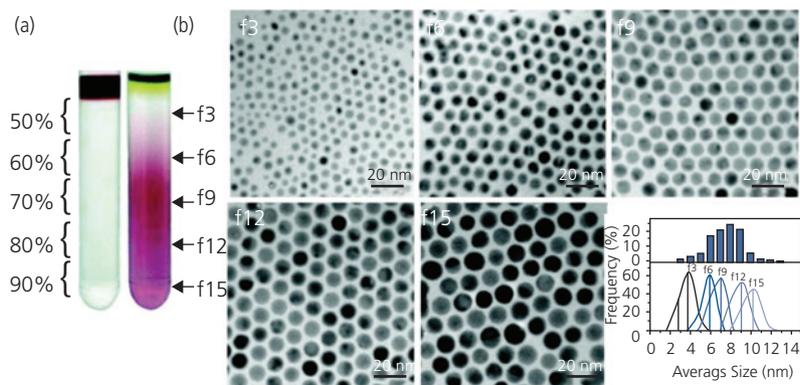

An example of separation of a polydisperse population of Au nanoparticles of varying diameters in a gradient of a mixture of cyclohexane in tetrachloromethane ( $\text{CCl}_4$ ) is shown in Fig. 5.15 (Bai et al., 2010). The solvents are useful in creating the separations, while also eliminating clustering by preventing

contact between the nanoparticles which would otherwise adhere to each other due to their attractive van der Waals forces.

The Au nanoparticle population stratification was obtained by centrifugation for 12 min at 25,000 rpm (corresponding to 80,000g). The size distributions before and after ultracentrifugation are shown at the lower right in Fig. 5.15b. The width of each diameter distribution is  $< 1.5$  nm, whereas the starting population had a width of  $\sim 12$  nm.

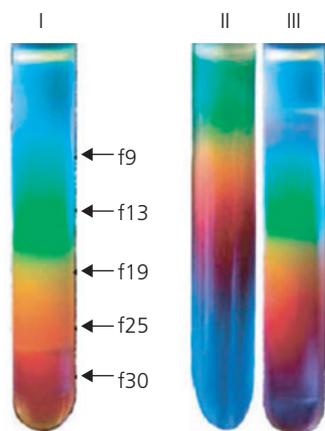

Semiconducting nanoparticles suspended in polymer matrices have found uses in light emitting devices (Coe et al., 2002) and photodetectors (Konstantatos and Sargent, 2010) (see Chapters 6 and 7). An advantage of DGU is that the polymer matrix can be dissolved in the solvent density gradient along with the particles forming the colloid. Both the polymer and the selected fraction of the distribution can be simultaneously decanted and subsequently used in devices. Figure 5.16 shows the results of DGU of a population of CdSe nanoparticles mixed with polystyrene in a solution gradient used in their separation. The nanoparticles range in radius from 2.5 nm to 5 nm.

DGU has also been used in separating populations of CNTs of varying diameters and conductive properties. Indeed, one of the major roadblocks to employing CNTs for electronic applications is often only a single type of tube is needed for a particular purpose. The efficient separation of tubes according to their chirality (and hence their conductive properties), and the elimination of bundles and clusters has impeded their widespread use in organic electronics applications. Nevertheless, mixtures of single-walled CNTs of different diameters and chiralities along with

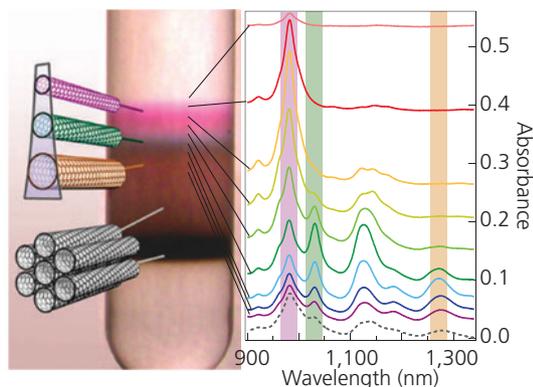

**Figure 5.15** (a) A stratified density gradient obtained by varying the mixture of two solvents, and then layering the mixtures in the vial. The positions of the bands of concentration of  $\text{CCl}_4$  mixed in cyclohexane are indicated, with the Au colloid on the surface (dark band). The stratified Au nanoparticle gradient after DGU is shown in the image on the right. (b) Images of the Au nanoparticle populations extracted from the corresponding positions in the vial. Scale bars are 20 nm. A histogram of the diameter distribution before DGU is shown in the upper graph at the lower right. The diameter distribution for each population shown after DGU is plotted in the lower graph (Bai et al., 2010).

bundles wrapped in surfactant molecules, have been effectively separated by DGU as in Fig. 5.17 (Arnold et al., 2006).

## 5.4 Bulk crystal and thin film growth

In this section we describe several methods to achieve high quality, ordered bulk and thin film

organic crystals, as well as amorphous films. The quality of the film ultimately depends not only on its purity, but also on its morphology. Since high purity is prerequisite to good device performance, we will henceforth assume that the materials source is adequately purified. Then, structural order results in improved energy (i.e. exciton) and charge transport, whereas amorphous materials often have higher luminescent efficiencies. Controlled doping during growth to increase the conductivity or modify the luminescent properties of materials is another means for achieving the desired properties. Hence, morphological control is an essential ingredient of all optoelectronic devices. Here, we concentrate on many ways to achieve this in bulk crystals as well as in thin films using vapor or liquid phase growth.

### 5.4.1 Bulk single crystal growth

Single crystals of covalently bonded materials are generally grown from the melt, and then the crystals are cut into thin slabs, or wafers. The wafers serve as seeds to the active epitaxial layers subsequently grown on their surfaces. Single crystalline layers are achieved via matching of the epitaxial lattice structure to that of the substrate (Section 2.6). This limits the choice of materials that can be compatibly grown without introducing strain defects into the epitaxial layer.

Due to the far higher elasticity of organic materials arising from their electrostatic (van der Waals) adhesive forces, a strict condition of lattice matching is not as important to achieve unstrained growth. Furthermore, given the enormous diversity of organic molecules and their equally diverse crystalline structures, it is often difficult to match the lattice of the epitaxy to that of the bulk crystal. When the compositions of the epitaxy and the substrate are the same, the growth is known as *homoepitaxy*. In contrast, *heteroepitaxy* refers to the situation when the compositions differ. Although the growth of bulk organic crystals has not received substantial attention in recent years, very pure, large ( $\sim 1 \text{ cm}^3$  or larger) single crystals are useful for understanding their fundamental electronic, linear and nonlinear optical, and mechanical properties, and their dependence on crystal direction. Single crystal growth also finds uses in laboratory-scale devices that can approach the fundamental limits to performance.

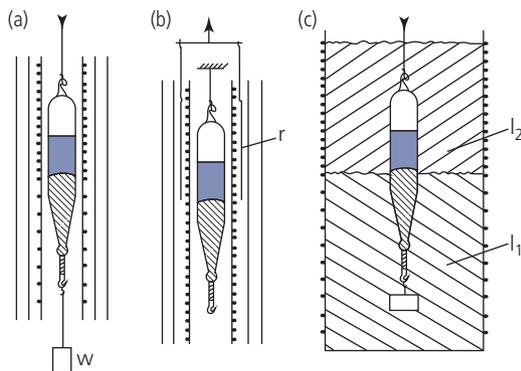

There are two principal methods for growing bulk crystals: *Bridgeman* and *Czochralski growth*. The Bridgeman method starts by inserting a sealed ampoule containing the purified source material into a tube furnace that supports an abrupt, although

small ( $<1^{\circ}\text{C}$ ) temperature step along its length (see Fig. 5.18 for three possible vertical Bridgeman configurations) (Karl, 1980). One region is cooled to just below the solidus temperature of the melt, the other, just above. This sharp temperature gradient can be created by using a multi-zone, or bias-wound furnace (Fig. 5.18a), or by placing a reflecting surface outside of the furnace windings that intensify the heat within its volume, as in Fig. 5.18b. Alternatively, in Fig. 5.18c, we show the ampoule inserted into a container with two immiscible liquids, and surrounded by a dual-zone heater. If the melting temperatures of the materials in solution are below that in the ampoule, they will conduct heat to the ampoule without intermixing (provided the temperature difference is small), thereby sustaining the needed temperature step gradient.

*Zone melting* is a variant of the Bridgeman technique. It uses a multi-zone furnace similar to that used in zone refining shown in Fig. 5.2. The crystal is grown and simultaneously purified by slowly translating the melted zone along the length of a polycrystalline or amorphous ingot.

In the Bridgeman method, a meniscus forms at the solid-liquid interface. The temperature step is slowly scanned ( $\sim 1\text{ mm/h}$ ) from one end of the ampoule to the other by either changing the position of the ampoule or the reflector. This increases the size of the crystal as the cooler region expands along its length. Great care must be taken to scan the growth front sufficiently slowly to ensure single crystal formation. Figure 5.19 shows an anthracene crystal grown by the Bridgeman method.

While in principle the Bridgeman process is simple, it has several shortcomings. Seeding the crystal

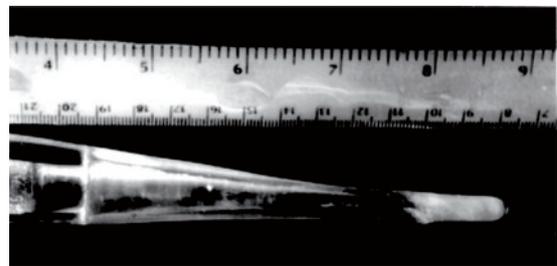

**Figure 5.18** Three configurations used in the vertical Bridgeman process. Suspension of an ampoule of material in a (a) bias-wound vertical furnace, (b) furnace with a translating cylindrical reflector; and (c) a reservoir containing two immiscible liquids,  $l_1$  and  $l_2$ . Here,  $w$  = weight used to draw the ampoule downward. The melt is indicated by the blue region, and the solid is cross-hatched.

growth occurs via spontaneous condensation of the supercooled solution at a nucleation site (e.g. an imperfection on the surface of the ampoule), and thus it is not possible to choose the crystal orientation along which growth proceeds. However, growth along a particular crystalline direction can be induced using a seed crystal inserted at the cold end of the ampoule, and the temperature is adjusted such that the seed does not fully dissolve at the onset of growth.

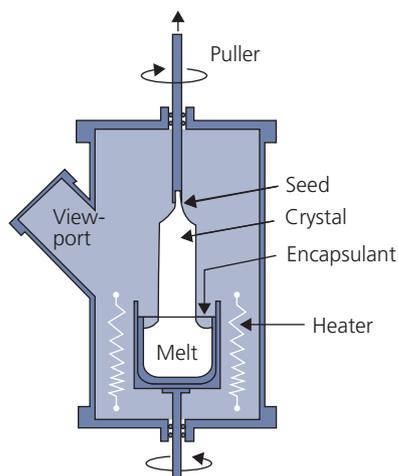

Due to self-seeding, the crystal can adhere to the ampoule wall, and must be carefully removed by either slight dissolving in solution, breaking the ampoule, or using a very thin knife blade inserted between the crystal and the ampoule wall; all methods that present risks of damage. Using an ampoule material whose coefficient of thermal expansion is smaller than that of the material it contains can also aid in separation on cooling to room temperature. However, thermal stresses introduced at the crystal/ampoule interface can propagate into the crystal, resulting in dislocations. Finally, as the growth front moves, impurities are segregated in the same manner used in zone refining. Given the different distribution coefficients of the impurity and the source material, the Bridgeman process does not allow for doping of the single crystals.

Many of these shortcomings are eliminated in Czochralski growth, commonly used for producing inorganic semiconductor single crystal boules. It was first introduced for organic crystals by the growth of benzyl and benzophenone (Bleay et al., 1978). The growth of a single crystal commences from a seed crystal positioned at the tip of a cooled needle, as shown in Fig. 5.20. The seed is lowered into a crucible heated to just above ( $\Delta T \sim 0.2\text{--}2^{\circ}\text{C}$ ) the melting temperature of the purified source material. It is then slowly withdrawn at speeds of  $0.1\text{--}1\text{ mm/h}$  from the melt into a

**Figure 5.19** An anthracene crystal grown by the Bridgeman process (Arulchakkaravarthi et al., 2002)

K., Santhanaraghavan, P., Jayavel, P., Selvan, R., Sivaji, K., Gopalakrishnan, R. & Ramasamy, P., Investigations on the growth of anthracene and trans-stilbene single crystals using vertical Bridgman technique copyright 2002 with permission from Elsevier.

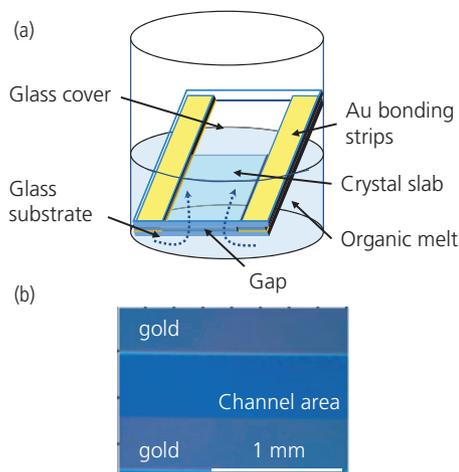

**Figure 5.20** Czochralski growth reactor showing its basic components (Singh, 2003).

chamber heated to just below the solidus temperature of the crystal. Slow “pulling” of the seed lifts the crystal from the melt; the speed determines both the perfection of the resulting boule, and its diameter (i.e. smaller diameter boules are grown as the pulling speed is increased). The vessel pressure is maintained by addition of gas into the chamber, thereby preventing decomposition or deposition of material onto the vessel walls. Multicomponent crystals and alloys can be grown under positive pressure to keep both constituents in the melt throughout the growth process.

Czochralski growth can result in crystals of many cubic centimeters in volume. By careful positioning of the seed crystal, growth can be initiated and maintained along any desired crystal axis. Finally, doped and heterogeneous crystals can be grown under the appropriate conditions of pressure and temperature.

Establishing single crystalline growth does not necessarily require the presence of a seed. For example, single crystalline anthracene has been grown in the gap formed between two glass slabs separated by 140 nm thick Au metal spacers, as illustrated in Fig. 5.21. The sandwich is placed in a container partially filled with molten anthracene in a nitrogen atmosphere at 240°C; slightly above its melting point. The liquid anthracene is drawn by capillary action into the channels between the Au strips, and crystallizes by decreasing the temperature at a rate of  $\sim 1^\circ\text{C}/\text{min}$ . Crystallization is initiated at the Au/liquid interface (Kéna-Cohen et al., 2008). For narrow channels ( $<3\ \mu\text{m}$  wide) and slow cooling ( $<1.5^\circ\text{C}/\text{min}$ ), the process reproducibly yields larger than centimeter-sized

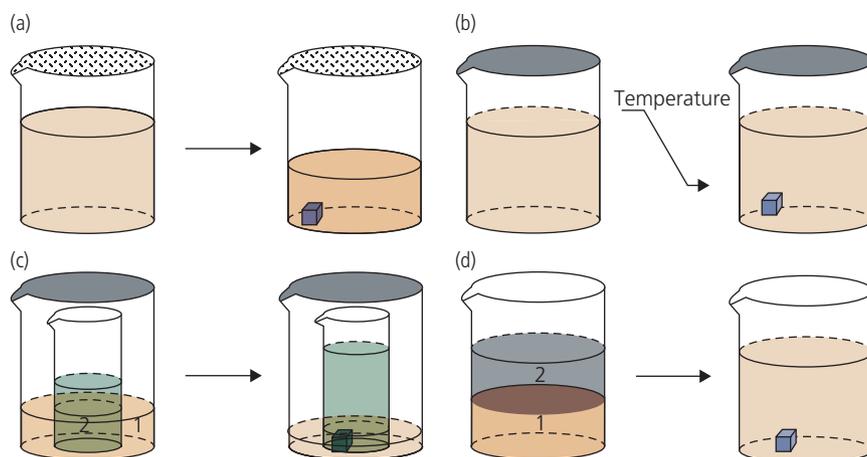

**Figure 5.21** (a) Growth of a thin, single crystalline organic slab between two glass sheets cold-weld bonded together by Au stripes. The sum of the thicknesses of the stripes on the substrate and cover determine the crystal thickness, and their separation its width. The molten solution of the source organic (the melt) is drawn by capillary action (dashed arrows) into the gap between the slabs. As the melt is cooled, the slab solidifies, nucleating at the edges of the Au strips. (b) Micrograph of a single crystal of anthracene grown in a channel between two Au bonding strips (Kéna-Cohen et al., 2008).

anthracene single crystal slabs. The crystallinity was confirmed by electron and x-ray diffraction that indicated the crystal **a** and **b** crystal axes lay in the glass substrate plane. For most of the channels, the **b**-axis was found to lie along, or very nearly along the channel length.

There are numerous variants for growth of small (microns to millimeters) crystals from the source material dissolved in a solvent such as DCM, chloroform, etc. Several solvent-assisted growth techniques are illustrated in Fig. 5.22. In the solvent evaporation method (Fig. 5.22a), the purified source material is dissolved, and then the solvent is allowed to slowly evaporate from a loosely covered beaker into a controlled atmosphere such as ultrapure nitrogen. At some point, the solution becomes supersaturated, and the organic material spontaneously condenses. Eventually, all the solvent evaporates, leaving behind a crystalline solid that is subsequently removed from the container. Solvent exclusion from the solid can also occur by slow cooling of the solution until it is supersaturated, similarly resulting in a polycrystalline precipitate, as shown in Fig. 5.22b.

Figure 5.22c illustrates the vapor diffusion method. Here, the source material is dissolved into a solvent (solvent 2) in which it is highly soluble, producing a supersaturated solution. The open

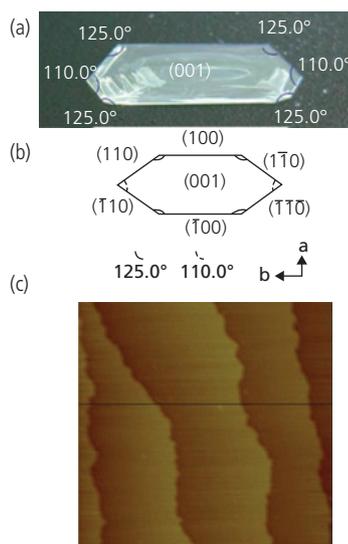

**Figure 5.22** Several methods for solvent-assisted single crystal growth. Growth by (a) solvent evaporation, (b) solvent cooling, (c) vapor diffusion, and (d) liquid interdiffusion in a solution containing two solvents, **1** and **2** (Jiang and Kloc, 2013).

Jiang, H. & Kloc, C. 2013. Single-crystal growth of organic semiconductors. MRS bulletin, 38, 28-33 reproduced with permission

vessel containing the solution is placed in a second, high volatility solvent (solvent **1**) in which the source material is less soluble. As solvent **1** evaporates, it enters the inner vessel, leading to supersaturation and eventual precipitation of the source. The rate of crystal growth can be controlled by temperature that varies the relative rates of evaporation of the two solvents. Liquid diffusion, shown in Fig. 5.22d, is similar to vapor diffusion, except that the two solvents, including one containing the source, are added to the same beaker. The two solutions interdiffuse at their interface. Since the solubility of the source is lower in solvent **1**, the interface becomes supersaturated, initiating growth. Growth continues until the two solvents are completely intermixed and the solute is exhausted. We will show in Section 8.7.1 that the liquid interdiffusion process results in high quality single crystal TIPS-pentacene microribbons employed as the channels in thin film transistors (Kim et al., 2007).

Solvent-assisted growth has the advantages of being simple to implement, and it allows for the direct observation of growth as the solvent evaporates. However, it is difficult to control and almost invariably results in polycrystalline growth since there is no well-defined seeding process. The solvent must be completely removed and highly pure to ensure good quality crystal growth with a minimum of point defects, impurity incorporation, high angle grain boundaries, and so on. Also, it is difficult if not impossible in most circumstances to uniformly dope the crystal since impurity incorporation depends on the distribution coefficients of the various constituents. The coefficients are a function of the relative

**Figure 5.23** (a) Approximately 1 cm long single anthracene crystal grown by slow evaporation from solution. (b) Identification of lattice planes of the crystal in (a). (c) Atomic force microscope image of the (001) surface of the crystal. A terrace structure is observed. Each step in the terrace is one monolayer high. (Zhang et al., 2009)

concentrations of the dopant, host and solvent which varies continuously as the solvent and solute are depleted.

An example of anthracene crystals grown from solution is shown in Fig. 5.23. Several crystals, ranging in size from millimeters to >2 cm, were harvested

from a solution that was allowed to evaporate for 4 weeks. Importantly, the growth proceeded layer-by-layer, which results in stepwise terraces on the crystal surface. The terrace height was found to equal  $d_{001} = 0.92$  nm of the bulk crystal lattice. Each terrace length is approximately 1.5  $\mu\text{m}$  long, providing a slight relief to the (100) plane (Zhang et al., 2009).

Growth along a particular crystal axis is achieved by placing a seed within the supersaturated solution with only a single crystal face exposed to the liquid. This imposes growth along the direction facing the liquid. Then, by controlling the solution temperature, growth rates of  $\sim 1$  mm/h can result in highly uniform and large single crystals (see Fig. 5.24).

Vapor phase growth, also known as *physical vapor transport* (PVT) growth, is done in vacuum or in the presence of a dilute, ultrapure carrier gas such as  $\text{H}_2$ , Ar, or  $\text{N}_2$  in vessels similar to that used in thermal gradient sublimation (see Fig. 5.7). Crystal nucleation occurs at the vessel walls, resulting in crystallites that are typically only a few millimeters thick by a centimeter in length. Growth proceeds at the material sublimation temperature, which needs to be well below the decomposition temperature. This is in contrast to Bridgeman and Czochralski techniques where growth at the melting point can be very close to its decomposition temperature. Vapor phase growth is unsuitable for materials that cannot be evaporated. An advantage of this technique is that sublimation in a thermal gradient is effective at eliminating impurities, resulting in a high quality crystal without needing to take steps to remove excess solvents or other contaminants found in liquid solutions.

Vapor phase growth results in the development of free, unstrained surfaces, and when not intentionally seeded, several crystals that grow along different axes

**Figure 5.24** Single crystals of the nonlinear optical material benzophenone grown from seeded solution along the (110) direction. The boules measure 1–2 cm in diameter (Sankaranarayanan and Ramasamy, 2005).

can be harvested in a single sublimation. As shown in Fig. 5.25, rubrene crystals grow as needles of varying lengths and diameters, whereas other materials (e.g. tetracene) and under different conditions (temperature gradient, gas flow rate, gas composition, etc.) grow as flakes and sheets. Doped and multicomponent (i.e. binary, ternary, quaternary, etc.) crystal mixtures can be grown simply by careful addition, and homogeneous mixing of multiple organic sources into the growth reactor (Karl, 1980). Doping and organic mixtures are achieved by using a carrier gas during growth that accurately dilutes the multiple components to their desired concentrations, similar to the conditions used in *organic vapor phase deposition* (OVPD) of thin organic films (see Section 5.4.2).

High quality, large single crystals are grown in a furnace tube containing a temperature gradient considerably smaller than used in thermal gradient purification. The source material is evaporated either in vacuum or in a slowly flowing inert carrier gas into a slightly cooled ( $<1^\circ\text{C}$ ) zone of the tube. There, nucleation occurs adventitiously on irregularities on the vessel walls. The crystals are allowed to grow slowly ( $\sim 0.1$  mm/h) in a layer-by-layer mode due to the shallow temperature gradient. Near-equilibrium growth is essential to minimize the formation of dislocations due to strain, incorporation of impurities, and to prevent dendritic growth.

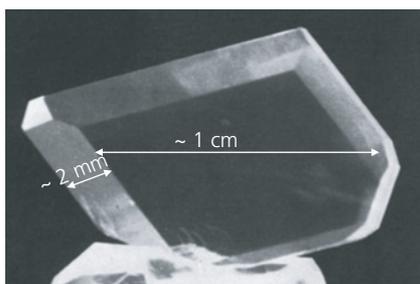

Growth along a particular lattice direction can be achieved by placing a seed at the cooler end of an ampoule positioned within the sublimation zone. The seed temperature is elevated slightly above its sublimation temperature to present a fresh growth surface, and then the temperature is lowered to promote nucleation at the seed surface. Thereafter, growth proceeds along the lattice direction imposed by the seed. Alternatively, the seed can be placed at the end of a small heat sink such as a metal needle inserted into the growth zone. Condensation preferentially occurs at this cold point containing the seed.

**Figure 5.25** Centimeter-long needles of rubrene grown by physical vapor transport (de Boer et al., 2004).

The geometry in Fig. 5.7 is not ideal for the growth of large crystals, which can only controllably occur within a narrow zone where the temperature difference allows for slow, near equilibrium growth. For this purpose, vessels are used that have two parallel surfaces (called plate sublimators); one controlled at the sublimation temperature and the other in close proximity that is at the condensation temperature, perhaps only a fraction of a degree lower than the sublimation plate. Numerous crystals can nucleate over the large surface area for condensation, and can grow to large volumes, as in Fig. 5.26.

Single crystals have been extensively used as the channel materials for organic thin film transistors as a means to achieve very high field effect mobilities, with selected results found in Table 5.2. To fabricate the transistors (with details on structures provided in Chapter 8), the single crystals are mechanically attached to the gate dielectric and the device contacts. The mobilities are generally higher than achieved for similar materials directly deposited from the vapor or solution phase (Reese and Bao, 2007).

**Figure 5.26** A 2 mm thick by 10 mm long pyrene single crystal grown by plate sublimation (Karl, 1980).

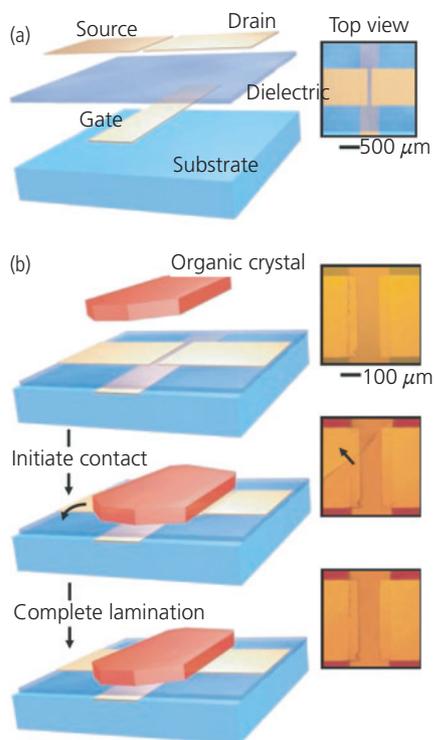

While single crystals are useful for understanding fundamental properties, they must be individually positioned between contacts. Further, they must be handled with care to avoid surface damage as well as generation of bulk defects that can be induced by flexing or stretching during device fabrication. An example procedure for fabricating organic transistors using rubrene crystals grown by physical vapor transport is shown in Fig. 5.27. The base layers of this bottom gate/bottom contact configuration (see Chapter 8) form a flexible stamp used to pick up the rubrene single crystal flake. The substrate and gate dielectric material is the flexible elastomer, PDMS. Once the gate, drain and source contacts along with the gate insulator are deposited, the flexible stamp picks up the organic crystal which adheres to it by van der Waals forces. The crystal itself is 0.2–1.0 mm thick along the *c*-axis of rubrene. The dimensions along the basal *a*–*b* plane are approximately 2–3 mm on a side. The gentle pick-up of the crystal avoids strain and flexing that inevitably degrade the crystal quality.

An interesting feature of this stamp transfer process is that it is both reversible and repeatable. Thus, the crystal can be attached and released numerous times, orienting it along different axes to measure the field effect mobility as a function of crystalline direction. A polar plot of the mobility is shown in Fig. 5.28, which is a compilation of measurements taken by rotating the sample through two entire 360° cycles. The points, obtained from both the linear and saturation transistor operating regimes over both cycles shows the reproducibility, and hence non-destructive nature of stamp transfer. Interestingly the highest mobilities of 4.4 cm<sup>2</sup>/V s are obtained along the  $\hat{b}$ -axis, which is four times that along the  $\hat{a}$ -axis. This is consistent with the closer molecular spacing of 7.2 Å along  $\hat{b}$ , vs. 14.4 Å along  $\hat{a}$ .

**Table 5.2** Mobilities measured for OTFTs that employ single crystal channels. From Reese and Bao (2007)

Channel material	Growth process	Charge carrier	Mobility (cm <sup>2</sup> /V s)	Structure <sup>a</sup>	Gate dielectric
Pentacene	Vapor	Hole	2.2	TC, TG	Parylene
Tetracene	Vapor	Hole	2.4	BC, BG	PDMS
Anthracene	Vapor	Hole	0.02	BC, BG	SiO <sub>2</sub>

<sup>a</sup> BC = bottom contact; TC = top contact; BG = bottom gate; TG = top gate.

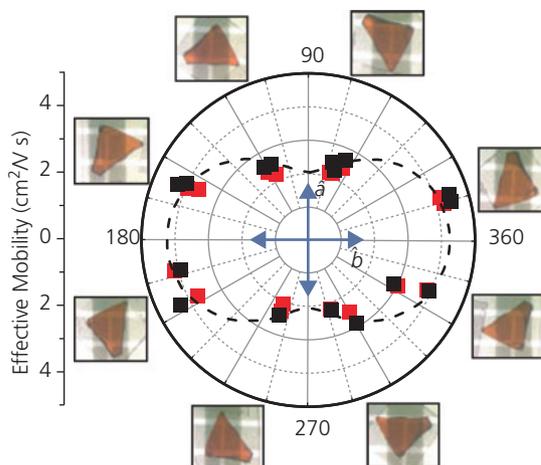

**Figure 5.27** Fabrication of a rubrene single crystal field effect transistor. (a) Preparation of the stamp comprising a flexible PDMS substrate, gate electrode, 2–4 mm thick PDMS gate dielectric and the source and drain electrodes. All electrodes are Ti/Au, where the Ti is used for adhesion to the PDMS. These base layers are used as a stamp. (b) The organic crystal is picked up by the stamp along one edge, and then adheres by van der Waals forces to the electrodes. The images at right are of the device before and after organic channel attachment. The arrow in the center image shows the direction of attachment of the crystal after making initial contact along the edge at the lower right corner (Sundar et al., 2004).

We caution that field effect mobilities obtained from the transistor characteristics are not equivalent to time-of-flight mobility measurements as described in Section 4.4.3. Indeed, the field effect mobilities are extracted from measurements of the conductivity along the surface of the organic at its interface with the gate insulator. Hence, the field effect mobility depends on preparation, contact quality, pressure applied to the organic (Nisikawa et al., 2006), and interface contamination from the environment (Pflaum et al., 2006). Hence, very high room temperature transistor mobilities ( $>5 \text{ cm}^2/\text{V s}$ ) occasionally claimed for these values should be viewed with caution, since they may not reflect an intrinsic material property.

#### 5.4.2 Thin film growth

Soft materials enable many different methods for deposition. This ability lies at the heart of their versatility. Self-assembled, epitaxial, and quasiepitaxial

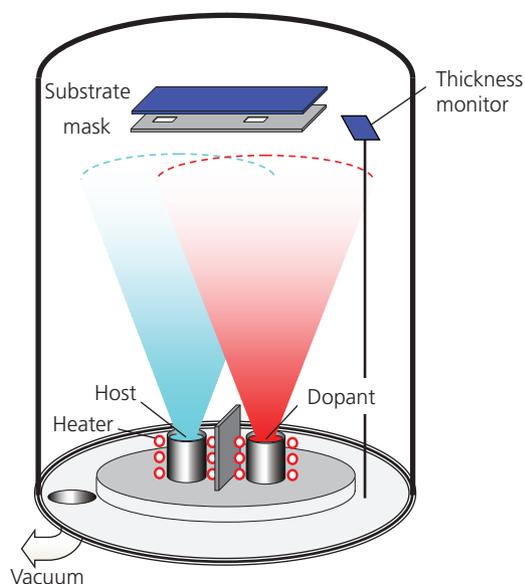

**Figure 5.28** Field effect mobility as a function of rubrene crystal orientation relative to the source-drain direction. The  $\mathbf{a}$  and  $\mathbf{b}$  crystal axis directions are indicated. Mobilities are obtained from both the linear (black squares) and saturation (red squares) regimes of transistor operation. Also shown are photographs taken at several different orientations (Sundar et al., 2004).

structures can develop on a variety of surfaces without the constraints of lattice matching that dominates the structures of “hard” materials such as covalently bonded semiconductors. Given the range of possible deposition methods available to organics, and the variety of structures that can be achieved, in this section we necessarily confine ourselves to a discussion of only the most commonly used methods. Both deposition from vapor (whether in vacuum or in an inert gas) and from solution are described. The interested reader is directed to the literature to find out about other methods, using what follows as an introduction to the topic.

##### 5.4.2.1 Vacuum thermal evaporation

Thermal evaporation in vacuum is by far the most common means for depositing small molecule organic thin films. The configuration used for VTE is illustrated in Fig. 5.29. The organic source material is loaded into a “boat,” or crucible, that is resistively heated in a high vacuum chamber to the source evaporation temperature. Materials that either sublime or evaporate from the liquid phase at elevated temperatures are compatible with VTE. By co-evaporating two or more materials from different crucibles, blends and doped films are controllably produced. Sequential deposition of several materials results in the growth of multi-layer structures whose functionalities are determined by composition and layering scheme. The rate of film growth and the total thickness deposited *in real time* are typically measured by a quartz crystal thickness monitor positioned near the substrate. The

**Figure 5.29** Schematic of the basic elements of a vacuum thermal evaporation system.

monitor can also be used in a feedback loop to control the temperatures of the crucibles, thus providing highly controlled film deposition. Alternatively, the film properties can be measured and controlled using optical absorption in either reflection or transmission modes, or by ellipsometry. For these purposes, an optical beam is obliquely incident onto the substrate surface, and the intensity and spectrum of its specular reflection is measured using a photodetector and monochromator placed opposite to the light source at the angle of incidence.

The substrate is positioned at a sufficient distance from the thermal sources to prevent heating, and to ensure uniform thickness and composition of the deposit. On the other hand, the distance must be much less than the ballistic range of the evaporated molecules from the crucible. To achieve high uniformity, the source-to-substrate distance should be at least three to five times the maximum substrate diameter, although this becomes impractical for very large substrates used in manufacturing displays, lighting or solar cells. Table 5.3 lists the approximate substrate sizes used in display manufacturing. The use of linear evaporation sources and other strategies (see below) can relax this distance requirement. To improve uniformity even further, the substrate is rotated at a few revolutions per minute around an axis that is off-center from the crucible orifice. The preferred orientation is shown in Fig. 5.29 where the organic materials are evaporated upward toward the substrate. This avoids dust within

**Table 5.3** Approximate “mother” glass substrate sizes used in display manufacturing

Substrate generation <sup>a</sup>	Dimensions (in mm) <sup>b</sup>
1	300 × 400
2	400 × 500
3	550 × 650
4	680 × 880 or 730 × 920
5	1000 × 1200 or 1100 × 1300
6	1500 × 1800
7	1900 × 2200
8	2200 × 2400
9	2400 × 2800
10	2850 × 3050
11	3200 × 3600

<sup>a</sup> The generation is typically labeled as “Gen,” that is, a generation 10 substrate is referred to as Gen 10. As a rule of thumb, the substrate area (in m<sup>2</sup>) is roughly equal to its generation.

<sup>b</sup> Actual sizes depend on manufacturer. Thicknesses also vary, but are typically 0.3–0.7 mm.

the chamber from falling onto the substrate surface, and also prevents the organic source from falling out of the crucible, or boat.

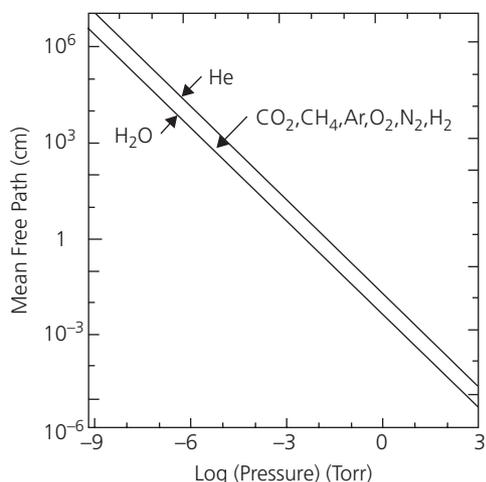

VTE is done in a high vacuum environment, typically ranging from 10<sup>-6</sup> torr, to ultrahigh vacuum (UHV) approaching 10<sup>-11</sup> torr. When deposition occurs at UHVs (loosely defined as pressures,  $P < 10^{-8}$  torr), the process is known as *organic molecular beam deposition* (OMBD).

The mean free path of the background gas molecules,  $mfp$ , should be much larger than the chamber size in a vacuum deposition system. From kinetic theory,

$$mfp = \frac{k_B T}{\sqrt{2} \pi d^2 P}, \quad (5.14)$$

where  $d$  is the background gas atomic or molecular diameter. The  $mfp$  is plotted vs. pressure in Fig. 5.30 for common background gases. In most deposition systems, the background gases with the highest partial pressures are H<sub>2</sub> and N<sub>2</sub>. At  $P < 10^{-6}$  torr, then  $mfp > 10$  m, which is considerably larger than chambers used in VTE.

The concentration of contaminants in the high vacuum environment is very small, and hence the purity of the starting organic material is maintained, and even improved by evaporation (Salzman et al., 2005). As in the case of gradient sublimation, vacuum pumps used in VTE should avoid organic oils used in mechanical rotary pumps that rough the chamber from atmospheric pressure, and in high vacuum

**Figure 5.30** Mean free path of several gases as a function of pressure.

diffusion pumps. The most convenient pump for rapid, high vacuum pumping is the turbo pump, although it is not effective in removing the lightest gasses such as  $\text{H}_2$ . Capture pumps such as cryopumps are also clean and fast, although care must be taken during regeneration to avoid contact with vapors that are released from many pumping cycles of potentially toxic organic compounds. It is also important to use crucible materials (e.g. Mo, W, ceramics) that do not react with the evaporant, and that the evaporation temperature be kept well below the decomposition temperature of the organic compound.

The evaporation rate is exponentially dependent on temperature, viz.

$$r_{\text{evap}} = r_0 \exp(-\Delta H^{\text{vap}}/RT), \quad (5.15)$$

where  $\Delta H^{\text{vap}}$  is the enthalpy of evaporation. Hence, the rate can be adjusted between  $0.01 \text{ \AA/s}$  and  $100 \text{ \AA/s}$  with only a small change in crucible temperature. In Table 5.4 we list the evaporation enthalpies of a few example compounds commonly found in organic electronic devices.

Growth rates of  $0.1\text{--}10 \text{ nm/s}$  are commonly used since achieving precise thickness control at higher rates is challenging in depositing the thin layers ( $\sim 100 \text{ nm}$ ) used in organic electronic devices. If the rate is too slow, a high concentration of impurities is incorporated into the films in systems with only modest vacuums. In a study of film quality, OLED hole and electron transporting layers of  $\alpha\text{-NPD}$  and  $\text{Alq}_3$ , respectively, were grown at rates of from  $0.01$  to  $1000 \text{ nm/s}$  at a system base pressure of  $<10^{-6}$  torr (Matsushima et al., 2012). The growth rate was varied

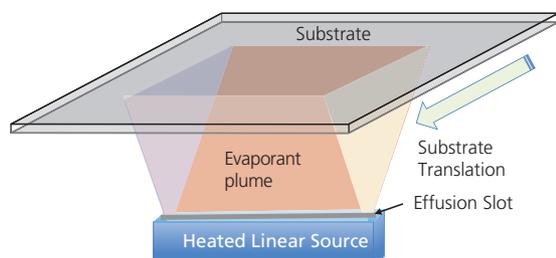

**Table 5.4** Enthalpies of evaporation of several common organic compounds (Shtein et al., 2001)

Material	Function	$\Delta H^{\text{vap}}$ (kcal/mol)
DCM2	Fluorophore	110
PtOEP	Phosphor	128
Ir(ppy) <sub>3</sub>	Phosphor	166
CBP	Electron Transport	143
$\text{Alq}_3$	Electron transport	138
$\alpha\text{-NPD}$	Hole transport	139
CuPc	OPV donor	176

by positioning the substrate at distances  $0.5\text{--}18 \text{ cm}$  from the molecular source boat, while also varying the source temperature. With the exception of the charge mobilities, almost all of the film properties, including surface roughness, PL lifetimes, and morphology measured by X-ray diffraction, were unaffected over this six order of magnitude variation in deposition rate. The most significant change was a three-fold increase in hole current in  $\alpha\text{-NPD}$  by a factor of three as the rate increased to  $10 \text{ nm/s}$ , compared to a decrease in electron current in  $\text{Alq}_3$  by a factor of  $0.17$ . This is attributed to changes in bulk mobilities related to morphology within these films. Optical birefringence measurements indicate that the planar  $\alpha\text{-NPD}$  molecule forms more ordered stacks in the vertical direction at the higher rates, whereas it is likely that the more isotropic  $\text{Alq}_3$  simply becomes more porous. Indeed, very high deposition rates are likely to yield a high density of voids not found in layers that are deposited more slowly. That is, the adsorbed molecules have more time to seek equilibrium positions within the film before being buried at energetically unfavorable locations by subsequently arriving molecules.

Although this tradeoff between film quality and deposition rate is weak for  $\alpha\text{-NPD}$  and  $\text{Alq}_3$ , it may be more pronounced in other molecular systems. While manufacturing throughput depends on a high rate to complete the film deposition in a minimum amount of time with thickness variations of  $< 10\%$ , this need must be balanced against the rigorous demands for high performance devices. With these considerations in mind,  $\sim 10 \text{ nm/s}$  is a practical upper limit to the deposition rate in most circumstances.

In-line organic source boats illustrated in Fig. 5.31 are used for deposition on very large substrates. In this configuration, the substrate is held close to a boat of comparable width. The substrate is translated over the boat opening throughout the layer growth. The

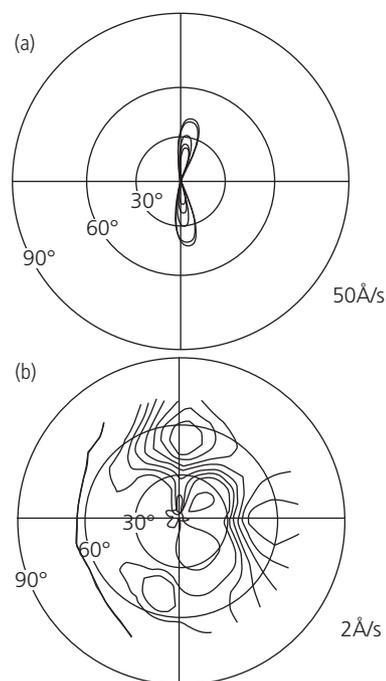

**Figure 5.31** Schematic layout of a linear source evaporation system. The source boat is uniformly heated above the source sublimation temperature. The molecules exit the effusion slot, forming a large plume that covers the substrate as it is translated to achieve full coverage.

film thickness is determined by the width of the plume,  $W$ , and the velocity of the translating substrate,  $v$ , via  $d = Wr_{\text{evap}}/v$ . For multilayer structures, the substrate is translated from source-to-source placed in a series along the length of the vacuum chamber, each containing a different organic species. Doped films are grown by placing two or more linear sources in close proximity, and then tilting them such that the deposition plumes overlap at the substrate plane. The substrate can be oriented as in Fig. 5.31 (bottom-up evaporation), or the entire system can be rotated by  $90^\circ$  to allow for the substrate to stand vertically as it is translated—a relatively compact configuration that is convenient for handling the largest substrates.

In-line sources have proven effective for the manufacture of large OLED displays (typically Gen 8 and larger). They do, however, present challenges beyond those encountered using point sources. Care must be taken to ensure complete overlap of the evaporants when doping thin films to avoid variations in dopant concentrations at the edges of the deposit. Also, the thin film thickness depends on the control of two variables: evaporation *and* substrate translation rate.

Film morphology (i.e. its roughness, crystalline order and orientation, etc.) can be controlled by varying the deposition rate, molecular structure and composition, and substrate temperature from below room temperature to as high as  $\sim 100^\circ\text{C}$ . A dramatic demonstration of the effects of deposition rate on morphology is shown by the X-ray diffraction pole figures of PTCDA grown on a glass substrate at room temperature in Fig. 5.32. These pole figures reveal the crystalline texture of the film by plotting the intensity of the intermolecular, (102) Bragg reflection as a function of polar angle with respect to the film normal. Rapid, non-equilibrium growth at a high deposition rate of  $50 \text{ \AA/s}$  results in a surprisingly high degree of order.

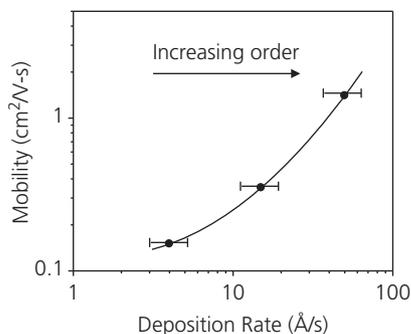

**Figure 5.32** X-ray pole figure of the (102) PTCDA diffraction intensity vs. polar angle. A 100 nm thick film is deposited at (a)  $50 \text{ \AA/s}$  and (b)  $2 \text{ \AA/s}$ . Each contour in (a) corresponds to a 10%, and in (b) to a 1% difference in X-ray intensity between adjacent contours (Forrest et al., 1984).

Reprinted from Forrest, S. R., Kaplan, M. L. & Schmidt, P. H. 1984. Organic-on-inorganic semiconductor contact barrier diodes. II. Dependence on Organic Film and Metal Contact Properties. *J. Appl. Phys.*, 56, 543 with permission of AIP Publishing.

The double-lobed x-ray intensity pattern aligned to the  $0\text{--}180^\circ$  polar axis, and with peaks at  $\pm 11^\circ$  from the substrate normal in Fig. 5.32a reveal a twinned crystal whose (102) planes are tilted at these same angles (Forrest et al., 1984). In contrast, at a lower deposition rate of  $2 \text{ \AA/s}$  shown in Fig. 5.32b, there is no apparent pattern in the X-ray contours. This suggests that the film is a randomly oriented powder in the substrate plane, that is, it is amorphous.

As can be inferred from the discussion of quasiepitaxy in Section 2.6.2, the kinetics of growth are critical factors in determining morphology. The order at high growth rates is indicative of rapid self-assembly that occurs under non-equilibrium conditions: nucleation begins at only a few locations around the substrate followed by rapid and ordered growth that covers the substrate surface. Pretreatment of the substrate (e.g. by handling, rubbing, etc.) may in fact *template* a directionality to the substrate, whereby there is a preferred alignment direction that results in the lowest crystal energy (Yang et al., 2015). At lower deposition rates, the molecules have an opportunity to move along the substrate surface, creating random

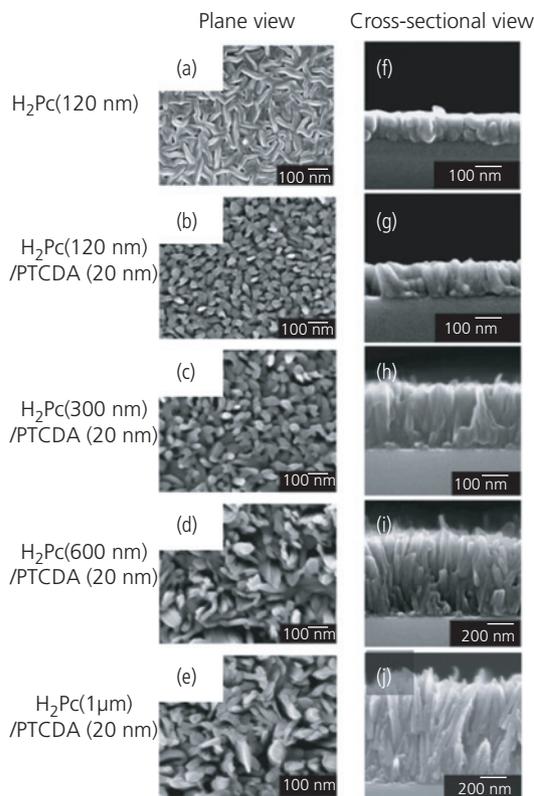

**Figure 5.33** Out of plane hole mobility vs. deposition rate. Comparing this result to that in Fig. 5.32, higher rates result in increasing order, and hence a higher charge mobility (Forrest et al., 1984).

nanocrystalline piles that are not oriented relative to each other (see Fig. 5.32b). The rate dependent ordering is also reflected in the out of plane hole mobility measured for these same samples with results in Fig. 5.33. The mobility increases with deposition rate, corresponding to more ordered and extensive crystalline stacks. This is expected since single crystals lack high angle grain boundaries that result in carrier scattering, which would be reflected in a decrease in charge mobility.

The order in the films in Figs. 5.32 and 5.33 arise from a combination of adventitious templating by the substrate, as well as by the strong tendency of PTCDA to assemble into large crystalline “rafts” with molecules lying flat, or near flat on the glass surface. Deposition of very thin layers of PTCDA and other molecules with similar tendencies to self-order can thus be used as templates that drive the order of subsequently deposited layers that have weaker intermolecular interactions. Indeed, such templates can be used to force molecules in the adlayer to lie flat on the template, whereas they would ordinarily stand on edge, or vice versa, depending on the adlayer molecules interactions with the template (Lassiter et al., 2010, Yang et al., 2015). Intentional manipulation of order and orientation of the thin film structure is critical to device performance, resulting in increased emission efficiency in OLEDs, power conversion efficiency of OPVs, and the conductive properties of OTFTs.

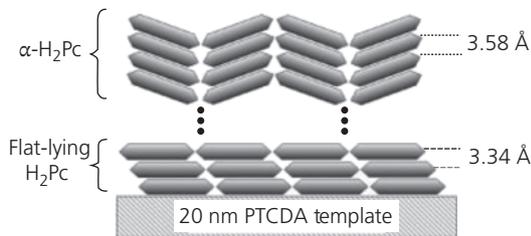

While exogenous layers can form a template to control the morphology of subsequently deposited films, the range of control is limited. That is, a structure that is forced by the template eventually relaxes into its equilibrium crystal structure as the thickness of the adlayer is increased. Relaxation, in turn, results in accumulation of disorder. Hence, the layer should only be deposited to a thickness that is within

**Figure 5.34** Plane and cross-sectional SEM views of  $H_2Pc$  films grown on a bare glass substrate (a, f) and at various thicknesses on a 20 nm thick, pre-deposited PTCDA template layer (b–e; g–j) (Sakurai et al., 2005).

Copyright 2005, The Japan Society of Applied Physics

the Matthews–Blakeslee strain limit discussed in Chapter 2. Lattice relaxation is exemplified by an  $H_2Pc$  film deposited onto a 20 nm thick ordered PTCDA template layer pre-deposited on a glass substrate. Micrographs of the  $H_2Pc$  film surface and cross sections for various layer thicknesses are shown in Fig. 5.34. The layer grown directly on glass (Fig. 5.34a and f) shows no preferred order, with crystalline needles distributed in random directions. Cross-sectional views of the films grown on template layers show a preferential orientation of the domains perpendicular to the surface. The crystal facets are also apparent in the corresponding plane views. However, the thickest films (>300 nm, Figs. 5.34d, e, i, and j) show that the domains diverge from a completely vertical aspect. These micrographs, along with X-ray diffraction data, indicate that the  $H_2Pc$  molecular layers in the thinner films lie flat on the similarly flat lying PTCDA layer, while as the  $H_2Pc$  film thickness is increased, the structure relaxes into its  $\alpha$ -phase equilibrium, herringbone crystal habit. This tendency

**Figure 5.35** Crystal structure evolution of an H<sub>2</sub>Pc film on a PTCDA template on glass as the H<sub>2</sub>Pc film thickness increases. Molecular plane spacings for the two possible film structures are shown. After Sakurai et al. (2005).

to assume its equilibrium structure as the film thickness is increased is illustrated in Fig. 5.35.

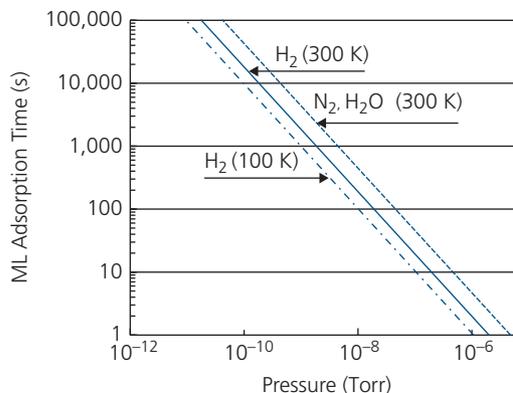

While the films in Figs. 5.34 were grown in UHV by OMBD, templating appears to be independent of the level of vacuum. Indeed, it has also been observed in films grown via OVPD. It is simply a result of the balance of forces between the substrate and the layers grown on its surface. These forces are modified by either increasing or decreasing the van der Waals attraction between the adlayer and the template, or with the original substrate. Numerous template molecules have been employed, although planar aromatic hydrocarbons such as PTCDA, NTCDA, and larger molecules with similar structures appear to be the most effective at creating order in subsequent layers. This is due to their extended  $\pi$ -systems that form highly attractive surfaces to a range of conjugated molecular structures.

#### 5.4.2.2 Organic molecular beam deposition

The UHV process of OMBD has led to unprecedented advances in the ultraprecise control over both the thickness and morphology of small molecule organic materials (Forrest, 1997). This is primarily a result of the uniformly controlled heating of organic source materials in an ultraclean environment using Knudsen evaporation cells that ensure both controlled material flux as well as *in situ* purification of the source material. The UHV environment also leads to nearly complete elimination of the incorporation of impurities during film growth.

To preserve the purity of the starting or source material, the incorporation rate of exogenous contaminants must be substantially less than the film growth rate. From kinetic theory, the time for a monolayer (ML) of background gas atoms with partial pressure,  $P$ , to be adsorbed onto a substrate surface is (Weston, 1985)

$$\tau_{ML} = \frac{N_{surf} \sqrt{2\pi m_g k_B T}}{\kappa P}, \quad (5.16)$$

**Figure 5.36** Monolayer (ML) adsorption time vs. background chamber pressure, assuming,  $\kappa = 1$ ,  $T = 300$  K, and  $N_{surf} = 10^{14}$  molecules/cm<sup>2</sup>. The H<sub>2</sub> adsorption time at 100 K is also shown.

where  $N_{surf}$  is the density of surface atoms required to form a complete monolayer,  $m_g$  is the mass of the gas molecule, and  $\kappa \leq 1$  is the atomic sticking coefficient (i.e. the ratio of atoms that stick to a surface to those incident on it). Equation 5.16 is plotted in Fig. 5.36 assuming that the principal residual gas in a vacuum system is H<sub>2</sub>, N<sub>2</sub>, or H<sub>2</sub>O, where  $\kappa = 1$ , and  $N_{surf} = 10^{14}$  molecules/cm<sup>2</sup>. The time required to adsorb a monolayer of H<sub>2</sub> is  $\tau_{ML} \sim 20$  s at a background pressure of  $10^{-7}$  torr, and 40 min at  $10^{-9}$  torr. Since N<sub>2</sub> and H<sub>2</sub>O are somewhat more massive, their presence can lead to additional contamination, albeit at a somewhat reduced adsorption rate. Some morphologies are optimally produced on cooled substrates, in which case the substrate itself serves as a sync, or pump, for background impurities (Forrest, 1997). The plot in Fig. 5.36 shows that cooling to 100 K reduces the monolayer diffusion time by nearly a factor of two from its value at room temperature. To minimize the incorporation of impurities, it is important to employ the fastest growth rate possible that is compatible with achieving the desired film morphology and thickness control. Practical growth rates in UHV thus lie in the range from 0.1 to 5 ML/s.

Films of Ga phthalocyanine chloride (GaPcCl) grown at a rate of  $0.5 \text{ \AA}/\text{min}$  on (001) KBr substrates at a base vacuum  $3 \times 10^{-9}$  torr show a higher degree of crystalline order than films grown at only  $5 \times 10^{-6}$  torr (Tanigaki et al., 1991). Furthermore, scanning tunneling microscope images reveal layer-by-layer growth when PTCDA is deposited on graphite in UHV, whereas clumping into islands is prevalent at lower vacuum (Forrest et al., 1994). It was speculated that impurities and water incorporated during growth at lower vacuum provide sites for crystal

nucleation, leading to island growth. Maintaining the source material at elevated temperatures in UHV for long periods, as is done in conventional OMBD systems, reduces moisture, and hence leads to improved source purity.

UHV systems employ stainless steel chambers, as in Fig. 5.37. Typically, growth occurs by evaporation of the source material in a background vacuum ranging from  $10^{-9}$  to  $10^{-11}$  torr using highly purified organic source material heated from a Knudsen cell (Herman and Sitter, 1989). The evaporant is collimated by passing through a series of orifices, after which it is deposited some distance away ( $\sim 10$ – $20$  cm) on a substrate held perpendicular to the beam. The molecular flux is controlled by a combination of oven temperature that is maintained above the sublimation temperature of the source but well below its decomposition temperature, and a mechanical shutter that can switch the beam flux from “on” to “off.” Structures consisting of alternating layers of different compounds are grown by sequentially shuttering the beam flux from more than one Knudsen cell (So et al., 1990, So and Forrest, 1991).

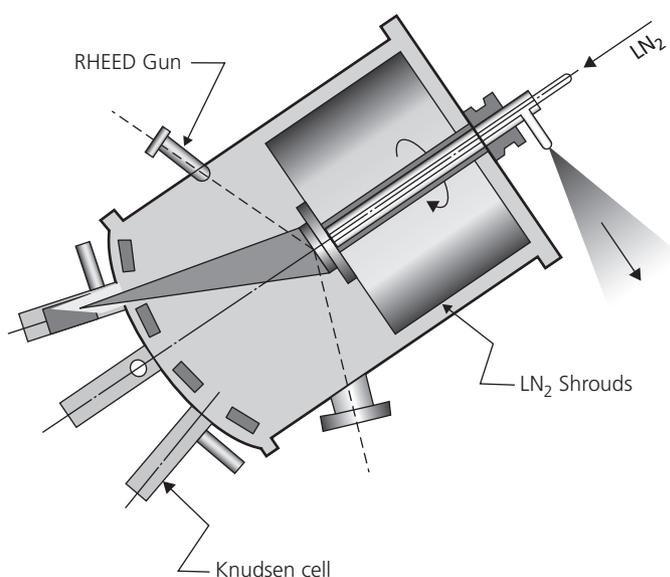

Samples enter and exit the OMBD chamber via vacuum load locks, avoiding times needed to pump the system down to UHV. The source materials are stored in the Knudsen cells for extended periods of time at temperatures somewhat below the evaporation temperature in the UHV environment. Since many of the organic molecular materials are hygroscopic, vacuum storage at elevated temperatures

leads to thorough drying and outgassing of the sources, thereby achieving material purity over the long term exceeding that of the source materials initially loaded into the chamber.

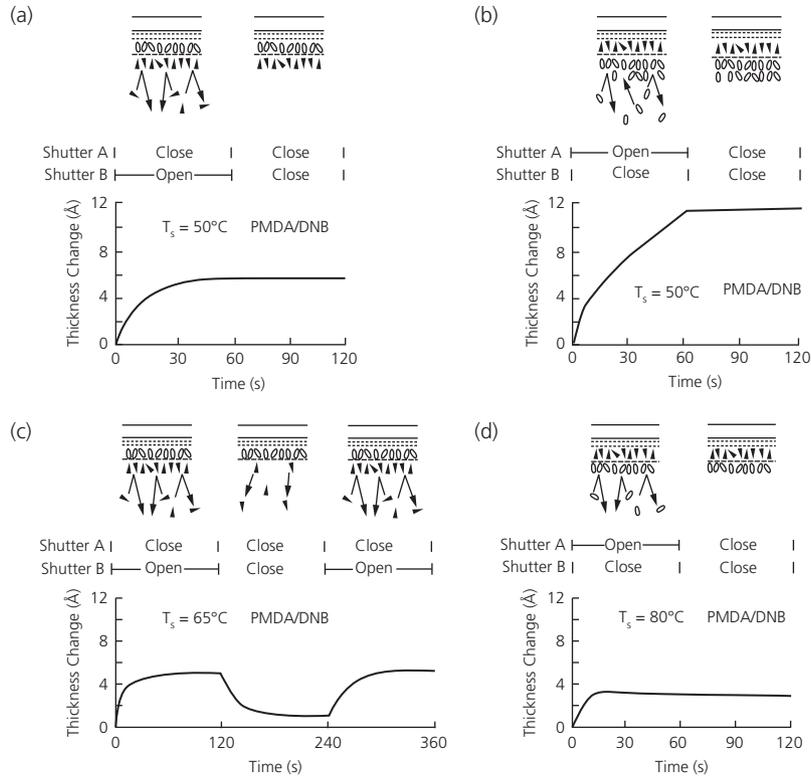

Due to the volatility of many organic materials, high throughput pumps are employed to achieve UHV. As in VTE, diffusion and other oil-based pumps should be avoided since the oils can contaminate, and even react with the organic compounds. A preferred arrangement is to use a high capacity cryopump during growth, and an ion pump between growths to maintain UHV. The chamber itself is lined with liquid  $N_2$  filled shrouds on which residual gases, and particularly  $H_2O$  are condensed (or gettered). This combination can lead to a base pressure of  $5 \times 10^{-11}$  torr.

Varying the substrate temperature is one means for controlling film structure (Vincett et al., 1981, Debe et al., 1988, Mobus et al., 1989, So et al., 1990, Forrest et al., 1994). At low substrate temperatures, the sticking coefficient of impurities and residual gas atoms approaches unity (cf. Fig. 5.36). High deposition rates can minimize impurity incorporation.

The substrate temperature can also be used to control the molecular desorption rate, thereby enabling ML growth of organic molecular materials and heterostructures (Yoshimura et al., 1991). *Molecular layer deposition* (MLD) is similar to *atomic layer epitaxy* (ALE) used for growing inorganic semiconductor multiple quantum well structures, where the growth of each layer is self-terminating due to the

**Figure 5.37** OMBD chamber used in the deposition of organic thin films in an ultrahigh vacuum environment (Forrest, 1997).

**Figure 5.38** Molecular layer deposition of PMDA (open ellipses) and DNB (filled triangles) using temperature to control the layer saturation. Separate shutters A and B are positioned immediately above the evaporation sources for PMDA and DNB, respectively, enabling independent control of their molecular fluxes (Yoshimura et al., 1991).

thermodynamic conditions and the composition of the molecular constituents. In Fig. 5.38 we show the MLD growth of PMDA alternated with DNB. These molecules have considerably different desorption temperatures ( $T_{desorp}$ ) from the substrate and each other. When the substrate temperature is  $T_s > T_{desorp}$ , the molecular sticking coefficient is  $\kappa \ll 1$ , preventing deposition. MLD proceeds by first depositing molecule A whose binding energy ( $E_{A-B} = k_B T_{A-B}$ ) to molecule B is higher than that of the molecule to itself (e.g.  $E_{B-B} = k_B T_{B-B} < E_{A-B}$ ). When the substrate temperature is adjusted to  $T_{B-B} < T_s < T_{A-B}$ , only a single monolayer of molecule B is deposited on a layer of molecule A. To deposit a second ML of molecule A, the substrate temperature is changed to  $T_{A-A} < T_s < T_{B-A}$ , and the process is repeated. This combination of steps results, therefore, in the saturated growth of single monolayer films in an alternating layer-by-layer mode by controlling the substrate temperature while introducing a beam of molecules of the desired composition.

The MLD process applied to PMDA and DNB in Fig. 5.38 utilizes the strong bonding between carbonyl-oxy-carbonyl groups of PMDA to the

amino group in DNB *vs.* the relatively weak bond energies of these functional moieties to themselves. At  $T_s = 50^\circ\text{C}$ , the thermal energy is greater than the intermolecular binding energy of DNB ( $T_s > T_{B-B}$ ), thereby permitting only a single, saturated ML of DNB to deposit on an initial layer of PMDA where  $T_s < T_{A-B}$  (see Fig. 5.38a). However, growth of PMDA on DNB at  $T_s = 50^\circ\text{C} < T_{A-A}$  is halted only by closing the shutter positioned between the molecular effusion cell and the substrate, as indicated in Fig. 5.38b. When the substrate temperature is increased to  $T_s = 65^\circ\text{C}$ , DNB is desorbed (Fig. 5.38c). The alternate process of saturated single monolayer growth of PMDA is therefore achieved at  $T_s = 80^\circ\text{C}$ , as shown in Fig. 5.38d. This procedure is slow since the temperature must be stabilized between each layer deposition, although it can be effective for achieving controlled layer-by-layer growth.

One further advantage of UHV growth is that several in-situ film diagnostics can be employed both during and immediately after growth (Herman and Sitter, 1989). In particular, *reflection high energy electron diffraction* (RHEED) provides in-situ and real time information of the thin film crystalline structure

(Haskal et al., 1992, Tada et al., 1992). *Residual gas analysis* (RGA) is used to determine the molecular species as well as any contaminants within the OMBD chamber, and also measures the film-substrate adhesive energy by *thermal desorption spectroscopy*.

Given its combination of ultrahigh purity and *in situ* diagnostics, OMBD has led to significant advances in our understanding of growth dynamics as well as fundamental optoelectronic properties of organic molecular crystals. Many of these same advantages have been effectively used in growing extremely high quality inorganic semiconductors such as GaAs and InP using the analogous process of molecular beam epitaxy.

#### 5.4.2.3 Organic vapor phase deposition

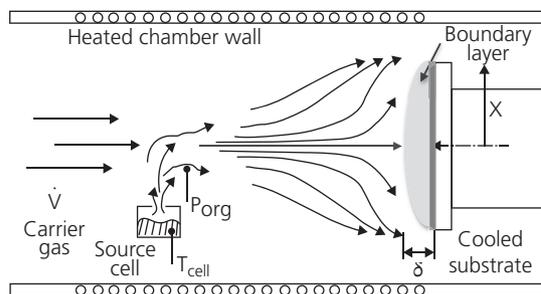

OVPD differs from VTE since the molecules are evaporated into a hot inert carrier gas (e.g. N<sub>2</sub> or Ar) that transports them to a cold substrate where adsorption occurs (Baldo et al., 1998a, Shtein et al., 2001). The pressure of a carrier gas during growth imparts kinetic energy to the molecules adsorbed onto the substrate, as well as resulting in diffusive transport of the molecules in the gas phase. The additional kinetic energy (beyond that provided by temperature) allows the adsorbate to seek the most energetically favorable attachment sites on the underlying layers, while diffusive transport randomizes the direction of incidence. The combination of these and other attributes discussed below give OVPD the ability to control film morphologies that are not possible using other growth methods.

The pressure within the chamber typically ranges from 0.1 torr to 1 atm, with flow rates having a low *Reynold's number* such that laminar flow is established. The Reynold's number ( $Re$ ) is a dimensionless ratio of the inertial to viscous forces. For a *kinematic viscosity*,  $\nu$ , and a volumetric flow rate of the gas,  $\dot{V}$ , then,

$$Re = \frac{\dot{V}D}{\nu A}. \quad (5.17)$$

Here,  $D$  is the chamber diameter and  $A$  its cross-sectional area. For "fully developed" laminar flow,  $Re < 2300$ , whereas turbulent flow ensues at  $Re > 4000$ . Intermediate Reynold's numbers correspond to the transition flow regime. Typically in OVPD,  $Re \sim 1-10$ , or well within the laminar flow regime.

The OVPD apparatus is shown schematically in Fig. 5.39. The hot inert carrier gas infuses a boat containing the organic source material, uniformly evaporating it into the chamber where the solute (i.e. the molecules) are further diluted in the inert gas (the solvent) stream. The chamber itself is heated, such

**Figure 5.39** Schematic diagram of an OVPD chamber. The source material is located in the inert gas stream, allowing for equilibrium pick-up of the molecules. These are carried in a hot-walled chamber by the carrier gas to a cooled substrate where they are physisorbed. Immediately above the substrate is a diffusive gas boundary layer (shaded region) (Shtein et al., 2001).

that no condensation occurs on its walls. This is in contrast to VTE where the chamber walls are cold. Hence in VTE, material accumulates in areas other than the substrate, ultimately resulting in inefficient materials use, and the necessity for periodic chamber cleaning to remove thick deposits. These eventually flake off the walls, creating dust within the vacuum environment. In OVPD, however, the hot chamber walls are free of deposit, and thus never require cleaning. Furthermore, the infusion of hot gas throughout the source material, which is often a powder with low thermal conductivity, uniformly volatilizes molecules. This results in thermal equilibrium within the source cell whereby the molecules form a saturated vapor whose concentration is easily controlled via adjustment of the cell temperature. In contrast, evaporation in vacuum occurs only at points where the organic is in contact with the heated source cell. The evaporation rate can abruptly change as materials settle into voids developed during sublimation. This makes the deposition rate irregular and more difficult to control.

In vacuum, the molecules travel along ballistic trajectories (i.e. along the line of sight) from the evaporation source to the substrate. This differs from OVPD where the ballistic range of the evaporated molecules is very short. Here, the *ballistic range* is the distance between the evaporation source and where the molecules reach their terminal velocity and, hence, no longer follow straight, line-of-sight paths. Kinetic theory can be used to estimate the ballistic range which limits the dimensions of the source cell and chamber. When molecules are evaporated from the source cell at  $T_{source} \sim 200-500^\circ\text{C}$ , they undergo collisions with the residual gas which results in their deceleration and loss of kinetic energy. For a molecule of radius  $r \ll mfp$ , the position of the molecule of mass  $M$  vs. time

from evaporation in the absence of significant external forces is

$$x(t) = v_0\tau(1 - e^{-t/\tau}), \quad (5.18)$$

where  $\tau$  is the characteristic time it takes to reach terminal velocity, and  $v_0$  is the initial velocity of the molecule at the source. Assuming all intermolecular collisions are elastic (which is not necessarily the case due to the internal degrees of freedom of motion of the molecules), then (Kubo, 1971)

$$\tau = M/\alpha = \frac{M}{P\pi r^2} \frac{3}{16} \sqrt{\frac{2\pi k_B T_g}{m_g}} \quad (5.19)$$

where  $\alpha$  is the drag constant of the molecules used in their equation of motion, and  $T_g$  is the temperature in the vacuum chamber. Again, from kinetic theory,

$$v_0 = \sqrt{\frac{8k_B T_{source}}{\pi M}}, \quad (5.20)$$

which gives a ballistic range of a molecule of mass,  $M$ :

$$R_B = \frac{3}{4} \frac{k_B}{P\pi r^2} \sqrt{\frac{M}{m_g}} T_{source} T_g. \quad (5.21)$$

As an example, we consider the evaporation of molecule with  $M = 300$  amu at a pressure of  $P = 0.1$ – $1$  torr, and where the principal background gas is  $N_2$  with  $m_g = 14$  amu, giving  $R_B \sim 0.4$ – $4$  mm. Hence, in OVPD the molecules remain in the vicinity of the source until they are swept out by the carrier gas, allowing for the source itself to be supersaturated with molecular vapor. Material pick-up by the carrier gas occurs in a controlled, equilibrium environment rather than in the kinetic regime of VTE.

Under equilibrium conditions, the supply of organic species is limited either by the flow velocity of the carrier gas or by the rate of evaporation. Material evaporates from the surface of the organic solid at rate,  $r_{evap}$ , given by (Shtein et al., 2001)

$$r_{evap} = k_{evap} \cdot P_{org}^{eq}. \quad (5.22)$$

where the equilibrium vapor pressure of the organic material is  $P_{org}^{eq}$ , and  $k_{evap}$  is a kinetic constant of proportionality. Vapor re-condenses at a rate,  $r_{cond}$ , proportional to the pressure of organic in the source cell,  $P_{org}$ , viz.

$$r_{cond} = k_{cond} \cdot P_{org}. \quad (5.23)$$

where  $k_{cond}$  is a kinetic constant for condensation. Organic vapors are carried out of the source at a rate,  $r$ , that is proportional to the volumetric flow

velocity of the carrier gas, and the concentration of organic vapor in the source cell,  $P_{org}/RT_{cell}$ :

$$r = \dot{V} \cdot \frac{P_{org}}{RT_{cell}}. \quad (5.24)$$

Here,  $T_{cell}$  is the evaporation cell temperature, and  $R$  is the ideal gas constant. From this analysis we obtain the partial pressure of the organic evaporant in the carrier gas stream:

$$\frac{P_{org}}{P_{org}^{eq}} = \frac{k_{evap}}{\dot{V}/RT_{cell} + k_{cond}}. \quad (5.25)$$

As noted above, the pressure is related to evaporation rate, which in turn is exponentially dependent on the enthalpy of evaporation of the organic species, viz.

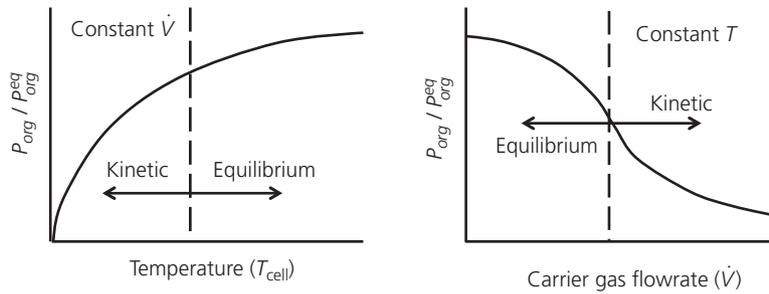

$$P_{org}^{eq} = P_0 \cdot \exp(-\Delta H^{vap}/RT_{cell}), \quad (5.26)$$

where  $P_0$  is an empirical constant specific to each compound.

At high evaporation temperatures and sufficiently low gas flow velocities, the vapor and solid in the source region equilibrate (i.e.  $P_{org} \approx P_{org}^{eq}$ ), and the concentration of organic exiting the source is constant. The resulting flux of organic species in the equilibrium evaporation regime is thus proportional to the vapor pressure and the carrier gas flow rate. At the other extreme of low evaporation temperature and high gas flow, the carrier gas sweeps the organic out of the source region as quickly as it evaporates, forcing the system away from equilibrium. In this case, the concentration of organics in the gas stream is proportional to  $r_{evap}$ , and inversely proportional to  $\dot{V}$ . In the kinetic evaporation regime, therefore, the flux of organic material leaving the source is independent of the carrier gas flow. Figure 5.40 illustrates how the vapor pressure of organics exiting the source varies with temperature and flow rate in both the equilibrium and kinetic evaporation regimes.

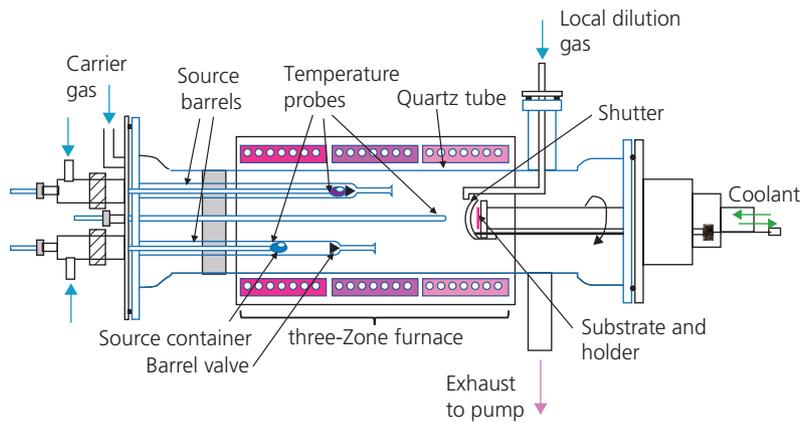

In addition to the two modes of evaporation, there are two regimes of deposition—equilibrium- and transport-limited. Similar to evaporation, in equilibrium-limited deposition the substrate temperature is sufficiently high to establish dynamic adsorption/desorption equilibria between the solid and the gas phases. Since the probability of condensation increases with decreasing surface temperature, the substrate should be kept sufficiently cold to ensure a molecular sticking coefficient,  $\kappa \approx 1$ .

As the carrier gas transports the organic vapors from the source to the substrate, a stagnant *boundary layer* of thickness,  $\delta$ , develops above the substrate across which organic molecules must diffuse prior to

**Figure 5.40** Gas transport regimes (kinetic vs. equilibrium) in OVPD and their dependence on thermodynamic conditions within the chamber (Shtein et al., 2001).

Reprinted from Shtein, M., Gossenberger, H. F., Benziger, J. B. & Forrest, S. R. 2001. Material Transport Regimes and Mechanisms for Growth of Molecular Organic Thin Films Using Low-Pressure Organic Vapor Phase Deposition. *J. Appl. Phys.*, 89, 1470 with the permission of AIP Publishing

**Figure 5.41** Schematic illustration of a laboratory OVPD reactor.

condensation (see Fig. 5.39). Thus, the film deposition rate depends on the relative rates of the convective and diffusive transport within the boundary layer. The molar rate of transport of organic molecules in the convection-limited regime is given by

$$r_{conv} = \frac{P_{org} \dot{V}}{RT}, \tag{5.27}$$

where  $P_{org}$  and  $T$  are the partial pressure of the organic vapor and the temperature of the carrier gas in the deposition chamber, respectively. The rate of diffusion across the boundary layer is (Shtein et al., 2001)

$$r_{diff} = D_{org} \cdot \frac{P_{org}/RT}{\delta}. \tag{5.28}$$

The net rate of deposition,  $r_{dep}$ , across the boundary layer is, then

$$r_{dep} = \frac{P_{org}}{RT} \cdot \frac{\dot{V}}{1 + \dot{V}\delta/D_{org}} \tag{5.29}$$

with

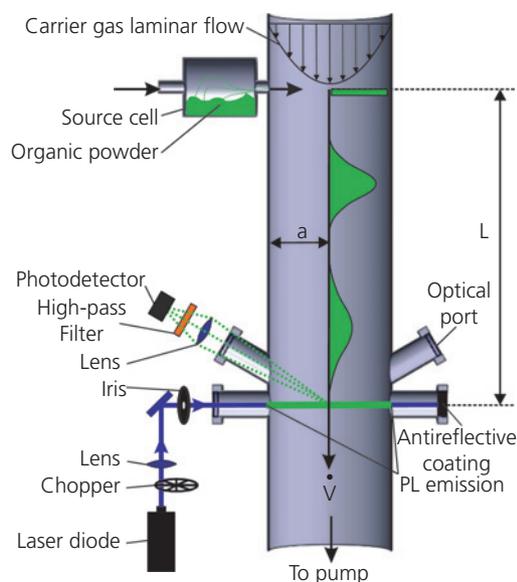

$$\delta = \sqrt{\frac{\nu \cdot x}{\dot{V}}}, \tag{5.30}$$

where  $x$  is the radial distance from the axis along the plane of the substrate holder. Equation 5.29 indicates that, at low carrier gas flows the deposition rate is limited by convection, while at the higher gas flows it is limited by diffusion across the stagnant boundary layer, which contracts quadratically with  $\dot{V}^{-1}$ .

A simple, practical design of a laboratory-scale horizontal OVPD reactor is shown schematically in Fig. 5.41. The furnace tube (quartz) is surrounded by a multiple zone furnace, with the hottest zones toward the gas and source inputs to the left, and the coldest zone near the substrate. This sets up a thermal gradient similar to that used in thermal gradient sublimation that forces diffusion of gases and evaporants toward the cold substrate. The substrate itself is actively cooled to prevent re-evaporation. Each molecular source material is held in a source container within its own tube or “barrel” to prevent cross-contamination. The source barrel is valved at its output to regulate flow of a

source material into the main furnace tube. The valve must be designed to withstand the reactor temperatures which can be  $> 500^{\circ}\text{C}$ . The source barrels are fed with their own carrier gases, joining an additional dilution gas stream in the main tube. Since the gasses enter from the hot end of the furnace, they are heated before arriving in the source and growth zones. A shutter positioned in front of the substrate can be included to further interrupt growth, although considerable source control is afforded by the barrel valves alone. Thermocouples are placed within the source barrels and at the substrate to monitor temperatures in each zone.

The gas dynamics can be measured *in situ*, and in real time using *laser induced fluorescence* (LIF) and ellipsometry (Rolin et al., 2012, 2014). In LIF, a laser beam locally excites organic species dissolved in the carrier gas while transiting the hot reactor vessel, resulting in fluorescence emission whose intensity and spectrum can indicate the organic concentration and gas temperature, respectively (see Fig. 5.42). At  $P < 1$  torr typical of OVPD, the boundary layer extends

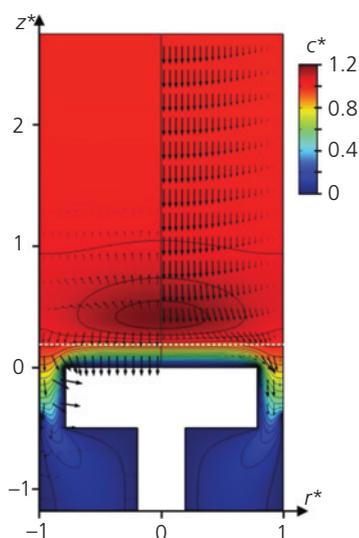

**Figure 5.42** Schematic of an OVPD vessel (length,  $L$ , radius,  $a$ ) with a laser induced fluorescence (LIF) monitor. Molecular concentrations from pulsed material injection along the length of the tube are illustrated by the spreading bell-shaped curves. Here,  $\dot{V}$  = molar velocity, and PL = photoluminescence from the molecular species. In LIF, a laser is used to optically pump the molecules whose resulting PL is measured with a photodetector. The intensity of the signal provides the concentration of molecules in the laser beam path in real time, and the temperature is determined by the peak PL wavelength (Rolin et al., 2012).

Reprinted from Rolin, C., Vartanian, G. & Forrest, S. R. 2012. Laser induced fluorescence monitoring of the transport of small organic molecules in an organic vapor phase deposition system. *J. Appl. Phys.*, 112, 113502 with the permission of AIP Publishing.

to a distance of  $\delta > 10$  cm from the cooled substrate surface in a chamber with a diameter of 25 cm. The calculated flow pattern in the vicinity of the substrate in a vertical OVPD chamber showing the extent of the boundary layer is illustrated in Fig. 5.43 under typical conditions used in organic film growth.

Most practical organic optoelectronic devices use multi-component or doped thin films. Because gas diffusivity is high, host and dopant molecules interdiffuse in the deposition chamber en route to the substrate, provided that the transit time is longer than the characteristic diffusion time. It has been shown that complete intermixing is achieved when the chamber length is approximately equal to its diameter (Lunt et al., 2009). An alternative for achieving mixing is to use a shower-head gas diffuser that is placed in close proximity to the substrate, well within the boundary layer itself (Schwambera et al., 2002). In both cases, the doping of one material into a second is controlled by differentially regulating the introduction of the various species into a diluting gas stream by adjusting the gas flow rate from each source cell, as

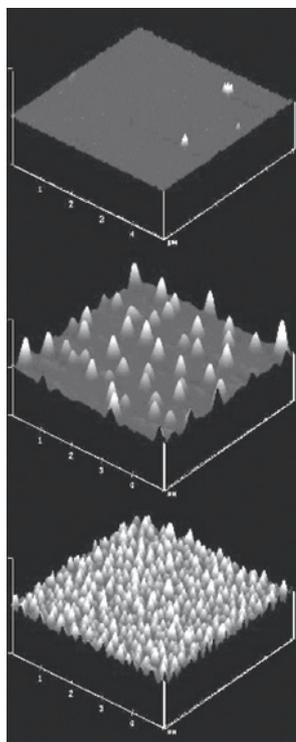

**Figure 5.43** Organic concentration  $c^*$  in the OVPD chamber calculated for a chamber pressure of 1.5 torr,  $\text{N}_2$  carrier gas flow rate of 200 sccm, and an organic concentration of  $7.5 \mu\text{mol}/\text{m}^3$ . The position along the chamber axis,  $z^*$ , and radially,  $r^*$ , are normalized to the chamber radius, and  $c^*$  is normalized to the total organic concentration. Arrows in the left and right panels depict, respectively, the relative diffusive and convective fluxes of the organic species. The lengths of the arrows indicate the magnitude of the flux. Thin black contour lines above the substrate holder (the white "T") indicate the extent of the boundary layer, where the diffusive flux is opposite to the direction of convective flux of the organic material (Rolin et al., 2014).

well as the temperature of the carrier gas. By adjusting the gas flow rate, a high degree of stability and control over the relative concentration of species is possible. This situation cannot be easily achieved using only temperature control employed in VTE due to the exponential dependence of evaporation rate on temperature (cf. Eq. 5.15).

The morphologies of  $\alpha$ -NPD thin films in Fig. 5.44 illustrate the surface morphologies attained under different thermodynamic conditions used in OVPD. At  $T_{cell} = 270^\circ\text{C}$ , a carrier gas flow rate of  $> 10$  standard cubic centimeters per minute (scm), and a deposition rate  $< 1$  nm/s, lead to molecularly smooth films, similar to those grown by VTE. For higher evaporation temperatures and deposition rates, the films roughen due to incorporation of  $>20$  nm diameter spherical clusters. Increasing  $V$  reduces the deposition rate, thereby resulting in smoother films.

*Homogeneous nucleation* occurs when organic molecules in the gas phase undergo rapid cooling in proximity to the substrate within the boundary

**Figure 5.44** Atomic force micrographs of 200 nm thick  $\alpha$ -NPD films deposited on silicon by OVPD. Each scan is a  $5\ \mu\text{m}$  square, with a vertical range of 50 nm. Films are deposited at rates of (in order, from top to bottom): 0.84, 1.07, and 1.18 nm/s, having rms surface roughnesses of 0.8 nm, 3.6 nm, and 4.5 nm, respectively (Shtein et al., 2001).

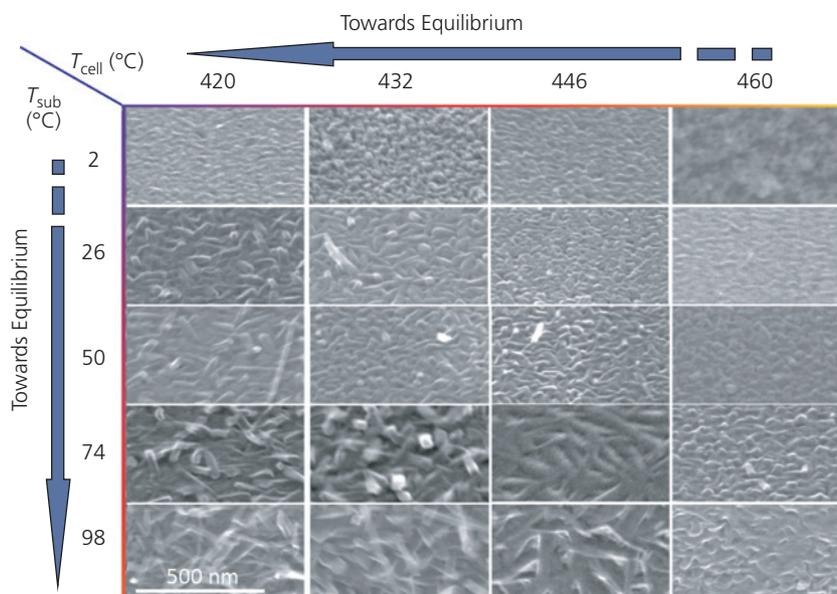

Reprinted from Shtein, M., Gossenberger, H. F., Benziger, J. B. & Forrest, S. R. 2001. Material Transport Regimes and Mechanisms for Growth of Molecular Organic Thin Films Using Low-Pressure Organic Vapor Phase Deposition. *J. Appl. Phys.*, 89, 1470 with the permission of AIP Publishing

layer. If the boundary layer becomes supersaturated with the organic solute, homogeneous nucleation creates an aerosol of organic clusters within the inert carrier gas. The clusters settle onto the substrate, producing rough surfaces in Fig. 5.44. Larger deposition rates increase the organic concentration near the cold substrate, and hence the number of clusters increases. Cluster growth is reduced by maintaining a sharper temperature gradient near the substrate, or by using higher carrier gas flows where the mass transfer rate to the substrate exceeds the cluster formation rate.

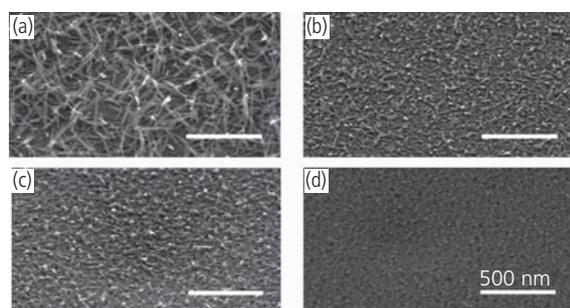

Considerable control over morphology can be asserted well before gas phase nucleation is observed. Indeed, it is precisely the ability to fine tune morphology that makes OVPD a powerful growth technique in organic electronics. Figure 5.45 provides a matrix of CuPc thin film morphologies accessible to OVPD as the substrate and source cell temperatures are varied at a fixed flow rate. In this matrix. The gas flow rates, deposition times and pressures are held constant for all samples. Except for  $T_{cell} = 460^\circ\text{C}$  and  $T_{sub} = 2^\circ\text{C}$  where the high-evaporation rate and rapid cooling near the substrate result in an aerosol of particles, the surface texture shows a monotonic dependence on temperature. The arrows point in the direction of conditions closer to equilibrium. That is, the introduction of molecules into the gas stream exponentially slows with a decrease in cell temperature. Thus, adsorbed molecules have a longer duration to seek low energy (near-equilibrium) surface sites before being buried by subsequently arriving material. Similarly, increasing the substrate temperature adds kinetic energy to the surface molecules, allowing them to move more quickly to sites of lower energies. Films generated near to equilibrium show a needle-like morphology, indicating the growth of crystallites that protrude above the otherwise flat film surface. Amorphous films are produced far from equilibrium.

Figure 5.46 shows the complementary data obtained at fixed temperatures, but at varying carrier gas flow rates. These micrographs are in order of increasing rate (from Fig. 5.46a to d), and hence toward less equilibrium growth conditions. As in Fig. 5.45, near-equilibrium growth results in long and narrow crystallites, whereas at high flow rates, the growth is far from equilibrium, resulting in flat and amorphous film morphologies.

Apparently, the presence of a carrier gas during deposition and the independent control of multiple chamber pressure and temperature conditions can be exploited to create a broad variation in thin film morphology. Thus, the films can approach an equilibrium morphology, depending on the balance between kinetic and the diffusion limited conditions.

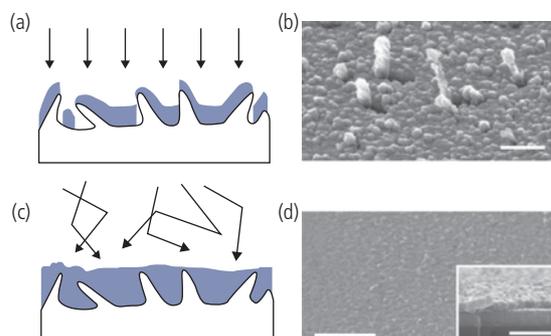

**Figure 5.45** Scanning electron microscope (SEM) images of CuPc films grown on ITO vs. substrate and source cell temperatures at a constant The carrier gas flow rate is 100 sccm, and the chamber pressure is 0.45 torr (Yang et al., 2005b).

**Figure 5.46** SEM images of the surface morphologies of CuPc obtained at flow rates of (a) 100, (b) 125, (c) 150, and (d) 200 sccm at constant source and cell temperatures.

An example of the different morphological control exerted by OVPD compared to VTE is the growth of CuPc on a microcrystalline ITO surface shown in Fig. 5.47. Local strain imparted by the ITO results in a Stranski–Krastanov growth mode, whereby a thin wetting layer gives way to long crystalline protrusions that rise well above the film surface, similar to the morphology in Fig. 5.46a. The directional deposition of by VTE results in shadowing of the evaporant by the protrusions leaving voids in the film (see Fig. 5.47a). Indeed, this is observed in the SEM image in Fig. 5.47b of a PTCBI/BCP/Ag composite layer deposited onto the CuPc surface. Voids are clearly apparent to the right of each protrusion since the deposition source is offset slightly to the left of the center of the image. Directional deposition is also

**Figure 5.47** Deposition by (a) VTE or the kinetic regime of OVPD results in directional trajectories from source to substrate. If there are irregularities on the substrate surface, directional deposition can result in a coating (shaded regions) that leaves voids and gaps. (b) SEM image of OVPD-grown CuPc nanocrystalline protrusions resulting from strained Stranski–Krastanov growth on a polycrystalline ITO substrate. The CuPc is coated with a layer comprising PTCBI/BCP/Ag grown by VTE. Voids are visible to the right of each crystallite. (c) In the diffusive OVPD growth regime, the adsorbed layer conformally coats the substrate surface, burying the irregularities. (d) SEM image of a CuPc film as in (b), coated by a 50 nm thick layer of PTCBI showing complete substrate coverage. Inset: Cross-section of the film showing the absence of voids. Scale bars (white) in the SEM images are 500 nm (Yang et al., 2005a).

accessible in the kinetic growth regime of OVPD. However, in the diffusive regime, the molecular paths within the boundary layer are randomized, resulting in complete conformal coating of the surface features (Fig. 5.47c), shown for OVPD grown PTCBI in Fig. 5.47d. There are also no voids in the cross-sectional

image in Fig. 5.47d, inset. Such morphological control, ranging from uniform blends to nanocrystallites (Yang et al., 2007), to continuous crystalline layers extending across entire substrate surfaces (Lunt et al., 2007) are made possible by varying conditions used during growth. In Chapters 6–8 we show that this leverage over morphology provides a means for creating thin film structures that result in higher performance OLEDs (Zhou et al., 2005), transistors (Shtein et al., 2002), and solar cells (Yang et al., 2007, Song et al., 2014).

While hot OVPD reactor walls prevent condensation, if two materials with widely different evaporation and decomposition temperatures are co-deposited, the low evaporation/decomposition temperature species can potentially decompose on contact with walls heated to prevent adsorption of the species with the higher evaporation temperature. To prevent decomposition, the different layers can be evaporated in separate chambers held at temperatures appropriate to the particular species being evaporated, with the substrate translated between the chambers as required. When two such materials must be co-doped into a single film, their widely different sublimation and decomposition temperatures may be accommodated by decreasing collisions with the chamber walls by increasing the carrier gas flow rate. Alternatively, a lamellar protective gas “curtain” injected along the periphery of the furnace tube can minimize molecular collisions with the walls. These complexities do not exist in VTE deposition, where each species is separately heated to its individual evaporation temperature and then is ballistically transported through the cold-walled vacuum chamber to the substrate.

#### 5.4.2.4 Film deposition from liquid solution

Casting films from the solution phase is widely used for the deposition of large molecular weight or low decomposition temperature materials that cannot be deposited from the vapor phase. Hence, solution processing has been almost universally adopted for the deposition of polymers and many fragile, or large molecular weight species. The organics must be soluble to be deposited from solution, which may require chemical modification or functionalization. This modification may, in turn, adversely impact the optical and conductive properties of the molecule, since the solubilizing groups may sterically hinder or alter the desired molecular packing and film morphology.

Spin-on and casting are the two most frequently used means for solution deposition. Additional means include spray-on, uniform spreading using a

*doctor blade*, *slot dye coating*, and attachment of free standing films by lamination. *Solution casting* entails the feeding of the solubilized molecules onto a substrate that is either stationary, or is translated beneath the solution source (Siemann, 2005). The spin-on method is accomplished by placing a drop of solvent containing the solute onto a substrate that is rapidly rotated. Ultrathin films are produced by the competition between centrifugal force that draws the film toward the substrate edges where the excess is ejected, and evaporation of solvent that results in an increase in viscosity as the film solidifies.

Determining film thickness vs. spin rate is complicated by the interplay between fluid flow in the surface plane, and evaporation. The change of film thickness,  $h_f$ , with time,  $t$ , of a liquid with initial viscosity,  $\eta_0$ , and density,  $\rho$ , on a disc rotating at angular velocity,  $\omega$ , is (Emslie et al., 1958)

$$\frac{dh_f}{dt} = -\frac{2\rho\omega^2 h_f^3}{3\eta_0}. \quad (5.31)$$

This is counterbalanced by the evaporation rate (Bornside et al., 1987):

$$r_{ev} = \left[ \frac{cD_g p_s M_s}{\eta_g^{1/2} \rho RT} \right] \sqrt{\omega} (x_{s0} - x_g). \quad (5.32)$$

Here,  $c$  is a constant,  $D_g$  is the diffusivity of the solvent in the gas phase,  $p_s$  is the vapor pressure of the pure solvent at temperature  $T$ ,  $\eta_g$  is the kinematic viscosity of the gas,  $M_s$  is the molecular weight of the solvent,  $x_{s0}$  is the initial mass fraction of the solvent to the polymer solute, and  $x_g$  is its mass fraction in equilibrium with the gas phase. From these two expressions, we obtain the film thickness when the fluid flow ceases (i.e. the wet film becomes immobile and resistant to further changes in thickness) (Hall et al., 1998):

$$h_{wet} = \left[ \frac{3\eta_0}{2\rho^2 \omega^{3/2}} \frac{cD_g p_s M_s}{\eta_g^{1/2} \rho RT} (x_{s0} - x_g) \right]^{1/3}. \quad (5.33)$$

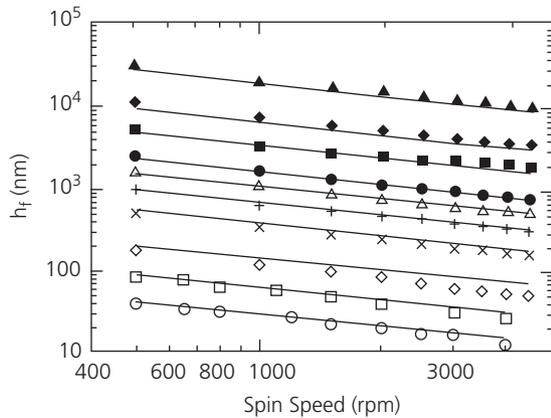

Since the final film thickness is determined by evaporation only, we have

$$h_f = h_{wet} (1 - x_{s0}) \propto \left[ \frac{\eta_0}{\omega^{3/2}} \right]^{1/3} (1 - x_{s0}). \quad (5.34)$$

That is, the film thickness dependence on rotational velocity follows  $1/\sqrt{\omega}$ . This dependence is illustrated in Fig. 5.48 for the case of polystyrene of different concentrations (and hence initial viscosities) in a toluene.

The functional dependence on rotational velocity holds for a wide range of film thicknesses, from

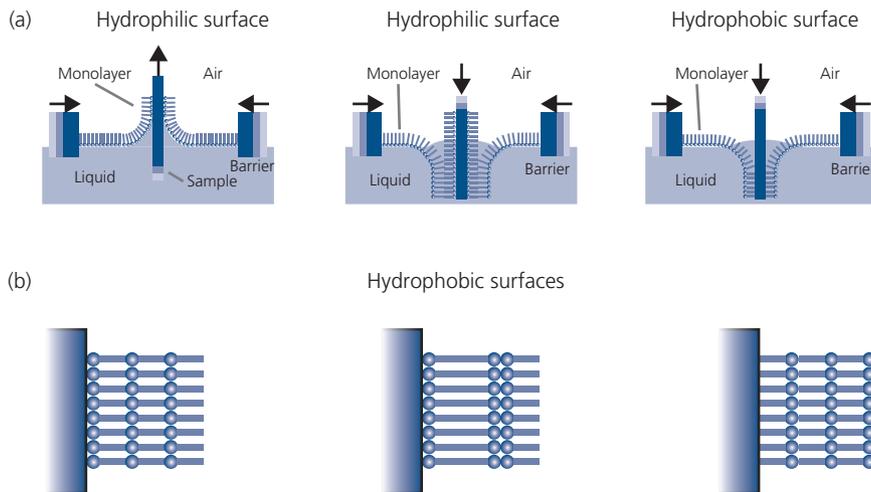

hundreds of microns to less than 10 nm, with typical rotational velocities from 500 to 5000 rpm. While spin-on deposition is useful for laboratory demonstrations, it is not scalable to substrate sizes that exceed a few tens of centimeters. Also, solvent flow around sharp edge features on a patterned substrate can cause non-uniformities in film thickness that can affect the device properties. Conversely, balancing film viscosity, temperature, and rotational speed can planarize an

**Figure 5.48** Polystyrene (PS) film thickness vs. spin speed for different PS concentrations in a toluene solution. From bottom, the wt% of PS in toluene is 0.5, 1, 2, 4, 6, 8, 10, 15, 20, and 30. The straight lines corresponding to Eq. 5.33, at  $T = 303$  K,  $m_g = 0$ ,  $\eta_s = 0.1553$  cm<sup>2</sup>/s,  $c = 0.5474$ ,  $\rho = 0.87$  g/cm<sup>3</sup>,  $M_s = 92$  g/mol,  $p_s = 0.029$  atm,  $D_g = 0.086$  cm<sup>2</sup>/s, and  $\eta_0$  is an inverse function of  $m_{s0}$  (Hall et al., 1998).

otherwise irregular surface (Bornside, 1990). Spray-coating or doctor blades that are translated across the substrate surface can produce nanometer thick films on substrates without size limitations.

Monolayer deposition control, and even layer-by-layer growth can be achieved by solution casting using the *Langmuir–Blodgett* (L-B) technique (Blodgett and Langmuir, 1937). This method is based on casting a single layer of molecules onto the surface of a shallow trough filled with water. The molecules are functionalized with a *hydrophilic* unit on one end, and a *hydrophobic* unit on the other. By withdrawing a substrate with a hydrophilic surface from the trough, a single layer of molecules attaches to the substrate surface. The surface energy of the molecules on the substrate must be greater than that on the water. As shown in Fig. 5.49a, this method is capable of applying one monolayer at a time until the desired total film thickness is achieved. Furthermore, the functionality and orientation of the molecules can be varied layer-by-layer by choosing whether to submerge or withdraw the substrate from the solution at a particular step. Several molecular orientations that can be achieved by variations in the dipping sequence are shown in Fig. 5.49b. To deposit a continuous, nearly defect-free film, barriers surrounding the trough are moved inward to exert pressure on the floating monolayer of source molecules. After each translation of the substrate into the solution, the

**Figure 5.49** Langmuir–Blodgett process for layer-by-layer growth of molecules having a hydrophilic end group (circles) and a hydrophobic tail. (a) Using a substrate with a hydrophilic surface, a monolayer of molecules is attached as the substrate is withdrawn from the solution. On re-submersion, the now hydrophobic surface picks up a second ML of hydrophobic molecules. Alternatively, a hydrophobic surface picks up the ML during submersion. The submersion/withdrawal cycle can be repeated many times to build up thick films one monolayer at a time. After each cycle, barriers at the edge of the trough are moved inward to maintain an unbroken monolayer on the solution surface. (b) Various layer orientations that can be assembled on a hydrophobic surface depending on the direction of motion of the substrate relative to the solution.

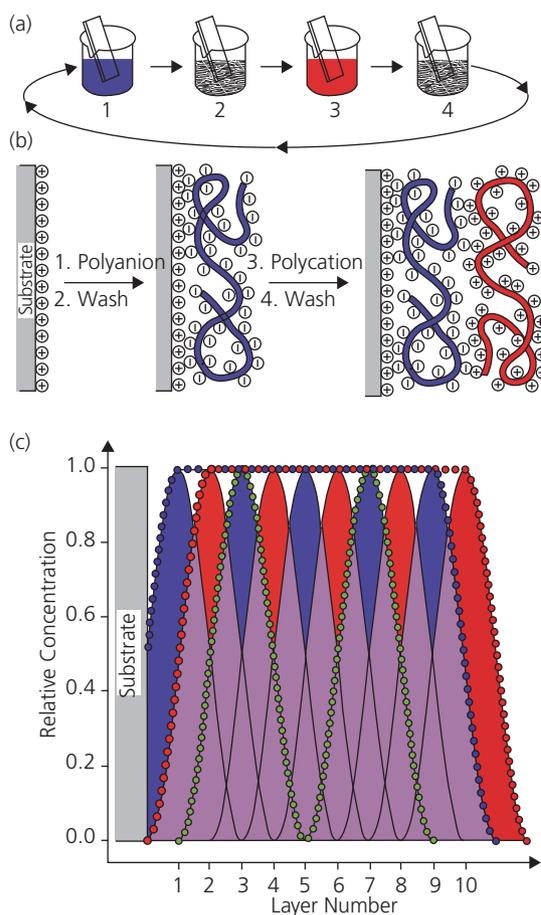

barriers are moved to eliminate gaps due to depletion of the molecules now attached to the substrate.

While capable of depositing films many thousands of monolayers thick, this technique has several limitations. The molecules, substrate and solution must be chosen to create a space-filling monolayer on each dip of the substrate that is free of defects such as tears or gaps, and to ensure that the orientation of the molecules in solution is uniform. Also, the surface of the solution must be unperturbed to ensure a defect-free molecular raft. Hence, the process is slow and impractical for coating large surface areas. A different strategy based on selecting charged molecules circumvents some of the shortcomings of the L-B technique. Here, alternating layers of cationic and anionic molecules are picked up using a charged, or neutral dielectric substrate (Iler, 1966). This method has been used to selectively deposit monolayers of large molecules and polymers as illustrated in Fig. 5.50 (Decher, 1997).

A shortcoming of solution deposition is the difficulty in growing multilayer structures where each layer has a different composition. After depositing the first film and removing all of the residual solvent by drying in vacuum or at elevated temperatures, the second layer is then deposited. However, if a similar solvent is used for the second layer as for the first, it can redissolve the first layer, thereby creating defects or non-uniformities in the film. To prevent layer dissolution, the second layer must use an “orthogonal” solvent, that is, a solvent that does not interact with the first deposited film. Examples of two orthogonal classes are hydrophilic and hydrophobic solvents (Gong et al., 2005, Meerholz, 2005). There is a third class of hydrofluoroether-based solvents that can also be introduced to provide further process flexibility (Zakhidov et al., 2008, Lassiter et al., 2013), although these have not been exploited to a significant extent.

Even by the use of three orthogonal solvents, the compositions and complexities of multilayer structures that are needed to achieve high performance electronic devices are severely limited. Hence, other approaches have been sought to meet this challenge. One example is to harden (or cure) the deposited layer by cross-linking using thermal or ultraviolet (UV) radiation, making it resistant to attack by subsequent solvent exposure. Alternatively, a film can be protected by capping it with a continuous, chemically inert layer prior to subsequent solvent-based depositions. This strategy has been employed, for example, in solution-processed tandem organic solar cells, whereby the intervening ZnO layer serves the dual purpose of protecting the first cell deposited on the substrate, as well

as providing a transparent charge injection layer separating the two sub-solar cells forming the stack (Gilot et al., 2007). Similarly complex structures use using metal nanoparticle layers combined with a material such as PEDOT:PSS that is water soluble (and hence impermeable to organic solvents used in depositing the top and bottom cells) prevent penetration of the solvent from the upper to the lower cells (see Fig. 5.51) (Hadipour et al., 2006, Che et al., 2018). Although barrier layers can prevent deterioration of active device regions, even small defects or irregularities can result in pin-holes that allow penetration of solvents into the underlying layer. Furthermore, the insertion of such

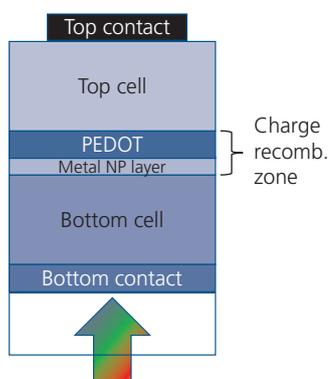

**Figure 5.50** Method for layer-by-layer deposition of high molecular weight compounds using electrostatic selection. (a) Each beaker contains a different solution: **1** contains the polyanion, **2** a wash, **3** polycation, and **4** a wash. (b) Moving the functionalized substrate between the beakers alternately deposits a single polyanion and polycation layer, building up the structure as shown. (c) Schematic diagram of the distribution of molecules within each layer, using the same color scheme for anionic (blue) and cationic (red) species as in (a) and (b) (Decher, 1997).

barriers is incompatible with device operation, and hence their use can limit design flexibility.

Finally, solvents can dissolve or physically damage small molecule layers that have been previously vacuum-deposited onto a substrate. When combining solution and vapor-deposited compounds, it is preferred to start by depositing the solution-based structure, followed by vacuum deposition of the small molecule layers.

From the foregoing discussion, we see that solution deposition is generally incompatible for use in devices with more than just a few functional layers. Nevertheless, solution processing remains attractive due to its compatibility with patterning via ink-jet printing, as well as its potential for low cost deposition over large substrate areas. Indeed, when it is followed by vacuum deposition of small molecule based multilayers, complex and functional layer systems and devices can be achieved. While providing constraints in device engineering, many promising methods for avoiding its limitations have been devised, making it an essential process in organic electronics.

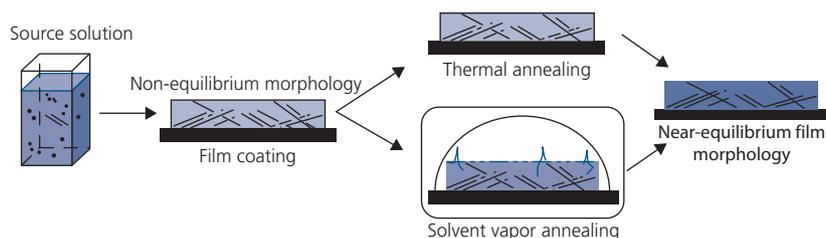

**Figure 5.51** Schematic of a tandem solar cell consisting of two sub-cells deposited using similar organic solvents, and an ultrathin metallic nanoparticle charge recombination zone combined with a thicker, water soluble transparent PEDOT:PSS hole conducting layer. The PEDOT prevents penetration of the organic solvent used in preparing the top cell from dissolving the pre-deposited bottom cell. The arrow indicates the incident solar radiation.

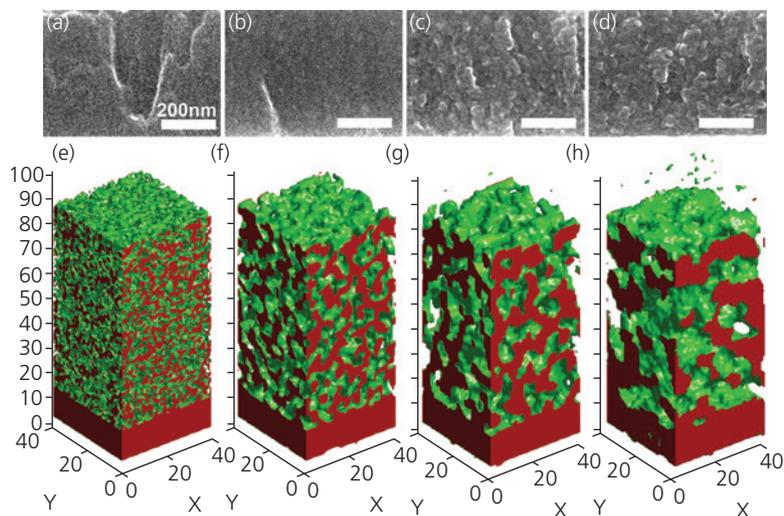

## 5.5 Post-growth control of structure

Often the desired morphology is not achieved during deposition. Indeed, the kinetics of growth often prevent molecules from finding their lowest energy, equilibrium positions within the solid, resulting in microcrystalline or even more frequently, amorphous thin film morphologies. To drive the film away from these unstable, or metastable morphologies to one closer to equilibrium, various post-deposition annealing strategies have been developed for both polymers and small molecules. The principle of annealing is to impart energy into the solid over a duration sufficiently long to allow the molecules to locally rearrange into phase-segregated crystallites in a structure closer to equilibrium. The methods used generally fall into two categories: *thermal annealing* and *solvent vapor annealing (SVA)*.

The processes and effects of annealing of a solution-cast film are illustrated in Fig. 5.52. The source solution comprising one or more molecular species dissolved in a solvent is deposited onto a substrate where it assumes a non-equilibrium morphology. Then the energy is added by either heating (thermal annealing) or by exposure to a solvent vapor in a sealed vessel (SVA). The molecules are able to migrate over limited distances within the film, allowing them to reorganize into a structure that is closer to equilibrium. If there is more than one molecular species, they may phase separate into entangled regions. Independent of the number of species, the annealed sample can develop crystalline domains that vary in size from nanometers to micrometers. The crystallites may also be separated by intervening amorphous regions, depending on the annealing conditions used. Similar processes can also be applied to vapor-deposited materials. In the following, we will explore both thermal and solvent annealing in greater detail. Indeed, structural annealing is a powerful method that can lead to remarkable improvements in organic solar cells and transistors, both of which require a degree of crystalline order to achieve high performance.

**Figure 5.52** A mixture of the material to be deposited and the solvent provides the source solution. The as-deposited material assumes a non-equilibrium morphology (*top*). Using either solvent vapor or thermal annealing, the film morphology reorganizes into a structure closer to equilibrium (*bottom*).

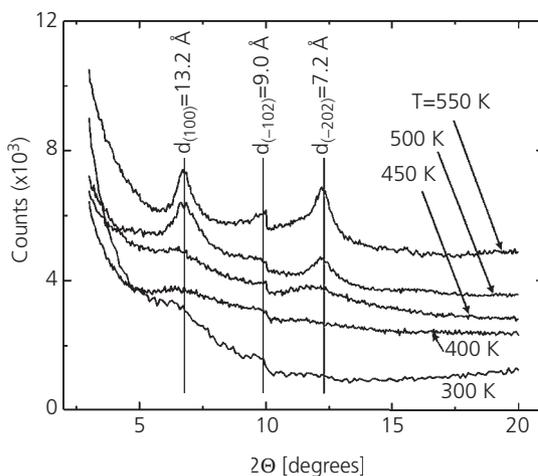

**Figure 5.53** Scanning electron micrographs of 4:1 CuPc:PTCBI films annealed under different conditions. (a) As-deposited, and annealed for 15 min at (b) 450 K, (c) 500 K, and (d) 550 K. (e–h) Monte Carlo simulations of the equilibrium configurations of a 1:1 CuPc:PTCBI mixture obtained at the temperatures corresponding to the micrographs immediately above. These configurations are based on the cohesive energy of each molecule, viz.  $E_{CO} = E_0 \exp(-\Delta H^{vap}/RT)$ , where  $E_0$  is a constant (Peumans et al., 2003).

First publication in Springer Nature, 2003.

### 5.5.1 Thermal annealing

Thermal annealing of mixtures of the small molecules, CuPc and PTCBI is shown in Fig. 5.53. Homogeneous blends of 4:1 CuPc:PTCBI were thermally annealed while the surface was confined to its as-grown flat morphology by a 100 nm thick Ag film (Peumans et al., 2003). Cross-sectional SEM images of films annealed at different temperatures are presented in Fig. 5.53a–d, along with spatial “maps” that simulate the structural evolution during annealing in Fig. 5.53e–h. The as-grown homogeneous mixture in Fig. 5.53a and e forms nanocrystalline domains consisting nearly exclusively of pure regions of each molecular constituent. The calculation assumes an equilibrium configuration is achieved when the sum of the free energy of all contacts between dissimilar molecules is minimized. The internal film structure is modified by annealing even though the film surface is held flat by the Ag cap.

In addition to forming clusters, annealing promotes crystallization within the domains themselves. Figure 5.54 shows X-ray diffraction patterns of the same blends immediately after growth, and following annealing for 15 min at 400 K, 450 K, 500 K, and 550 K. Several peaks emerge after annealing at 450 K and above. These peaks become more intense at higher annealing temperatures, indicating the growth of CuPc crystalline domains within the blends. It is inferred, therefore, that PTCBI is being excluded from the C<sub>60</sub> domains. No peaks are observed that can be

**Figure 5.54** X-ray diffraction patterns of 1:4 CuPc:PTCBI films annealed at different temperatures. The lattice  $d$ -spacings refer to diffraction from the CuPc crystal planes indicated. The domain size of  $(12 \pm 1)$  nm is calculated from the width of the diffraction peaks, and is consistent with calculations in Fig. 5.53 (Peumans et al., 2003).

First publication in Springer Nature, 2003.

attributed to PTCBI. This suggests that domains containing this species are amorphous, and they may also contain residual C<sub>60</sub> molecules. It was found that surfaces without an Ag capping film roughen considerably on annealing at these same temperatures and times, and large crystalline needles emerge from the surface at high temperatures.

Similar crystallization has been observed after annealing OPV active regions consisting of P3HT mixed with PC<sub>61</sub>BM. Both the individual constituents as well as the blends crystallize on heating to just above the melting temperature of P3HT ( $T_m = 205^\circ\text{C}$ ), or the PC<sub>61</sub>BM glass transition temperature ( $T_g = 155^\circ\text{C}$ ) (Ma et al., 2005, Verploegen et al., 2010). The  $T_g$  is the temperature where an amorphous (glassy) solid changes to a molten or elastic-like phase.

Crystallization of a polymer maintained at or above its melting or glass transition temperatures for time  $t$ , is described by the *Avrami equation* (Avrami and Bennett, 1978):

$$V(t) = V(0)[1 - \exp(-(kt)^n)], \quad (5.35)$$

where  $k$  is the reaction rate given by

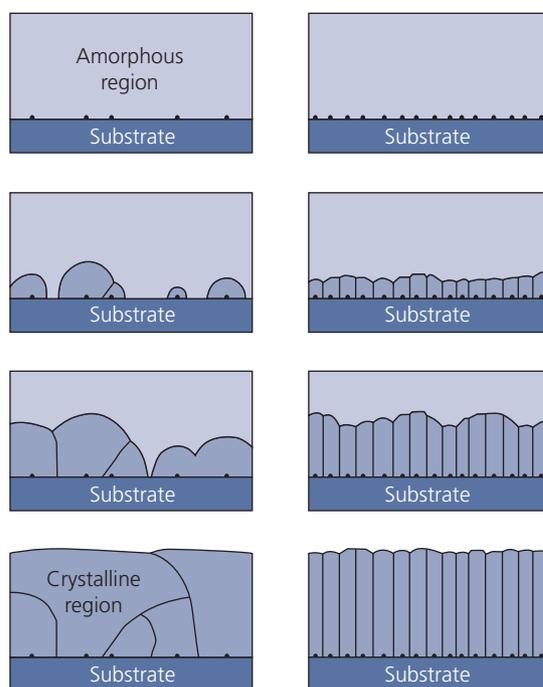

$$k = k_\infty \exp(-\Delta E/k_B T). \quad (5.36)$$

Here,  $n$  is a dimensionless exponent in the range 1–3 that roughly corresponds to the dimensionality of the crystallites of volume  $V(t)$  formed during annealing over time,  $t$ ,  $\Delta E$  is the activation energy for annealing, and is a constant (Avrami, 1940).

Crystallization starts from a “germ” nucleus that exists in the as-grown film. The nuclei arise from native structural heterogeneities that develop during deposition or synthesis, or they can form around extrinsic impurities or substrate defects. Once heated, crystallites nucleate around these irregularities and grow until the entire film volume is consumed. The dimensionality of the growth depends not only on the temperature (and time), but also on the density of nucleation sites. In the case of *heterogeneous nucleation* in Fig. 5.55, a high density of nucleation sites prevents lateral growth over large distances. This confines the crystallites, which must therefore grow vertically into an ordered orientation.

### 5.5.2 Solvent annealing

Control over crystallization following film growth can also be achieved when the deposit is exposed to a solvent, or its vapor. Indeed, SVA can lead to highly controlled nucleation and growth of crystallites in both polymer and small molecular weight solids. This process is typically used in conjunction with solution deposited films. During the initial film deposition, rapid evaporation of the solvent freezes the film into a morphology far from its most stable state. Once the film is free of its initial solvent, it is exposed for several minutes to the vapors of a second solvent of different composition from the first. The secondary

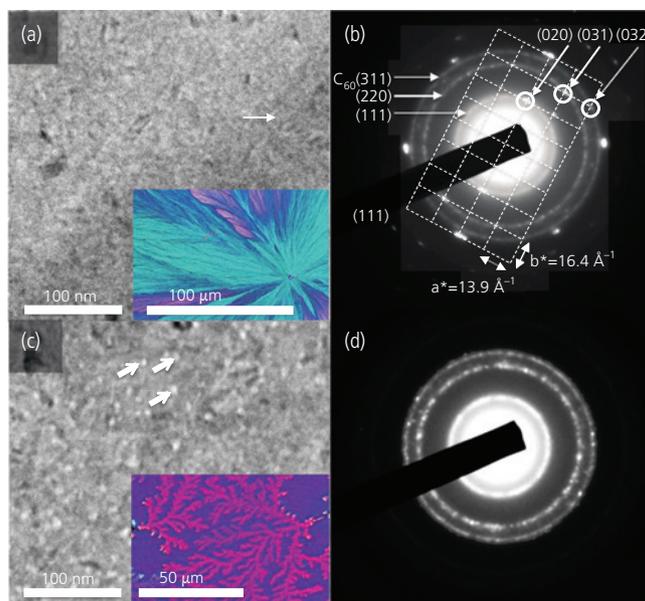

**Figure 5.55** Two different modes proposed for crystallization of PC<sub>61</sub>BM as inferred from X-ray data. (*left*) Nucleation at a low density of germ nuclei, with an Avrami exponent of  $n = 1.8$ , and (*right*) at a higher density of sites with  $n = 1$ . The higher exponent is indicative of nearly two-dimensional (2D) growth, whereas  $n = 1$  suggests ordered one-dimensional domain growth (Verploegen et al., 2010).

solvent molecules penetrate the film, enabling the molecules to seek a configuration closer to equilibrium.

Exposure to the solvent, DCM, of the active regions of solution-deposited DPASQ capped with VTE-grown C<sub>60</sub>/PTCBI films provides a dramatic example of the morphological modifications that films can undergo by SVA (Zimmerman et al., 2013). The small DCM molecules induce 2D, inhomogeneous spherulitic growth of crystals that proceeds rapidly along the substrate plane, radiating out from nucleation sites within the DPASQ film. When capped with C<sub>60</sub> and then subsequently exposed to the solvent vapor, crystallites form in the DPASQ that align to self-assembled nanocrystalline domains that spontaneously form during vacuum deposition of the C<sub>60</sub> layer. Indeed, C<sub>60</sub> has a strong tendency to crystallize on almost any surface into close-packed layers.

The crystallization of the underlying amorphous layer whose domains are aligned to the overlying crystal is an example of *inverse quasicpitaxial growth*. As in the case of conventional quasicpitaxy (Section 2.6.2), there is no well-defined commensurate relationship between the first layer and the cap. Inverse

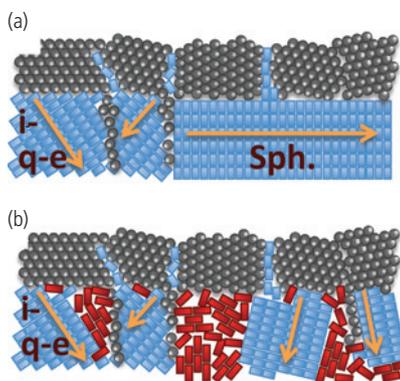

**Figure 5.56** (a, c) Transmission electron micrographs and (b, d) selected area electron diffraction (SAED) patterns after solvent vapor annealing (SVA) of (a, b) DPASQ/C<sub>60</sub>/PTCBI spherulite structures, and (c, d) blended squaraine/C<sub>60</sub>/PTCBI layers. R., Control of interface order by inverse quasi-epitaxial growth of squaraine/fullerene thin film photovoltaics. *ACS Nano*, 7, 9268. Copyright 2013 American Chemical Society.

quasiepitaxy differs since alignment of the underlying layers to the cap occurs following growth of the cap. In conventional quasiepitaxy, alignment is to the substrate. This suggests that there is a strong energy-driven tendency to crystallize even when a confining cap is present—a situation similar to that in Fig. 5.53.

The crystalline texture and morphological properties of an inverse quasi-epitaxial DPASQ/C<sub>60</sub> structure are elaborated in Fig. 5.56. A bright field transmission electron micrograph as well as an optical micrograph of a spherulitic crystal structure formed during SVA are shown in Fig. 5.56a. The DPASQ aligns to the predeposited C<sub>60</sub> cap, but is not in perfect registry, as indicated by the DPASQ diffraction spots that lie slightly off of the C<sub>60</sub> rings in Fig. 5.56b. However, when the asymmetric DPASQ is blended with its symmetric molecular analog, DPSQ, in a 4:6 ratio, the diffraction spots decorate the C<sub>60</sub> diffraction rings shown in Fig. 5.56d. The micrographic image of the dendritic structure is shown in Fig. 5.56c. This indicates that inverse quasiepitaxial growth does not proceed along the substrate plane, but rather perpendicular to it.

The morphological studies of Fig. 5.56 lead to the growth scenario in Fig. 5.57a. The upper layer (circles) depicts the self-assembled nanocrystalline cap C<sub>60</sub>

R., Control of interface order by inverse quasi-epitaxial growth of squaraine/fullerene thin film photovoltaics. *ACS Nano*, 7, 9268. Copyright 2013 American Chemical Society.

layer, and the lower squaraine layer (blue rectangles) shows the direction of fast crystallization (arrows) either in the film plane (thus forming a *spherulite*, Sph.), or into the film bulk (resulting in inverse

quasiepitaxial growth, i-q-e). In the blended squaraine in Fig. 5.57b, the squaraine layer phase separates into nanocrystalline DPASQ-rich areas (blue rectangles) that interdiffuse into the  $C_{60}$ , and the DPSQ-rich areas (red rectangles).

The impact that molecular order at interfaces has on charge recombination dynamics was discussed in Chapter 4. In general, a high degree of order between molecules increases conductivity and exciton diffusion, but it can also increase charge recombination. A balance between these competing processes has been achieved by SVA of small molecule OPV cells, whereby disorder at the interface is pinned, although order is developed within the bulk of the contacting layers (see Section 7.4.3). This apparently complex morphological tradeoff is obtained by capping the amorphous squaraine film with a vacuum deposited  $C_{60}$  layer. Adjacency of molecules at the interface is not disrupted by subsequent exposure to the solvent vapor that reorganizes the bulk layer structure, thereby nucleating the growth of conductive nanocrystalline channels (Zimmerman et al., 2012). Similar strategies for using SVA has also been applied to polymer OPVs with similar success at manipulating the nanomorphologies of donor-acceptor blends (Li et al., 2007). The process is now frequently used to improve performance of devices where crystalline order is advantageous.

Finally, SVA can control crystallinity to allow for high conductivity in the channels of organic field effect transistors. For example, when the solution processed hole conducting organic small molecule, triethylsilyl-ethynyl anthradithiophene, is exposed to 1,2-dichloroethane, the morphology changes from an amorphous morphology attained on spin-coating, to a polycrystalline structure whose grains are as large as 1  $\mu\text{m}$  in the transistor channel. The consequence of crystallization is an increase in the transistor field effect mobility from 0.002  $\text{cm}^2/\text{V s}$  for the as-spun-on sample, to 0.2  $\text{cm}^2/\text{V s}$  after SVA—a 100-fold improvement. The changes observed on SVA do not strongly depend on the polarity or the boiling temperatures of the solvents employed (Dickey et al., 2006). This provides further evidence that the solvent vapors act simply by mechanical intercalation between the larger molecules, allowing them to move to more energetically favorable locations during the process.

## 5.6 Film patterning

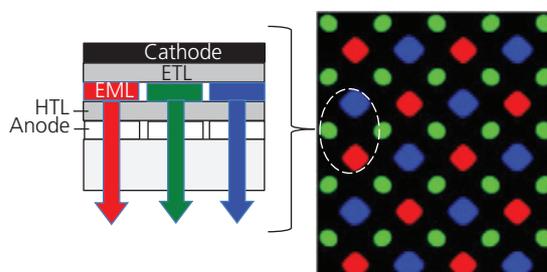

The primary goal in film growth is to cover the substrate surface with a highly uniform and pure layer (or layers) of the desired composition and morphology, using minimal energy and materials. However, almost every conceivable electronic device requires

patterning to define its active area. This entails the definition of electrode size and shape, and often the active organic material itself must be patterned to provide a well-defined path for optical, current or thermal transfer. Pattern sizes ranging from tens of nanometers to centimeters are common for optoelectronic components, ranging from quantum-effect devices to large area lighting appliances and solar cells.

An illustration of the challenges faced in patterning of electronic devices is in defining the red (R), green (G), and blue (B) pixels that comprise a full color OLED display. These sub-pixel elements can be as small as 10  $\mu\text{m}$ , depending on the resolution and overall size of the display (larger displays have larger pixels since the viewer is positioned farther from the screen). An example of the sub-pixel arrangement of an OLED display, and a cross section illustrating the patterning challenges is shown in Fig. 5.58. A display requires patterning of millions of very small pixels precisely spaced across very large (several meters) substrates at  $\sim 100\%$  yield. Pixel yield is the ratio of functioning devices to the total number fabricated. Furthermore, materials used for one device (or pixel) must not cross over into the region of its neighbor. This cross-contamination inevitably decreases the color purity of the image. Hence, the multiscale fabrication challenges for patterning very small devices over very large substrates are peculiar to the field of organic electronics, which uniquely benefits from scaling spatial dimensions over many orders of magnitude.

### 5.6.1 Shadow mask patterning

The most common means for patterning organic devices grown from the vapor phase, and for depositing contacts to solution processed thin films, is via the use of shadow masks. The mask is comprised of a thin metal such as Mo. The mask apertures through which

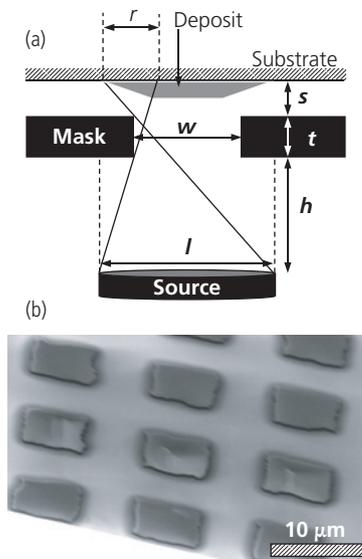

**Figure 5.58** An integrated R, G, B pixel (*left*) that comprises a side-by-side arrangement of the three color pixels. ETL = electron transport layer, EML = emission layer, and HTL = hole transport layer. A microscopic image of the light emission from a full color OLED display (*right*). Note that there are two small green pixels for every larger red and blue emitting pixel. This helps to balance color and lifetime in the display.

material is deposited are defined by conventional photolithography. The mask is placed in close proximity, or in contact with the substrate in the direction facing the evaporation sources. In VTE, the evaporant travels ballistically along a line of sight from source to substrate, depositing through the mask apertures. The pattern resolution is determined by the thickness of the mask,  $t$ , the width of the aperture,  $w$ , the distance from source to substrate,  $h$ , the separation between the mask and the substrate,  $s$ , and the linear dimension of the source,  $l$  (see Fig. 5.59a). Directly behind the aperture, the deposit reaches its full thickness that is monitored in real time with a quartz crystal microbalance. Due to the finite dimensions of  $s$ ,  $t$  and  $l$ , some material is deposited in the shadowed area, forming a penumbra of deposit of width (Shtein et al., 2003)

$$r \approx \frac{(s + 2t)l}{2h} \quad (5.37)$$

As the pattern size decreases, spreading of the deposit beneath the mask becomes a larger fraction of  $w$ , ultimately limiting the achievable pattern resolution. To improve resolution (i.e. by minimizing  $r$ ), the mask thickness,  $t$ , and  $s$  also must be decreased, while  $l$  is increased, although this latter dimension is fixed by the size of the vacuum system.

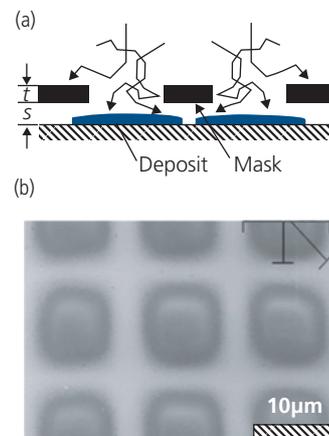

**Figure 5.59** (a) Shadow mask configuration used in patterning thin films by VTE, where molecular trajectories from source to substrate are ballistic. (b) Micrograph of a high resolution array of Alq<sub>3</sub> squares deposited through a shadow mask with  $w = 7.5 \mu\text{m}$  and  $s \ll w \sim 0 \mu\text{m}$  (Shtein et al., 2003).

One limitation of shadow mask patterning is that the aperture width and its distance to an adjacent aperture are limited to approximately the mask thickness. But as the mask gets thinner, its mechanical rigidity decreases, thereby making it more difficult to handle. Also, deposition through a shadow mask results in inefficient materials use since the deposit that falls in areas outside of the apertures is wasted. And the mask must be frequently cleaned to prevent clogging, which is a particularly acute problem for masks with very small apertures.

In spite of these limitations, shadow mask patterning is the dominant process used in production of OLED displays, and is currently used on substrates as large as Gen 8.5 (Table 5.3) to manufacture high resolution displays as large as 77" diagonal. Very large shadow masks need to be placed beneath the substrate as in Fig. 5.59a to prevent particles from falling onto the substrate surface. The mask must be held in intimate contact with the substrate by magnetic or electrostatic attraction. In the latter case, the substrate and mask are oppositely charged during deposition, and then are separated by reversing the electric field. Figure 5.59b shows an array of small ( $\sim 8 \mu\text{m}$  wide) squares of Alq<sub>3</sub> patterned using shadow masks where  $s \approx 0 \mu\text{m}$  (Shtein et al., 2003). The penumbra around the center pattern is due to the finite mask thickness.

Shadow mask patterning can also be used in OVPD, although it is more challenging to achieve high resolution due to the non-ballistic trajectories of the arriving molecules. Since  $s \geq mfp$  (cf. Eq. 5.14), the molecule

**Figure 5.60** (a) Illustration of shadow mask patterning via OVPD. The arrows show the molecular paths as they arrive at the substrate within the boundary layer. (b) Micrograph of an array of Alq<sub>3</sub> squares achieved by shadow mask patterning in OVPD at 0.1 torr N<sub>2</sub> background gas pressure, with  $w = 7.5 \mu\text{m}$ ,  $t = 3.5 \mu\text{m}$ , and  $s < 1 \mu\text{m}$  (Shtein et al., 2003).

Reprinted from Shtein, M., Peumans, P., Benziger, J. B. & Forrest, S. R. 2003. Micropatterning of organic thin films for device applications using organic vapor phase deposition. *J. Appl. Phys.*, 93, 4005 with the permission of AIP Publishing

undergoes several collisions with the carrier gas molecules within the boundary layer before reaching the substrate, as shown in Fig. 5.60a. This has the effect of spreading the deposit beyond the line-of-sight distance,  $r$ . By clamping the mask to the substrate, the pattern definition can equal that attained by VTE, as shown in Fig. 5.60b. Indeed, it has been calculated that patterns as small as 1–2  $\mu\text{m}$  are possible using shadow masks in the OVPD environment (Shtein et al., 2003).

### 5.6.2 Photolithographic patterning

Patterning conventional semiconductor devices at the nanometer scale uses photolithography, a photographic process whereby a photosensitive polymer (the photoresist) is spread onto the surface to be patterned. There are many variations to this mature process, including the use of positive or negative resists, multi-layer resists, pattern lift-off, and so on. Three principal variants of the photolithographic process are illustrated in Fig. 5.61, which we only briefly describe here. We refer the interested reader to the extensive literature on this subject for more details (see *Further reading*).

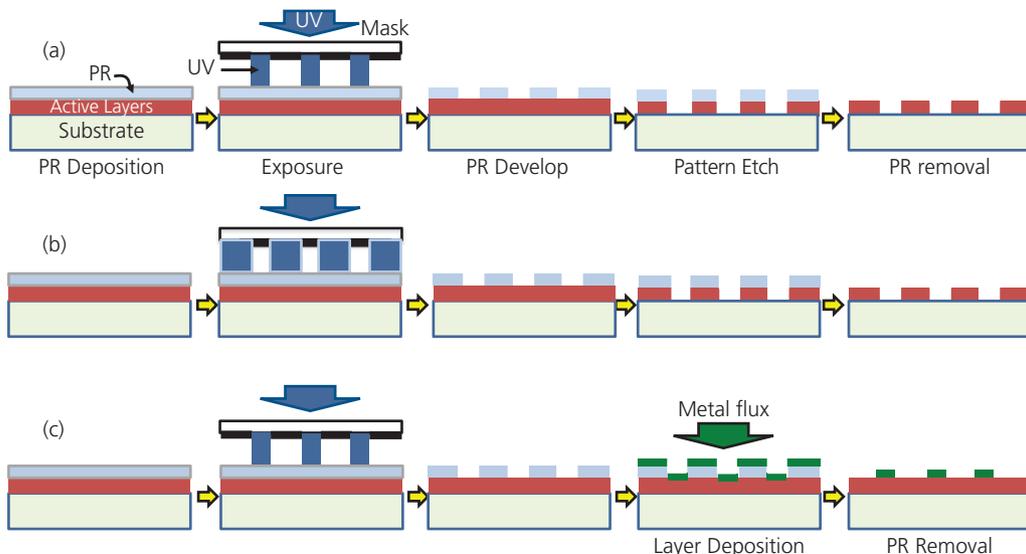

When using a positive photoresist (Fig. 5.61a), the desired pattern is exposed to UV irradiation of the resist through a mask. The UV light breaks the photosensitive bonds in the polymer, making it vulnerable to solvent attack. The sample is dipped into a solvent developer that dissolves the exposed areas, leaving the unexposed regions untouched (“what shows, goes”). The remaining photoresist pattern is the baked (i.e. cured) to render it chemically inert to process chemicals that are used on the underlying

substrate to replicate the pattern in the exposed areas. Thus, pattern replication proceeds by dipping the sample into an acid, or exposing it to a reactive gas that selectively attacks the semiconductor, but not the resist. By this means, the open areas of the resist establish the same pattern in the semiconductor, with pattern resolutions down to 10 nm. The final step is the removal of the photoresist by a second chemical exposure, this time using one that does not damage the underlying semiconductor.

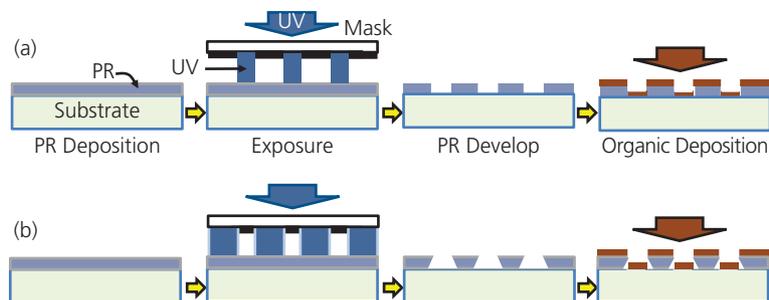

Negative photoresists simply reverse the process, that is, the UV exposed areas cross-link the photopolymer whose patterns then remain when developed (Fig. 5.61b). Lift-off is the third process whereby a hard layer (e.g. a metal or a dielectric) coats the semiconductor along with the pre-patterned resist surface (Fig. 5.61c). The resist is dissolved away beneath the coating, leaving it in exposed areas of the semiconductor where the resist was previously removed. Lift-off provides high resolution patterning of metals and insulators that are coated across the entire substrate surface.

A major advantage enjoyed by photolithography is its very high resolution, and the ability to sequentially add or substrate layers in a multi-step patterning campaign, with each layer aligned to the previous pattern to within only a few tens of nanometers. Hence, extraordinarily complex electronic circuits have benefitted from the flexibility and versatility of this highly evolved patterning technology.

Unfortunately, photoresists are seldom employed in the patterning of organic semiconductors (except in preparation of the substrate surface prior to organic film deposition) due to the likelihood of damage from

**Figure 5.61** Process flow for photolithographic patterning. (a) Positive photoresist (PR), (b) negative resist, and (c) photoresist lift off.

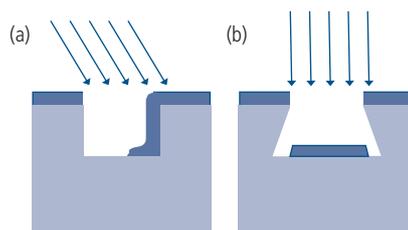

**Figure 5.62** Photolithographic patterning to achieve very high resolution vacuum deposited organic structures. (a) Deposition on a photolithographically patterned resist layer, and (b) deposition on an undercut feature forming an *in situ* shadow mask.

the wet chemistry involved in resist deposition, development and removal. Organic semiconductors are often attacked by the same solvents as those used in photolithography. This has led to modifications of conventional photolithography to achieve similarly high resolution patterning of organics.

One method of achieving nanometer-scale features in small molecular weight semiconductors is to pre-pattern the substrate surface itself using conventional photolithography prior to deposition of the active organic layers. By deposition of the organic on the resulting substrate ridges or troughs, the film replicates the morphology of the underlying topography, as shown in Fig. 5.62a. A problem occurs when the organic is incident from a non-normal direction, as illustrated in Fig. 5.63a. This results in shadowing from one of the sidewalls of the feature, breaking the deposit on only one feature edge, but giving continuous coverage on the opposite sidewall. While this may not be a problem for resistive organics where lateral conductivity along a sidewall is low, patterning a metal contact by this method to define the device area results in shorts between adjacent devices.

To confine deposited patterns at the micron scale while avoiding conductive line breaks or shorts, one can use the *in situ* shadow mask illustrated in Fig. 5.62b (Tang, 2001). A trapezoidal opening is created in either the photoresist itself, or in a pattern etched into the underlying substrate. The trapezoid is formed using a two-level photoresist system, where two chemically distinct resists are sequentially deposited. The top photoresist is exposed, developed and cured. This exposes the underlying resist layer which is uncured or softer than the top layer. Then a second solvent that only dissolves the lower resist creates the undercut. Alternatively, the first resist is coated with a metal or dielectric, which is then patterned using conventional photolithography to create openings to the resist. The metal acts as a mask that is undercut by

**Figure 5.63** (a) Incomplete sidewall coverage of a substrate feature due to off-center deposition of the incident molecules. (b) A reentrant trench in the substrate can produce a self-aligned deposited pattern when the incident molecular flux is normal to the surface. If at an angle, the coverage of the base of the feature can be complete. The coatings are shown in dark blue, the patterned substrate in light blue, and the incident molecular flux by arrows.

the solvent or acid etchant of the underlying layer. Once the undercut is formed, the organic semiconductor is directionally deposited to form the patterns, as shown in Fig. 5.63b.

Patterning contacts on an organic semiconductor using an undercut mask proceeds as follows: The organic is deposited by rotating the substrate relative to the evaporation source. This covers the substrate across the entire base of the approximately trapezoidal resist opening. Next, the contact metal is directionally evaporated such that its edges are confined only to the dimensions of the trapezoidal openings, thereby preventing metal shorts across the organic film pattern.

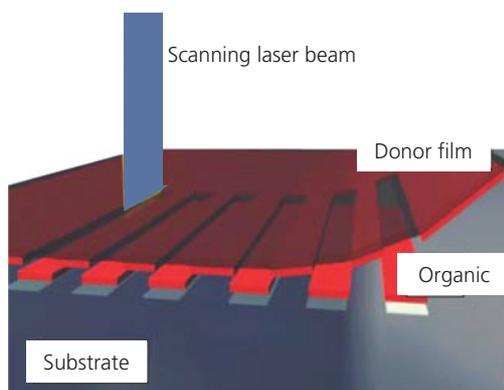

Deposition on substrate features can result in very high-resolution patterns without exposing the organic to often-damaging wet chemistry required in photolithography. However, the patterning is limited to only one or two levels. Complex electronic systems almost invariably require many levels of patterning of insulators, metals, and the active semiconductor layers themselves. As we will see in the following section, precision patterning of complex organic

structures can be achieved by the direct, additive printing of materials, rather than full surface deposition followed by material removal by conventional processes.

### 5.6.3 Laser induced thermal imaging

Rapid microscale patterning of multiple organic layers over large areas is required for many applications, none more challenging and relevant than the separate deposition of the micron-scale red, green and blue emitting layers required in full color OLED displays. Closely spaced R, G, and B pixels based on both polymers (Lee et al., 2002) and small molecules (Lamansky et al., 2005) can be patterned by *laser induced thermal imaging* (LITI) shown in Fig. 5.64. LITI is based on the local thermal evaporation of the organic material held in intimate contact with the target substrate. The light emitting polymer (LEP) used in the OLED active region is deposited on a transparent sheet with a light-to-heat conversion (LTHC) layer that consists of a material that strongly absorbs at the wavelength of a high power, focused laser beam scanned across its surface. The LTHC transfers the heat thus generated to the LEP, which delaminates from the donor sheet while attaching itself to the substrate. After printing, the sheet with LTHC and active semiconductor layers are replaced. This can be done in a continuous, roll-to-roll procedure for mass production of patterned substrates.

For the process to proceed quickly with uniform adhesion of the active semiconductor to the substrate, the laser power must be high and completely absorbed by the LTHC layer, which also must have a high thermal conductivity. The active organic material must be transparent to the laser radiation to avoid damage. Illumination from 1 W to 10 W Nd:YAG

**Figure 5.64** Patterning of OLEDs using laser induced thermal imaging. LEP is the light emitting polymer. Adapted from Lee et al. (2002).

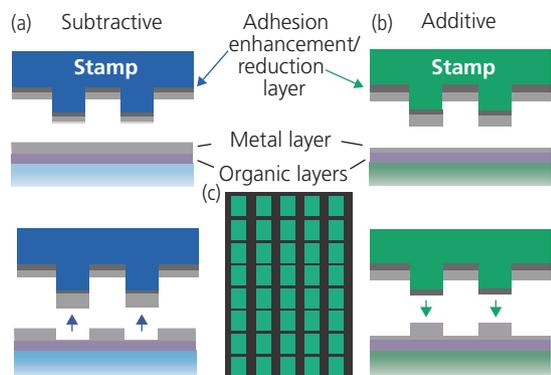

lasers (at 1.06  $\mu\text{m}$  wavelength) is sufficient to deposit material after only a few milliseconds (Lamansky et al., 2005). Effective heat transfer layer materials include graphite or carbon black. An important criterion is that the LEP must have a higher surface energy on the target substrate than on the LTHC layer such that the material is readily transferred. Furthermore, the strength of the film must be sufficiently low to allow for a clean break at the edges of the heated region to achieve high pattern resolution; conditions that limit the range of materials that are suitable for LITI. Rapid RGB pixel patterning has been demonstrated with edge resolutions and positioning accuracies of only a few microns using both small molecules and polymers as target organic semiconductors (Lee et al., 2004).

### 5.6.4 Nanoimprinting and stamping

Due to the low intrinsic conductivity of organic semiconductors, the device area is determined by the overlap of the anode and cathode contacts. Several strategies have been developed to rapidly pattern contacts at the micron (or smaller) scale. Patterning the contact that is pre-deposited onto the substrate (e.g. ITO) is done using photolithography prior to the deposition of the organics. However, patterning of the top contact presents a greater challenge since it must avoid processes that degrade the underlying organic semiconductor. Commonly, patterning is achieved using deposition of the metal through a shadow mask whose resolutions are often insufficient for many applications, and is problematic when deposition is over a very large substrate area (see Section 5.6.1).

To avoid these limitations while achieving nanometer-scale resolution, the dry process of transfer printing has been developed. For example, “cold-welding” metal transfer has very high pattern resolution, and is adaptable to a variety of device types, including OLEDs, OPVs and thin film transistors. An illustration of two methods of cold-weld metal transfer—one additive and the other subtractive—is shown in Fig. 5.65 (Kim et al., 2000, Kim and Forrest, 2003).

Cold welding involves applying pressure across an interface between two metallic surfaces. When the pressure is sufficiently high to break through energy barriers due to surface contamination, oxides or debris, the interface barrier collapses, bringing the now pristine metal atoms from each layer into contact. The electron systems are shared across the interface, which effectively disappears across the “perfect”

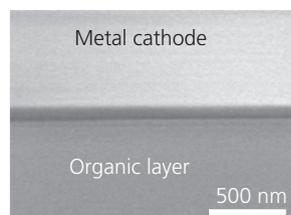

**Figure 5.65** Cold-weld metal transfer by (a) the subtractive method whereby metal deposited onto the organic layers is “lifted-off” using a hard stamp, and (b) the additive method that transfers the metal electrode from the stamp to the substrate by cold-welding to a very thin ( $\sim 5\text{nm}$ ) “strike layer” pre-deposited on the substrate. Following transfer, the contacts are isolated by removing the strike layer by plasma etching. (c) An OLED passive matrix array using whose contacts are defined by subtractive patterning.

bond (Taylor et al., 1991). The interfacial collapse occurs within only a few tens of picoseconds once a threshold pressure is exceeded.

In the subtractive process in Fig. 5.65a, the cathode metal is deposited on the organic layers, covering the full substrate surface. Next, a hard stamp (e.g. Si) is prepared by photolithographically defining and then etching protrusive features that are shaped into the desired contact pattern. The stamp is subsequently coated with the same metal as used for the cathode, using a layering scheme that ensures that the metal strongly adheres to the stamp surface. The stamp is pressed against the substrate to create a cold-weld bond between the metal on the protruding stamp surface and that on the organics. Sufficient pressure is applied to shear the metal at the sharp stamp edges, thereby separating it from the continuous metal blanket on the organic. The stamp and substrate are then parted, lifting away material that was under pressure. The adhesion of the metal to the organic must be weaker than to the stamp for the separation to be complete. The subtractive method creates a “negative” pattern, similar to the use of a negative photoresist in photolithography.

The subtractive method has been used to demonstrate passive matrix OLED displays (Kim et al., 2000). Given the need to shear the underlying films, very high pressures ( $> 100\text{MPa}$ ) are required, which are impractical when applied over large substrate areas. Nevertheless, the pattern resolution achieved is very high. Figure 5.66 shows edge definition down to only a few tens of nanometers for a cathode formed on an organic layer surface.

**Figure 5.66** Edge of a metal cathode patterned by subtractive cold-weld bonding (Kim et al., 2000).

From Kim, C., Burrows, P. E. & Forrest, S. R. 2000. Micropatterning of Organic Electronic Devices by Cold-Welding. *Science*, 288, 831. Reprinted with permission from AAAS.

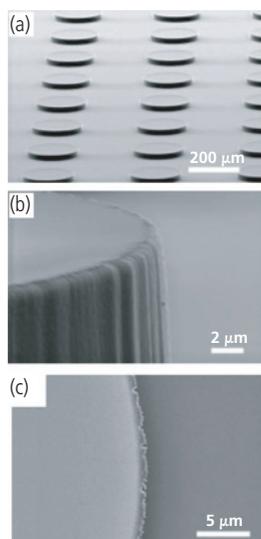

To reduce the pressure of contact formation, the additive method, which is analogous to a positive photoresist process, has been developed (Kim and Forrest, 2003). In Fig. 5.65b, a soft elastomeric stamp comprised of a material such as PDMS replaces the hard stamp used for subtractive patterning. To form the stamp, a solution containing the elastomer in a solvent is poured into a mold and cured. Peeling the hardened stamp from the mold produces protrusions whose highest surfaces are in the shape of the desired material to be transferred. Next, an adhesion reduction layer is deposited onto the stamp. This layer consists of a material such as BCP or pentacene that reduces the adhesion of the layer to be transferred from the stamp to the organic. Hence, the layer is easily and completely released from the stamp when it contacts the target substrate. The substrate preparation itself is also different than for subtractive patterning. Rather than depositing the metal at its final thickness onto the active organics, only a thin ( $\sim 5\text{nm}$ ) *strike layer* of the metal is deposited. The full thickness of the contact metal is deposited onto the stamp itself. By pressing the stamp against the strike layer, a cold weld bond is formed. When the stamp is detached from the organic thin film, the metal contact is left behind. The thin strike layer metal is removed by exposing the surface to a light dry etch such as an  $\text{Ar}^+$  plasma that selectively removes the thin metal without attacking the underlying organic layer.

The pressures required to form a bond by the additive process are significantly lower ( $\sim 100\text{--}200\text{ kPa}$ ) than for the hard stamp used in subtractive bonding. This difference is due to the conformal compliance of the soft stamp, allowing it to “flow” around dust particles or other surface irregularities that prevent intimate contact when harder stamp materials are employed (Cao et al., 2005). While the pressures applied are very low and hence are practical for use over large substrate areas, a disadvantage of the use of soft stamps is the considerably reduced pattern

resolution that results from distortions of the stamp when even a slight pressure is applied. An edge resolution of  $\sim 1\text{--}2\ \mu\text{m}$  is common, as shown by the micrograph in Fig. 5.67. To increase the resolution, a stiffer composition of the stamp (e.g. *h*-PDMS) can be employed, although this results in a concomitant increase in pressure required to form the cold-weld bond.

The ability of a material to preferentially adhere to the substrate or the stamp is critically dependent on the surface energies of the various materials. Care must be taken in selecting adhesion-reduction materials to ensure clean and complete release of the transferred material from the stamp. Similarly, in the subtractive process, very strong adhesion between the metal and the stamp ensures that the pick-up of the metal from the organic surface is complete.

It is difficult to overestimate the versatility and number of uses that stamp transfer of material provides. It has been used not only for the application of metals, but also for the transfer of the active organic layers themselves (Kim et al., 2005). Furthermore, it is useful for patterning contacts on distorted or shaped surfaces, such as in transferring photodiode contacts in hemispherical focal plane arrays (HFPA) shown in Fig. 5.68. The array consists of active organic layers of the photodiodes that are sandwiched between two orthogonal arrays of contacts patterned by cold-weld bonding. Each cross-point in the array is independently

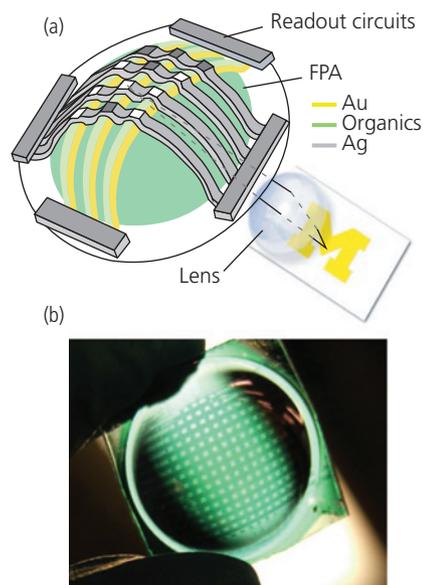

**Figure 5.67** Additive patterning using a soft (PDMS) stamp. (a) The stamp consists of an array of protrusive dots formed by injection into a mold. (b) Edge of the stamp exactly replicating depressions in the mold. Notice the rounded, rough edges. (c) Transferred metal contact onto an organic layer surface (Kim and Forrest, 2003).

addressed by the corresponding row and column electrodes. Such an array is useful in forming high definition images using only a single convex lens, similar to the architecture of the human eye (see Section 7.2.2). The soft organic materials allow for deposition on arbitrarily shaped surfaces that serve application needs inaccessible using conventional, brittle semiconductors. Cold-weld bonding allows for patterning on shaped surfaces at very high feature resolutions.

The process for fabricating the HFPA is shown in Fig. 5.69. A stamp is produced with long parallel ridges coated with a thin ( $\sim 10\ \text{nm}$ ), semitransparent Au layer. The stamp is placed in a hemispherical mold through which vacuum is applied to draw it into the required shape. The topological transformation of the stamp from its original 2D plane into a three-dimensional (3D) hemisphere introduces considerable strain that does not damage the metal strips since they only weakly adhere to the stamp. Thus, they are allowed to slip along the ridges as shear forces are applied during shaping. It is interesting to note that shear-slip strain relief inspired by this process has also been applied in the fabrication of HFPA's employing inorganic (GaAs) photodiodes (Fan et al., 2019).

**Figure 5.68** (a) Schematic illustration of a passive matrix hemispherical focal plane array (HFPA) where the metal contacts on the surface of a pre-formed transparent plastic hemisphere are applied on opposite surfaces of the active photosensitive organic layers to form an addressable, passive matrix detector array. A simple lens and the imaged object are also shown. (b) A 1 cm diameter HFPA fabricated by cold-weld contact transfer (Xu et al., 2008).

**Figure 5.69** Process sequence for fabricating the hemispherical focal plane array in Fig. 5.68. The top two rows show the fabrication of the soft elastomeric stamp consisting of an array of ridges and troughs. It is formed into a hemisphere by applying vacuum from a mold following deposition of the contact metal onto the stamp. The bottom row shows the transfer process of the metal contact lines onto the transparent plastic hemisphere. The hemisphere itself is thermoformed by heating above its softening temperature and drawn by vacuum into the same mold. A thin strike metal is deposited onto its full surface. The thin, semitransparent contact array is transferred from the deformed stamp followed by removal of the strike layer by  $\text{Ar}^+$  plasma etching. Not shown is the following full surface deposition of the organic photodetector layers over the metal contacts, followed by a second strike layer. The entire sequence is then repeated, with the second contact array positioned perpendicular to the first, thus completing the passive matrix (Xu et al., 2008).

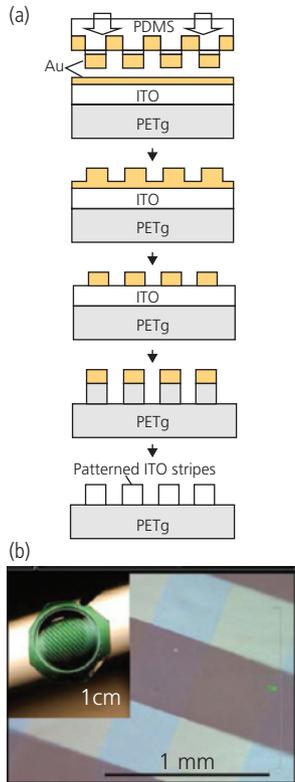

Reprinted from *Organic Electron.*, 9, 1122, Xu, X., Davanco, M., X.Qi & Forrest, S. R., Direct Transfer Patterning on Three Dimensionally Deformed Surfaces at Micrometer Resolutions and Its Application to Hemispherical Focal Plane Detector Arrays. Copyright 2008 with permission from Elsevier.

The transparent, thermoformable, glycol-modified PET (PETg) substrate is shaped using the same mold by heating while applying vacuum. The mold is cooled, freezing the substrate into a hemispherical shape. A thin Au strike layer is deposited along the outer surface of the hemisphere. The substrate and stamp are then joined in the mold (lower left, Fig. 5.69), at which point the vacuum is released. The relaxed elastomeric stamp presses against the strike layer, completing the cold-weld transfer. After a brief exposure to an  $\text{Ar}^+$  plasma to remove the strike layer that electrically shorts the contact stripes, the organic active layers forming the photodiode are deposited across the full hemispherical surface. The top contact array, consisting of a thicker Au layer, is then applied using the same strike layer/cold-weld process with the stamp now rotated  $90^\circ$  relative to the first contact array. The resulting device shown in Fig. 5.68b is a passive matrix array of detectors with orthogonal row and column contacts used to address each pixel.

The lower contact array employs a semitransparent Au layer that reduces light coupling into the detectors. While ITO is a more transparent anode material, it is brittle and hence cannot endure the stress of distortion into a spherical shape. To solve this problem, ITO can

be deposited *after* the substrate is thermoformed into a hemisphere. This is followed by deposition of a thin metal strike layer, and then cold-welding an array of thick Au lines using the additive process in Fig. 5.70. The strike layer is removed using  $\text{Ar}^+$  plasma, leaving a thick array of Au columns on top of the ITO. The ITO is removed from the regions between the Au lines using a suitable selective etchant that does not attack the Au lines that serve as a resist. The final step is removing the Au using a different etchant that does not attack the ITO. Completion of the array by organic deposition and attachment of the top, thick Au array of row contacts follows the conventional process in Fig. 5.69. The transparent ITO contacts, along with the detector active region and orthogonal Au contacts of the completed HFPA, are shown in Fig. 5.70b.

While we have described only one transfer and nanoimprint process, transfer patterning has taken many diverse forms that have been developed for use of fragile materials that are incompatible with conventional lithography. It has proven to be a versatile process that is scalable to large substrates. The interested reader is directed to the substantial literature on this subject for further details (Quake and Scherer, 2000, Rogers and Nuzzo, 2005).

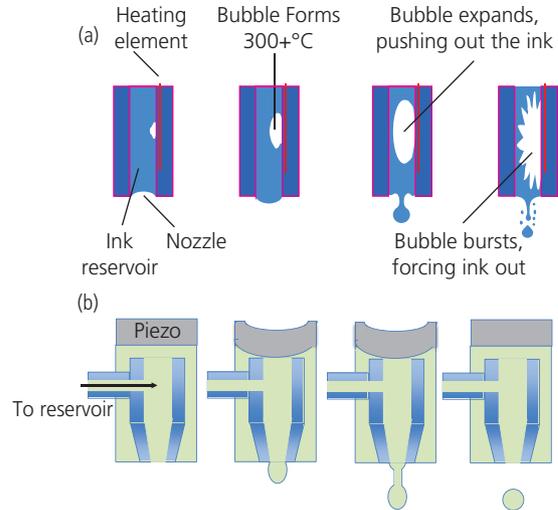

**Figure 5.70** (a) Patterning of ITO using a metal mask applied by additive cold-welding. (b) A completed HfPA using an ITO bottom contact array. The ITO array is faintly visible running nearly vertically, and the top Au contacts are the opaque, nearly horizontal lines in the image. Inset: Image of the HfPA (Xu et al., 2009).

### 5.6.5 Inkjet printing

Inkjet printing has become an ubiquitous means for printing, copying and reproducing documents and graphics for home, office, and business. It is a mature, high image resolution technology based on the precise projection of ink droplets of only a few picoliters from a nozzle onto a substrate (typically paper or plastic) held a few millimeters away. Since dye compounds used in ink jet printers are similar to those used for electronic applications, it is reasonable to adapt the technology for the printing of organic devices. Indeed, such an adaptation has been underway, with modifications to conventional inkjet print engines to suit the peculiar properties of electronic polymers and soluble small molecules. While many organics have been optimized as optoelectronic materials, their use in inkjet patterning requires that their fluidic (i.e. *rheological*) properties also be suitable for precise droplet formation and deposition. This added

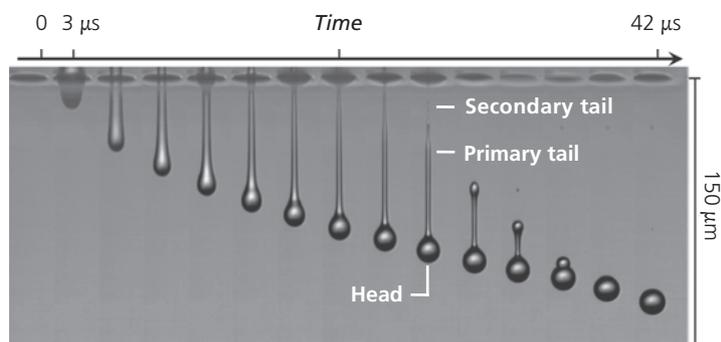

**Figure 5.71** Two inkjet print head designs. (a) Thermal and (b) piezoelectric inkjet printing engines.

performance criterion is not always compatible with the optoelectronic characteristics of the material, and hence inkjet printing of electronic devices has, to this date, not entered mainstream industrial use. Nevertheless, progress is being made, motivated by and the maturity, flexibility and resolution of the process.

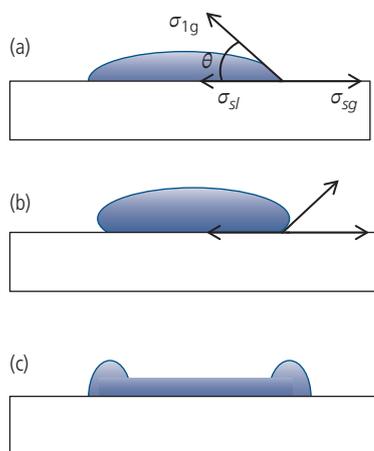

Several inkjet printing engine designs have been developed. Thermal inkjet heads contain a small heater within the nozzle injection system, as shown in Fig. 5.71a. The temperature of the fluid containing a solvent and a suspension of the electronic material is heated, forming a bubble. As the bubble expands, it forces a small amount of fluid out, projecting it toward the substrate. The rheological properties of the suspension must be suitable for controlled droplet formation at temperatures required to create the bubble without degradation of the semiconducting solute. This criterion limits the range of materials that can be adapted for printing, and hence is not generally used in electronics applications.

An alternative approach employs a piezoelectric transducer within the fluid container, Fig. 5.71b. A voltage is applied to the transducer, resulting in its flexure that reduces the container volume, thus expelling a precise volume of fluid. The method is fast (a few milliseconds are required to deflect the piezoelectric diaphragm) and highly precise. It is also non-destructive of the materials in the suspension. Piezoelectric inkjet printing is therefore a preferred means for local deposition of organic semiconductors.

The highest pattern resolution attainable via inkjet printing when the fluid, nozzle and deposition processes are optimized is  $\sim 50 \mu\text{m}$ . The ability to

**Figure 5.72** Silicone oil droplet formation and ejection from a nozzle visualized using flash photography with a frame spacing of  $3 \mu\text{s}$ . The width of the droplet is  $4 \mu\text{m}$  and the primary tail is  $\sim 25 \mu\text{m}$  long (van der Bos et al., 2014).

**Figure 5.73** Fluid on a (a) wetting and (b) non-wetting substrate surface. (c) Drying pattern of a droplet that exhibits the “coffee stain” effect.

consistently generate droplets of a well-defined volume depends on several properties of the solvent–organic semiconductor solution (or “ink”), including its surface tension, viscosity, temperature, wetting properties on both the nozzle and substrate surfaces, and its tendency to form precipitates or clusters that can clog the very small nozzle orifices. For example, if the surface tension is too high, droplet separation from the nozzle is uneven, and if it is too low the fluid can spray out of the nozzle without forming a droplet of the desired size. Surface tension in the range  $20\text{--}70 \text{ mN/m}$  is optimal to achieve controlled inkjet printing.

Likewise, viscosity plays a significant role in droplet formation. Figure 5.72 shows the droplet ejection process, where a tail forms on the droplet as well as on the fluid retained at the nozzle orifice. The droplet breakup distance,  $bu$ , depends critically on the viscosity of the fluid. If  $bu$  is too long due to a high viscosity,

the drop volume is larger than required, causing the resulting deposit to exceed the desired dimensions, or resulting in fluid splatter at the substrate. Additionally, a long droplet forms a non-spherical droplet whose tail can break up into multiple segments, thereby creating several additional droplets that trail the primary drop. Typical fluid viscosities that are optimal for high resolution printing are in the range  $1\text{--}50 \text{ cP}$ . An overly viscous fluid leads to poor separation of the droplet tail from the nozzle and nozzle clogging.

Complicating these processes is the formation of threads connecting the droplets due to viscoelasticity of the suspension. When a viscous fluid is passed through a small orifice, the shear stress at the surface of the orifice causes the viscosity to increase. This feature of a non-Newtonian fluid is known as *shear thickening*. A *Newtonian fluid* is one where the viscosity is invariant across its flow field, independent of external stresses (e.g. shear). The opposite effect is known as *shear thinning* whose occurrence depends on the composition and rheological properties of the suspension. Fluid thickening is particularly troublesome since it can completely prevent separation of the droplets, and can clog the very fine nozzle opening.

Pattern formation also depends on the interaction between the fluid and the target substrate surface. The relative surface energy of the substrate and the fluid determines if the fluid flows, or beads up. In Fig. 5.73a, the fluid is in contact with a wettable surface, that is, where the interfacial surface energy between the fluid and the solid,  $\sigma_{sl}$ , is greater than the surface tension of the solid and the ambient,  $\sigma_{sg}$ , in which case the contact angle is  $\theta < 90^\circ$ . In the opposite case where  $\sigma_{sg} > \sigma_{sl}$ , the surface is non-wetting and the droplets form beads that attempt to minimize their contact area with the

substrate, see Fig. 5.73b. The contact angle depends on these surface energies via the balance of forces expressed by the *Young equation* (Israelachvili, 2011):

$$\sigma_{sg} = \sigma_{sl} + \sigma_{lg} \cos \theta. \quad (5.38)$$

Here,  $\sigma_{lg}$  is the energy difference between liquid and the surrounding atmosphere. This balance of forces gives rise to a range of film morphologies that depend on materials properties, including the composition of the solvent and polymer and their relative concentrations, the substrate morphology (e.g. the crystal face to which the droplet is attached, and roughness), and substrate surface preparation (e.g. its level of hydrophobicity or hydrophilicity). For example, the surface can be functionalized using wetting agents such as OTS or self-assembled monolayers with functional groups that specifically modify the substrate surface energy. Other means include exposure to oxygen or fluorine-based plasmas (see Section 8.6.1).

As the solvent evaporates, the surface energies also determine the final shape of the deposit. An example is the “coffee ring effect” illustrated in Fig. 5.73c, where the polymer piles up near the edge of the deposit, as is the case of the thick dark residue of particles that are left behind when coffee is spilled onto a flat surface (Deegan et al., 1997). This profile results from pinning of the edge of the droplet to its initial position on the substrate, combined with preferential evaporation of the solvent at the periphery of the liquid/solid interface where molecules can escape with little chance for re-adsorption. This contrasts with the center of the deposit where re-adsorption on the large surface is relatively efficient. Hence, a net flow of solvent radiating from the center to the edges develops, carrying the solute (e.g. the polymer) that ultimately piles up along the edge, creating an uneven thickness profile. Edge accumulation can be reduced by exploiting the *Marangoni effect*, whereby a mixture of two solvents with different boiling points creates a reverse flow from the edge to the center of the liquid deposit (Hu and Larson, 2006). In this case, the latent heat of evaporation of the solvents reduces the temperature in the center of the droplet. Since surface tension decreases with increasing temperature, cooling creates a diffusive flow from the (warmer) edges toward the center. When two solvents are used, the higher boiling point constituent moves toward the edges, with the lower boiling point solvent depleted rapidly from the center. This dynamic balance sets up Marangoni flow that prevents large concentrations of the solute from

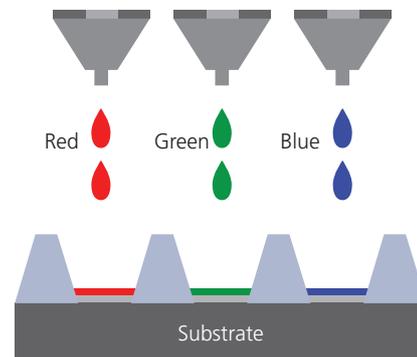

accumulating anywhere within the droplet as the solvent evaporates.

Surface irregularities and rounded profiles are undesirable side effects of the rheological properties of the solvent-solute mixture, and can never be completely eliminated in the inkjet deposition process. Hence, their presence ultimately limits the feature resolution, although many strategies have been employed to minimize their impact (Sirringhaus et al., 2006). One is to print into confined areas defined by polymer “wells” patterned on the substrate surface. The active organic inks are deposited into the appropriate well that confines the material. This method has been developed for printing red, green and blue light emitting layers of OLEDs in full color displays, as shown in Fig. 5.74. Contacts are subsequently deposited to complete the device (Kobayashi et al., 2000).

Although many of these strategies facilitate the printing of small electronic patterns, inkjet techniques have not yet been adopted for widespread application in organic electronics. As noted above, the difficulty in synthesizing a material that leads to high device performance with a stability that is required for most electronic applications, while also optimizing its rheological properties to make it suitable for inkjet deposition, represents a complex materials design challenge that in many cases has been unattainable. Yet the promise of inkjet printing to generate devices with the same ease as document printing continues to motivate considerable research in this area.

### 5.6.6 Organic vapor jet printing

The method of *organic vapor jet printing* (OVJP) is analogous to inkjet printing except that it is a dry, rather than a solution-based process. OVJP enables the direct, high-resolution, rapid patterning of

**Figure 5.74** Inkjet printing of a full color OLED display into an array of wells used to confine the ink within each pixel.

molecular organic semiconductors on a variety of substrates (Shtein et al., 2004). Like OVPD used in deposition over entire substrate surfaces, OVJP is inherently a local deposition technique whereby a hot inert carrier gas is seeded with organic vapor and then expanded through a microscopic nozzle to form a collimated beam of gas that carries molecules through a vacuum or low pressure environment. The organic molecules are accelerated by the lighter carrier gas, exiting the nozzle at hyperthermal velocities. When the resulting heterogeneous beam impinges on a cold substrate, the carrier gas quickly disperses. However, due their greater mass, the organic molecules retain their axial momentum, resulting in a confined deposit profile.

The deposition profile is controlled by the shape of the gas jet and substrate temperature (which determines the sticking coefficient), avoiding the need for liquid solvents or droplet-confining wells. The pattern itself is “written” by translating the substrate beneath the nozzle array. Consequently, this method broadens the choice of substrate material and shape, while reducing deposition and patterning of the organic layer to a single step. OVJP takes advantage of the high organic-to-carrier gas molecular mass ratio to achieve high resolution patterning. The method has been successfully used for depositing multi-colored OLEDs for both lighting (Arnold et al., 2008) and displays (McGraw and Forrest, 2013), and in defining the channels of organic thin film transistors (Shtein et al., 2004).

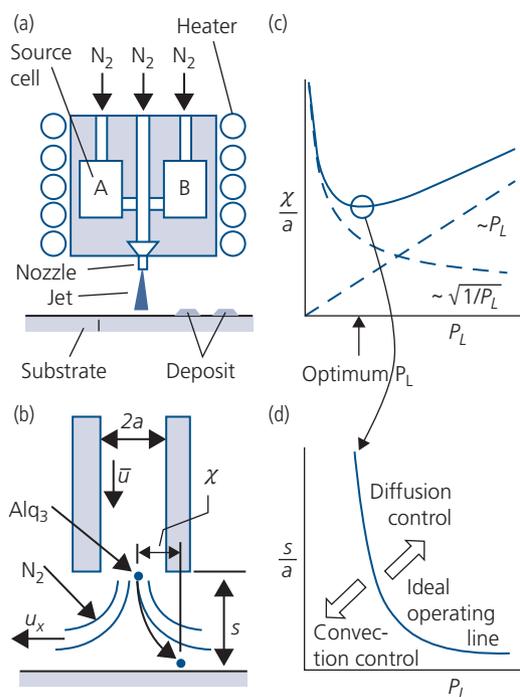

The OVJP concept and apparatus are schematically illustrated in Fig. 5.75a. The molecular organic sources, A and B, are heated while an inert carrier gas (e.g. N<sub>2</sub>) is injected into the source cells, picking up the organic vapor and expanding it through a collimating nozzle. Although the carrier gas flow field rapidly diverges due to the proximity of the substrate to the nozzle outlet, the relatively heavy organic molecules acquire trajectories substantially more collimated than the volatile carrier gas that escapes laterally along the substrate plane. The interplay between diffusive and convective transport at the nozzle orifice that ultimately dictates pattern shape is determined by such factors as nozzle radius,  $a$ , nozzle-to-substrate separation,  $s$ , and the deposition chamber pressure,  $P_L$ . The scaling is usually such that  $s$ , the pattern resolution, and the molecular mean free path ( $mfp$ ) at  $P_L$  are of the same magnitude, as indicated in Fig. 5.75b. Hence, downstream from the nozzle, transport is intermediate between continuum and molecular flow.

The gas jet monotonically diverges after exiting the nozzle. When a substrate is placed close to the nozzle, the jet is further dispersed relative to the

free-expanding beam due to a stagnation front formed immediately above the surface. This axial enrichment of the jet by the organic molecular species constitutes a key feature of OVJP. Since  $s \sim mfp$  at  $P_L$ , the organic molecules suffer few collisions within the nozzle-substrate gap. Assuming fully developed flow inside the nozzle, a low (<1% molar) concentration of the organic species and incompressible flow, the organic molecules travel radially outward from their original position in the nozzle by a distance  $\chi$  (Shtein et al., 2004):

$$\frac{\chi}{a} = \frac{m_g}{M} \frac{s}{mfp} + \sqrt{\frac{1}{3} \frac{\bar{c}s(mfp)}{\bar{u}a^2}}, \quad (5.39)$$

where  $m_g/M$  is the carrier gas-to-organic molecular mass ratio,  $\bar{c}$  is the mean molecular thermal velocity, and  $\bar{u}$  is the mean flow velocity inside the nozzle. The first term in Eq. 5.39 is due to horizontal momentum transfer to the organic molecules from collisions with the diverging carrier gas, while the second term is the scaling of the radial diffusion to the convective transport rate normal to the substrate.

**Figure 5.75** (a) Conceptual diagram of an OVJP apparatus. (b) Nozzle and exit gas flow defining the variables described in the text. The example of an Alq<sub>3</sub> molecule swept through the nozzle in a hot N<sub>2</sub> carrier gas is shown. (c) Plot of the normalized molecular beam width,  $\chi/a$ , vs. the background pressure,  $P_L$ , with the optimum pressure resulting in a minimum deposited feature size. (d) Normalized substrate-to-nozzle separation distance,  $s/a$ , as a function of  $P_L$ . The various flow regimes encountered are noted (Shtein et al., 2004).

Equation 5.39 shows the relative influence of process conditions on pattern resolution. In particular, given that  $mfp = k_B T / 2\sigma P_L$ , where  $\sigma$  is the cross-sectional area of the molecule (in the hard sphere approximation), the pattern dispersion has a minimum at some value of  $P_L$ , as shown in Fig. 5.75c. The maximum resolution is achieved when  $P_L$  is in the range 1–50 torr, typical of OVJP. Equation 5.39 also suggests that pattern resolution is enhanced by the use of a lighter carrier gas (e.g. He instead of  $N_2$ ). Practically,  $\bar{u}$  is fixed by the desired deposition rate via the concentration of the organic vapor. Thus, for a given nozzle radius,  $a$ , the remaining adjustable parameters are  $s$  and  $P_L$ .

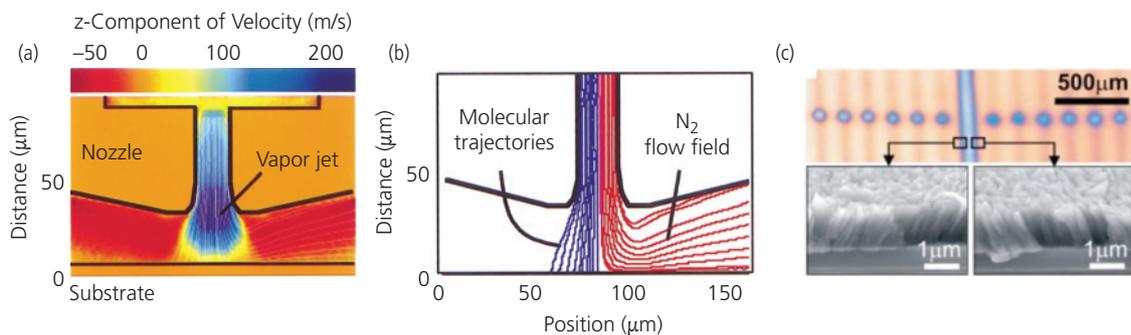

The operating conditions for maximum pattern resolution are plotted on the process diagram, Fig. 5.75d, where the operating line dictates values of  $s$  for any given  $P_L$ . For example, to maintain high pattern resolution ( $\chi/a \rightarrow 1$ ) even at large separation,  $s$ , the downstream pressure,  $P_L$ , must be decreased. The region above the operating line represents printing in the diffusion-limited regime, while the region below corresponds to convection-limited transport. Finally, the local dynamic pressure in the region between the nozzle and the substrate generally exceeds  $P_L$  and scales inversely with  $s$ .

Details of the flow calculated by *direct simulation Monte Carlo* (DSMC) are shown in Fig. 5.76a and b. The vertical velocity component of the flow field is plotted as a color-map in Fig. 5.76a, with the corresponding trajectories of the carrier gas and the organic molecules (in this case, Alq<sub>3</sub>) plotted in Fig. 5.76b. The velocity map shows the acceleration of the flow through the nozzle, reaching  $\sim 200$  m/s at the nozzle exit. The stagnation front lies immediately above the substrate surface where the dynamic pressure generally exceeds the ambient pressure,  $P_L$ . The heavy

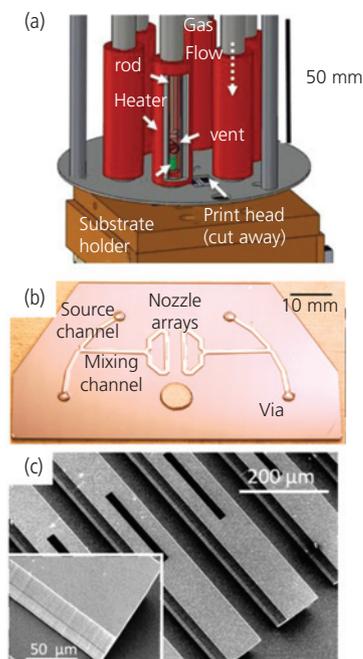

organic molecule trajectories, however, cross the carrier gas flow lines, resulting in a well-defined deposit.

Directional deposition is demonstrated in the micrograph in Fig. 5.76c for a pentacene line printed on SiO<sub>2</sub> using a 50  $\mu\text{m}$  diameter nozzle at a deposition rate  $>300$   $\text{\AA}/\text{s}$  and  $s = 35$   $\mu\text{m}$  (Shtein et al., 2004). The central line demonstrates that flat deposit profiles are achieved. Furthermore, SEM images reveal that the pentacene crystallites to the left and right of the jet axis tilt in toward the molecular source. Seeding the organic molecules in a fast-flowing carrier stream at hyperthermal velocities determines the incident molecular kinetic energy. This decouples the film crystallization dynamics from surface temperature, leading to highly ordered films even on relatively cold substrates. This effect has important implications for the performance of devices such as polycrystalline channel TFTs (Shtein et al., 2002), and it significantly broadens the choice of substrates to include fragile and/or bio-compatible materials.

For this technology to be practical, the rate of organic deposition must be sufficiently fast to enable high resolution printing on large area substrates in times comparable to that of competing methods such as deposition through a shadow mask. Inkjet printing of documents is, in fact, quite rapid due to parallelism arising from print heads comprising more than 1000 nozzles. Efforts have therefore focused on the scale-up of OVJP print heads from single nozzles, to nozzle arrays using Si fabrication-based photolithographic methods (McGraw et al., 2011, McGraw and Forrest, 2012). The print head is mounted on a feed-through flange mounted on a high vacuum chamber. Nitrogen carrier gas is supplied to the head via a heated metal manifold that connects it to the feedthrough. The manifold in Fig. 5.77a consists of tubes that contain

**Figure 5.76** (a) Calculated velocity flow field beneath an OVJP nozzle. (b) Trajectories of the molecules and carrier gas illustrating the “focusing” of the molecular deposit beneath the nozzle orifice. (c) Electron micrograph of a pentacene transistor channel grown by OVJP. The upper image is a plane view of the deposit with several dots adjacent to the channel stripe. The cross-section view (below) shows how directional flow from the nozzle results in pentacene nanocrystalline growth entrained along the gas streamlines as in (b) (Shtein et al., 2004).

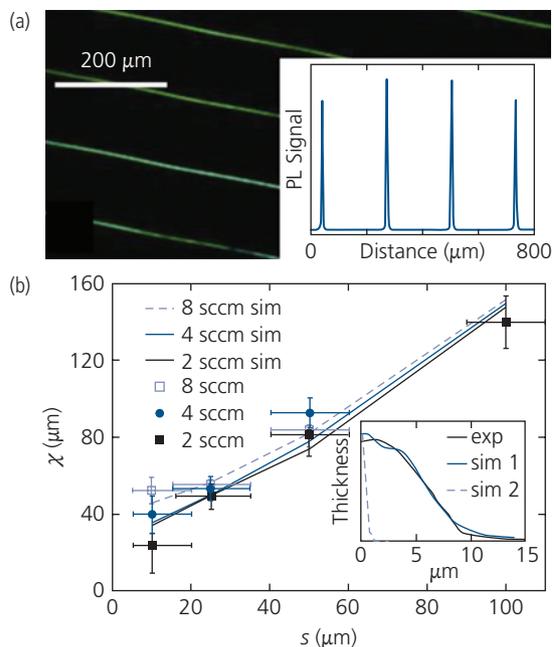

**Figure 5.77** (a) Scalable print head and substrate holder assembly (McGraw et al., 2011). (b) Microfluidic plate that directs and mixes organic vapors from the cylindrical material containers in (a) to the nozzle arrays. (c) Electron micrographs of a Si nozzle array consisting of 20  $\mu\text{m}$  wide by 200  $\mu\text{m}$  long nozzle slits. A detailed view of the nozzle and sidewall is shown in inset. The substrate is translated parallel to the long nozzle axis, leading to  $\sim 20 \mu\text{m}$  wide deposits (McGraw and Forrest, 2012).

separate organic vapor sources needed for a particular application. Each tube is independently heated to the sublimation temperature of the material contained within a glass or Pyrex vial within the tube. Hot carrier gas enters the vial, picks up the organic vapor, and carries it through a microfluidic channel plate (Fig. 5.77b) to the print head. A chilled substrate holder sits below the manifold. It is translated in two dimensions parallel to the substrate plane to “draw” the desired organic pattern.

The microfluidic gas distributor in Fig. 5.77b carries the organics from the source vials, mixes them with other compounds in situations where dopants or mixtures are required, and transports the molecules to the nozzle arrays in Fig. 5.77c. The nozzles are formed by etching the silicon-on-insulator (SOI) wafer device layer along the (111) Si plane, extending down from the top wafer surface. Rectangular nozzle orifices are defined by the intersection of the etched zone with the SOI wafer oxide layer, creating nozzles only a few microns wide. Since the process

**Figure 5.78** (a) Fluorescent emission from an array of Alq<sub>3</sub> stripes printed by OVJP. The stripes were deposited at a N<sub>2</sub> carrier gas flow rate of 2 sccm and a nozzle-to-substrate separation of  $s = 10 \mu\text{m}$ . Inset: Photoluminescence intensity profiles vs. position along a path perpendicular to the lines. (b) Feature size,  $\chi$ , as a function of nozzle-to-substrate distance,  $s$ , and N<sub>2</sub> flow rate. Simulated deposition feature sizes (lines) match the experimentally observed trends. Inset: Normalized thickness of an Alq<sub>3</sub> line measured using a profilometer (exp). The measured profile agrees with the simulated deposition profile generated for a 10  $\mu\text{m}$  nozzle width, flow rate of 2 sccm, and  $s = 5 \mu\text{m}$  (sim 1). Simulations suggest that a 0.5  $\mu\text{m}$  nozzle positioned at  $s = 0.5 \mu\text{m}$  can produce lines as narrow as 1.5  $\mu\text{m}$  wide (sim 2) (McGraw et al., 2011).

technology is Si-based, large arrays containing >1000 precisely placed and shaped nozzles can be fabricated using this approach.

Using 10  $\mu\text{m}$  wide nozzles located within 10  $\mu\text{m}$  of the substrate, organic features as narrow as 16  $\mu\text{m}$  have been achieved. Figure 5.78a shows fluorescent images obtained from Alq<sub>3</sub> stripes drawn using this nozzle geometry, with an intensity map shown in the inset. The dependence of the feature size for the 10  $\mu\text{m}$  wide nozzle on its distance from the substrate,  $s$ , is shown in Fig. 5.78b, along with the deposition profiles shown in the inset. The profile for the nozzle, as well as its dependence on  $s$  is fit well by DSMC. Importantly, these simulations suggest that a profile as narrow as 1.5  $\mu\text{m}$  can be achieved with a 0.5  $\mu\text{m}$  wide nozzle positioned at  $s = 1.5 \mu\text{m}$  (McGraw et al., 2011). As noted above, lines become wider and their edges become less

well defined with increasing  $s$ . For a  $10\ \mu\text{m}$  wide nozzle and  $s = 10\ \mu\text{m}$ , a diffuse edge of material extends approximately  $4\ \mu\text{m}$  beyond the line boundary. This degree of “overspray” is within the tolerances required for high definition display patterning.

Based on experimental results, the speed of printing of large organic electronic appliances can be estimated. For example, an array of 3000 nozzles, each with a  $20\ \mu\text{m}$  by  $800\ \mu\text{m}$  orifice, can simultaneously pattern  $30\ \text{nm}$  thick red-green-blue emissive layers to produce a full color, high definition  $60''$  ( $1\ \text{m}^2$ ) OLED display in approximately  $25\ \text{s}$  (McGraw et al., 2011). Multiple vapor streams can be integrated into a single print head to allow for the deposition of a full color pixel triad in a single pass without a loss of printing speed. The 3000 nozzle array would have a width of  $810\ \text{mm}$ , which can be produced using standard Si fabrication processes.

The most significant challenge to the large scale implementation of OVJP is the control of the nozzle-substrate distance,  $s$ , which determines the degree of parasitic material overspray into neighboring regions of the substrate beyond those directly targeted. As discussed,  $s < 10\ \mu\text{m}$  is optimal for printing very small features. Yet this must be maintained over large, rapidly translated substrates where dust, pre-patterned topographic features, surface roughness and other surface irregularities can interfere with the print head. Also, the gas exiting the nozzle in close proximity to the substrates imparts a high sideways velocity that can sweep the organic molecules laterally

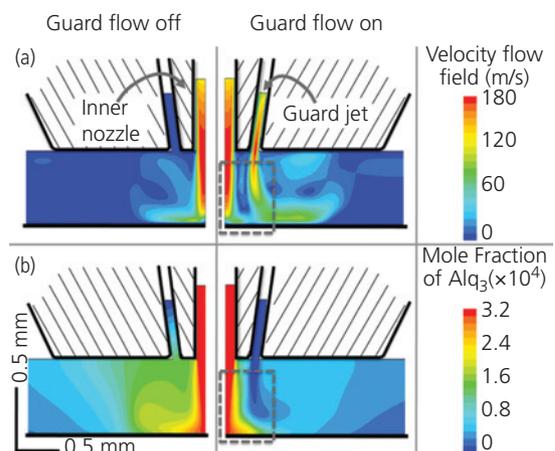

**Figure 5.79** Guard flow nozzle showing the central region where the organic source material is carried by a hot  $\text{N}_2$  gas to the substrate. The outer annulus carries hot  $\text{N}_2$  that serves as the guard flow. The circles surrounding the nozzle assembly represent the heating elements (Biswas et al., 2010).

before they can adsorb onto the substrate, as in Fig. 5.76. Several strategies have been developed to counteract lateral spreading, including shaping the nozzle to include relief that reduces the sideways gas acceleration beneath the nozzles, actively removing the exhaust by local application of vacuum (i.e. “skimming”), and placing dielectric barriers on the substrate between printed regions similar to wells used in liquid-based inkjet printing (McGraw and Forrest, 2013).

Confinement of nozzle flow into the desired area can also be accomplished by supplying a *guard flow*, as shown in Fig. 5.79. Here, a concentric nozzle is employed, with the center nozzle conducting the molecular source and its carrier gas, and the outer annular nozzle conducting an additional hot carrier gas (Biswas et al., 2010). The outer guard flow provides hydrodynamic pressure that “focuses” the molecular beam, preventing excessive spreading. This approach may also prevent the entrainment of contaminants into the molecular jet, allowing for deposition of device-quality materials even in atmospheric environments. A heavier gas than the carrier (e.g. Ar) is particularly effective at confinement of the central molecular jet.

Visualization of the effects of guard flows is shown in the simulation based on the Navier–Stokes equations for fluid transport in Fig. 5.80. This analysis provides evidence, as experimentally confirmed, that guard flows both focus the molecular beam while preventing ingress of species from the environment.

Fabricating arrays of concentric nozzles for printing over large areas complicates nozzle design and

**Figure 5.80** Simulation of (a) the velocity field and (b) the concentration of a heavy molecular species ( $\text{Alq}_3$ ) in  $\text{N}_2$  gas exiting a nozzle with and without the presence of a  $\text{N}_2$  guard flow (Biswas et al., 2010).

fabrication. Further, the increased gas flow from the guard beam added to that of the organic source beam slow the removal of the large gas volume between the nozzle and substrate; a problem that becomes increasingly acute as the number and density of nozzles increases.

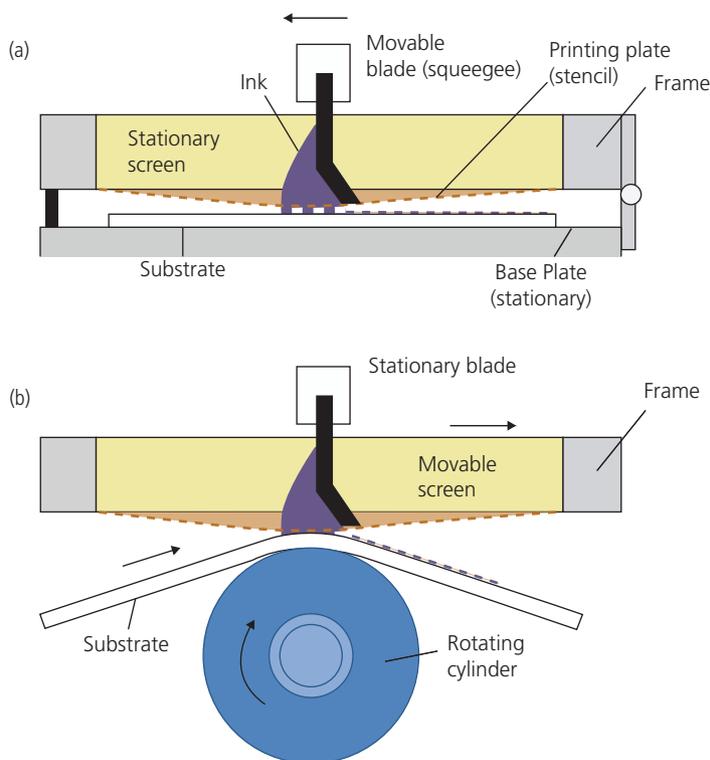

OVJP has several advantages over liquid-based inkjet printing. While it is compatible only with molecules that can be evaporated, no molecular modification is required to specifically adapt a species for use in vapor jet printing. The very high feature resolution approaching  $1\ \mu\text{m}$  makes it suitable for a wide range of transistor and light emitting device patterning scenarios. Also, the absence of surface tension produces a predictable deposit profile. Since the processing is free of liquid solvents, there is no interaction such as re-dissolution with previously deposited layers. Indeed, OVJP presents no constraints beyond those encountered in VTE or OVPD. Hence, wide flexibility in device design and materials choice is compatible with this dry printing method.

### 5.6.7 Other patterning techniques

There are numerous forms of rapid printing that have been developed for the graphics and print publication

industries. Several of these technologies are also adaptable to patterning organic electronic devices. After all, the inks used in graphics printing are closely related to organic semiconductor materials. Hence, it is logical to assume that similar printing techniques can be useful in both applications. Yet, there are important differences that distinguish these two printing regimes. Organic electronic devices demand precise control of the morphology of the printed region, and often require extremely high pattern resolutions when compared to passive printed media. In both instances, high throughput leads to low cost. Here we discuss several printing technologies that are adaptable to organic semiconductor device applications. Each has its benefits and limitations, but in general none has been developed to the extent that would warrant their use in volume device manufacturing. The various methods are introduced roughly in terms of their maximum throughput.

*Screen printing* (throughput  $\sim 2\text{--}3\ \text{m}^2/\text{s}$ ) is widely used for printing fabrics, signs, and other large graphical images. Thus, it has been adapted to very high speed and simple, low resolution printing of organic semiconductors and even metallic contacts. Two realizations of screen printers are illustrated in Fig. 5.81. Figure 5.81a shows screen printing to a flat plate, and

**Figure 5.81** A screen printing apparatus for printing on (a) sheets and (b) rolls (Kipphan, 2001).

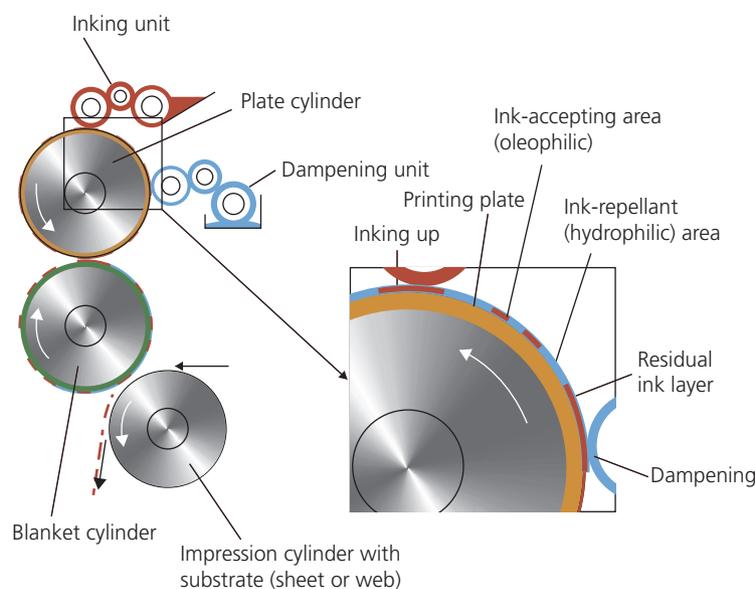

Fig. 5.81b is from a flat plate to a cylindrical roller. A silk screen with a fine mesh is placed in proximity (1–2 mm, typical) to the substrate on which the material is to be deposited. To create a pattern, a stencil material (typically a plastic or metal film) is embedded into the screen, or is placed onto its surface to mask those areas that are not to be printed. A semi-viscous electronic polymer or metal paste is then loaded onto the film surface and is pushed through the mesh by a rubber blade (often called a *doctor blade* or *squeegee*) that deforms the screen into contact with the substrate. The blade is translated at several centimeters per second across the substrate. The fluid penetrates the un-masked regions of the screen, leaving behind the desired pattern which is dried to remove excess solvent. The solution containing the molecular solute rides in front of the blade and is continuously replenished to avoid gaps in the printed pattern. Screen printing resolution is limited by the screen mesh openings, which are typically  $\sim 100\ \mu\text{m}$ , although smaller meshes have been produced. The highest pattern resolution is approximately twice this dimension. Also, the method favors thicker films that are limited by the size and thickness of the mesh. Viscoelastic effects can also affect film uniformity, similar to that encountered in inkjet printing.

Given its limitations, screen printing is not widely used to pattern organic electronics. Nevertheless, given its very low cost and high speed, research laboratories have pursued its use for printing metal contacts, OPV bulk heterojunctions (Shaheen et al.,

2001, Brabec and Durrant, 2008), OLEDs (Pardo et al., 2000, Lee et al., 2009), and OTFT active regions (Bao et al., 1997, Rogers et al., 1998).

*Offset printing* (throughput  $\sim 5\text{--}30\ \text{m}^2/\text{s}$ ) is a form of lithographic printing whereby the ink is applied to the plate, or in Fig. 5.82, the plate cylinder. The pattern to be printed is defined on the plate by having inked regions that are *oleophilic* (and hence hydrophobic), and hydrophilic ink-repellent regions. The plate is prepared by applying inks from the inking unit on a surface that has initially been treated with a film of water from the dampening unit. Dampening the cylinder ensures that no ink will transfer to the regions that should not be printed. The patterns are then transferred from the plate onto the blanket cylinder, which ultimately delivers the pattern to the substrate that rolls over the surface of the final, impression cylinder.

Offset printing is the most common form of printing, resulting in features that are finer than screen printing, typically  $10\text{--}50\ \mu\text{m}$ . Importantly, for organic electronics, the control of film thickness of from  $0.5\text{--}1.5\ \mu\text{m}$  is quite high compared to other high volume printing technologies. Also, registration of multiple layer patterns can approach  $10\ \mu\text{m}$ , allowing for a modest level of circuit complexity. The advantages of offset printing are somewhat countered by the complexity of the system comprising multiple contacting elements, and controlling the chemistry of the inks and dampening solutions in ways that are compatible with high device performance, yield and

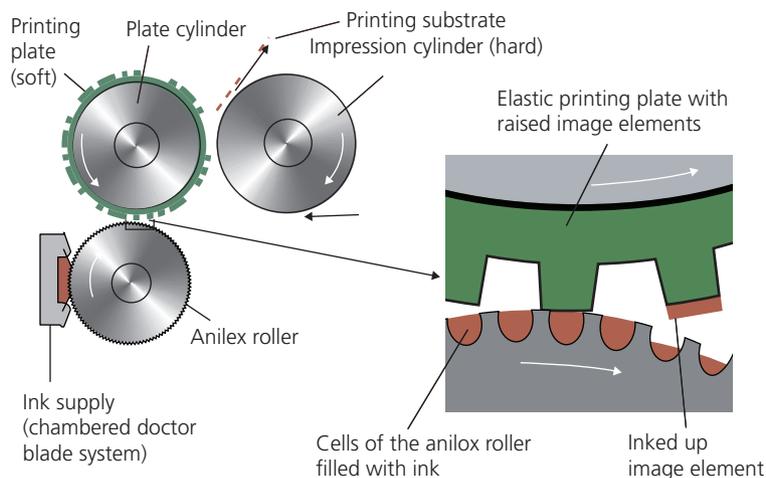

**Figure 5.82** Schematic of an offset printing apparatus (Kipphan, 2001).

pattern resolution. Offset printing has been used in producing PEDOT (Zielke et al., 2005) and metal nanoparticle ink-based (Fukuda et al., 2015) transistor source and drain contacts, as well as for transparent OPV electrodes (Kim et al., 2015).

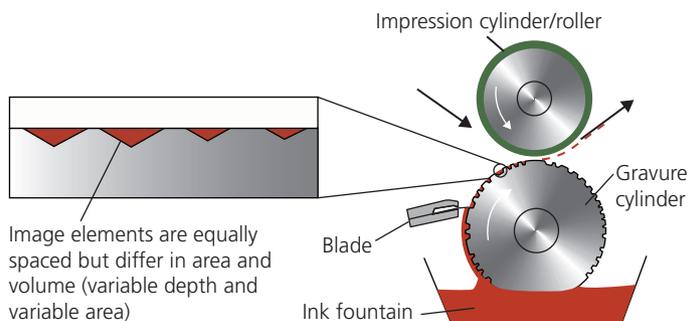

*Flexographic printing* (throughput  $\sim 10 \text{ m}^2/\text{s}$ ) is a variation on *letterpress printing*, and is shown schematically in Fig. 5.83. The image to be printed on the substrate is first embossed on a roller consisting of a soft material such as a hardened rubber or photopolymer that can hold ink on its surface, or absorb the ink. The printing plate itself is held on a hard cylinder or plate to give it structural stability. Prior to transfer to the plate, the ink is first spread over a cylinder containing a high density of ink-retaining wells. This ink-transporting cylinder is known as an *anilox roller*. The ink has a low viscosity compared to that used in offset printing since it must be retained by the roller and the printing plate. The uniformity of the liquid layer is maintained by a doctor blade. The printing plate finally transfers the inks to the substrate to form the desired image.

The combination of low-viscosity fluid with the soft, elastic printing plate, which is distorted under the contact pressure with the substrate, results in a low-resolution image. Flexography bears similarities with so-called pad printing (Kipphan, 2001), as well as the additive soft-stamping process described in Section 5.6.4 that also suffers from lower resolution than hard-stamping methods due to stamp distortion. Thus, feature sizes  $\sim 100 \mu\text{m}$  are typical of flexographic printing, which is at least two orders of magnitude larger than achieved by soft stamp transfer done on a batch, substrate-by-substrate process. Flexography has been used to generate diacrylate gate dielectrics in polymer thin film transistors (Cosnahan et al., 2018). However, given its pattern resolution limitations, it has not been widely exploited in the patterning of organic electronic devices.

*Gravure printing* (throughput  $\sim 50 \text{ m}^2/\text{s}$ ) differs from offset printing in that the image to be transferred is etched or engraved into the plate or cylinder, as shown in Fig. 5.84. The wells thus formed are filled

**Figure 5.83** Schematic of a flexographic printing apparatus (Kipphan, 2001).

**Figure 5.84** Schematic of a gravure printing apparatus (Kipphan, 2001).

with ink, with the excess removed by a doctor blade. The gravure plate transfers the ink to the substrate that is forced against the impression roller. The amount of ink and the resolution of the pattern is determined by the width and depth of the wells. Sidewall control is essential since ink residues can clog the wells or otherwise decrease the pattern resolution achieved. However, the wells themselves are well adapted to retaining low viscosity fluid, whereas in offset printing, the viscosity must be sufficiently high for the oleophilic regions to maintain pattern definition. The technique is capable of printing layer thicknesses  $< 1 \mu\text{m}$ .

The engraving or etching process to create the image on the cylinder is costly, and each change in image (corresponding to a particular circuit or device layout) requires the fabrication of a new cylinder. Furthermore, each separate layer (e.g. the R, G, and B pixels in a display) requires a separate cylinder or plate precisely aligned to the others in the production chain. Countering this complexity is the extremely high throughput of gravure printing. Features tend to be large due to the limited precision with which the ink wells can be fabricated, and the low viscosity fluid that makes pattern confinement difficult. Feature sizes of  $75 \mu\text{m}$  or larger are common, making this technique most appropriate for contact deposition or for the active regions in large area devices such as OLED lighting sources (Kopola et al., 2009, Hernandez-Sosa et al., 2013) and solar cells (Kopola et al., 2011, Voigt et al., 2011). Very high resolution patterns ( $< 10 \mu\text{m}$  feature sizes) of the polymer gate dielectric in thin film transistors have been achieved using precise engraving of the gravure cylinder. This *microgravure* process also demonstrated linear throughput speeds of nearly  $1 \text{ m/s}$  (Kang et al., 2012).

We conclude this discussion with a comparison of several printing methods in Table 5.5. While they remain at an immature stage of development for electronics applications, they continue to be of interest due to a primary promise of organic electronics—that

of manufacturing large-scale devices and circuits on flexible substrates at extremely low cost. The inherent similarities between inks used in creating graphical images and those used as electronic materials will continue to motivate development of high-speed printing for use in manufacturing of on-demand, organic electronic appliances.

## 5.7 Roll-to-roll production of organic electronics

A significant driver of low cost electronics is the fabrication of devices in a continuous process, where circuits and complex devices are rapidly produced “by the meter” rather than currently employed, substrate-by-substrate semiconductor batch processes. Increased output is enabled by continuous, *roll-to-roll* (R2R) manufacturing that employs one of the many rapid print patterning methods discussed in previous sections. Most of these patterning processes are already implemented, or can readily be adapted to the R2R environment.

Roll-to-roll, also referred to as *reel-to-reel* or *web* processing, is a general term that implies fabrication of the devices and circuits on a substrate by rapidly translating it from process to process in a continuous, uninterrupted manner. The processes themselves include the addition, subtraction, annealing (either thermally, by illumination, or solvent exposure), and patterning of multiple layers that comprise the electronic or photonic devices. Hence, while process speed is enhanced by continuous web-based manufacturing schemes, it becomes challenging to achieve high tolerance alignment of patterns on successive layers, simply due to the short residence time of the substrate at each process step, as well as the tendency to distort (via stretching, compression, twisting or other mechanical stress) the substrate web as it proceeds through the various manufacturing stages. Hence, web-based processing is only practical where very high alignment

tolerances ( $<20\ \mu\text{m}$ ) are not required, or where automatic, or self-alignment between layers is built directly into the process flow. Furthermore, since most active organic electronic materials degrade when exposed to air or moisture, some or all of the fabrication processes must occur in highly controlled, contaminant- and dust-free atmospheres—typically in vacuum or in high purity nitrogen. Indeed, while considerable work has focused on solution-based deposition in ambient due to its simplicity, it is unlikely that high performance and reliable devices and processes can be realized under such conditions. In contrast, R2R vacuum coating of extremely high volumes of materials is a standard process employed by the food industry, and has even been successfully used for organic electronic devices (Chaug et al., 2004). Nevertheless, enclosing large processing lines in a contamination-free environment can be difficult and costly, making it convenient to do some of the processing in separate chambers, whereby the web enters and exits via differentially pumped plenums, or where the entire web is included within the vacuum space. The last step in the fabrication sequence is packaging or lamination to protect the electronic devices. This is followed by cutting the web into discrete device or circuit segments. The substrate segmentation is called *singulation*.

Several web processing system layouts are shown schematically in Fig. 5.85. Roll-to-roll implies that the substrate is thin and flexible, typically comprised of a polymer such as PET or PEN, metal foil, very thin and flexible glass sheet, or even paper. While glass is brittle and fragile, if made sufficiently thin ( $<100\ \mu\text{m}$ ) it can be very flexible without being distorted by stretching. Since it is extremely smooth and impervious to atmospheric contaminants, if handled

carefully, flexible glass provides a nearly ideal substrate for web processing. The substrate is deployed from a feed reel through rollers to each process stage, and then the finished product is collected by a take-up reel (Fig. 5.85a). Lateral pattern registration is done at the edge of the web, and is adjusted along its length by active control of the tension. This is usually accomplished by rollers placed intermediate between process stations. Their relative positions are actuated in real time to dynamically tighten or loosen the web.

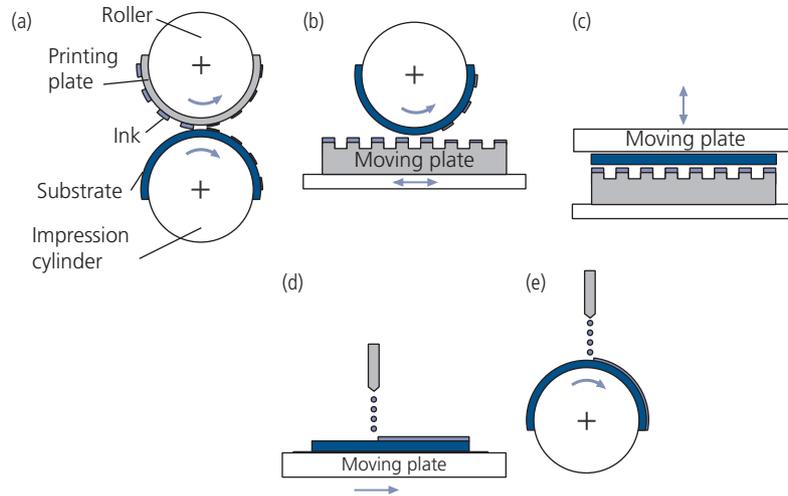

Another means to transport large substrates in a continuous or semi-continuous fashion is sheet-to-sheet, in which the substrates are already cut into manageable sizes, and continuously transported through a series of process stations (Fig. 5.85b). The translation from the feed stack to the output stack is via grippers, or robots that remove the substrate from the previous station, and then place it in the next while also performing the task of registration and alignment required in multilayer fabrication processes. This configuration has been widely adopted by the OLED display industry, where multiple layers are deposited in sequence on large, very thin glass substrates. Sheet-to-sheet manufacturing systems can extend to over 100 m in length to complete the multilayer film deposition process.

In the sheet-on-shuttle process (Fig. 5.85c), the substrates are placed on a continuous carrier or track, each substrate registered in its own fixture within the shuttle. The shuttle itself is translated using a gear mechanism that ensures precise alignment at each process position. Large substrates can be laid either horizontally or held upright. If a process step requires physical contact with the substrate (e.g. stamp patterning of metal contacts), the shuttle must be sufficiently robust to support the substrate as pressure is applied.

**Figure 5.85** Various web-based systems. (a) Roll-to-roll, (b) sheet-to-sheet, (c) sheet-on-shuttle, and (d) roll-to-sheet (Willmann et al., 2014).

Finally, combinations of the substrate handling processes in continuous or semi-continuous web environments is also possible, as shown in Fig. 5.85d. There are many situations where these combinations are essential; for example when some of the processes in circuit fabrication require a controlled environment whereas others do not. In this case, the web roll is removed from one process line and moved to another where sheet-based processing is more convenient. This movement decreases the manufacturing line output, or productivity, requiring the use of parallel systems to complete the slower process steps to ensure that they keep pace with the more rapid processes. That is, the rate of production is determined by the slowest step in the continuous chain. Another consideration is that the process may be continuous (e.g. printing stripes by gravure printing on a roller) or intermittent, in which case the substrate movement pauses while the process occurs (e.g. deposition of two dimensional patterns through a shadow mask). The duration of a particular process step is called the *takt time*, that is, the time that a machine must take to complete the step. The *takt time* can refer to that needed to complete a single step, multiple steps in a series, or even the entire fabrication process itself.

Figure 5.86 shows several different fabrication configurations that the substrate might encounter during the process sequence. They fall into two categories: contact and non-contact printing. Examples of contact printing described in Section 5.6 include stamping, gravure, or screen printing. Non-contact methods include inkjet and vapor jet printing. Full surface

**Figure 5.87** Continuous, double slot-die coating of the OPV active region along with the top cathode. When combined with the bottom anode already applied to the plastic substrate, the OPV cell structure is completed in a single process step (Sondergaard et al., 2012).

deposition of films via vapor phase deposition (e.g. OVPD and VTE), or liquid spray-on or spreading with a knife edge (i.e. a doctor blade or squeegee) are also compatible with continuously transported substrates in web fabrication environments. The application of materials can be done in either a flat sheet or continuous, roller-based configuration.

An example of application of a multiple component layer by slot-die coating is shown in Fig. 5.87. Here, the electrode material, PEDOT:PSS, is combined with a continuous flow of a donor-acceptor OPV mixture of P3HT and PC<sub>61</sub>BM, allowing for the simultaneous

deposition of two layers with significantly different functions and rheological properties. This is layered onto a PET substrate that supports the transparent anode consisting of the metal oxides, ITO and ZnO. Slot-die coating is similar to blade coating, in that the layers are formed by a sharp edge that ensures a constant thickness determined by the temperature, viscosity, translation velocity, and the surface tension (and hence the meniscus) of the liquid being spread over the substrate surface. As in all liquid-based processing methods, care must be taken in choosing compatible materials such that two or more layers do not interdiffuse or dissolve. In Fig. 5.87, PEDOT:PSS has an aqueous base, whereas P3HT:PC<sub>61</sub>BM uses an organic (hydrophobic) solvent to minimize interactions between layers. Slot-die coating is potentially a high productivity film deposition procedure, with substrate speeds in the range 0.1–200 m/min.

Some of the stations along the processing line must be devoted to metrology and control. These include *in situ* film thickness measurement, pattern alignment, and particle detection. These properties are monitored in real time, with results fed back to adjust the process flow to prevent it from producing large volumes of useless, non-functional product. All semiconductor manufacturing lines, whether done by batch or web, require such process diagnostics to ensure a high production yield of devices that perform at the required standard.

A further consideration is the method for recharging the deposition stations with fresh material. As substrates are translated through each station, source materials are consumed. To avoid halting the line to refill materials reservoirs, the manufacturing lines allow for continuous feed of materials to the deposition site (e.g. roller or plate) from an external location. Similarly, cleaning of components contained within the system (e.g. shadow masks, screens, and print heads) should also be an integral part of the systems, since routine maintenance ensures maximum productivity, as well as a minimum down time where the system is taken off-line to restore it to optimal operational order. Perhaps the biggest single problem in maintaining a web-based processing line is ensuring that dust and other debris do not accumulate on the substrate as it passes from station to station, or between rollers. Organic devices are typically only a few tens to hundreds of nanometers thick. Hence, even the smallest particles or irregularities on the surface of the web can result in pinholes in the device active regions, creating shorts or paths for the ingress of contaminants. Defect densities of 100–1000 m<sup>-2</sup> with radii ranging from 0.1 to 3 μm are commonly observed

on PET substrates, depending on the coatings applied; a level that may prevent high productivity (Graff et al., 2004). Furthermore, dust can cause substrate damage during stamping or mask attachment where pressure is applied to its surface.

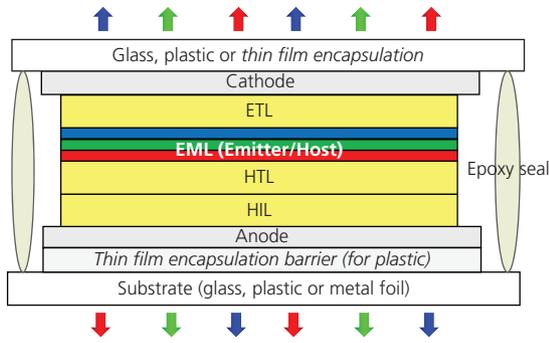

To date, there has been insufficient research on R2R processing to fully assess its usefulness in the manufacture of organic electronic circuits. The equipment is necessarily complex and large, and the consumption of costly source materials is also an impediment to its development. However, once devices, materials and processes that can benefit from such large scale manufacture are defined, it is anticipated that research efforts in this area will grow apace. The most likely applications to benefit from continuous R2R processing are OPVs and low cost organic transistor circuits (Sondergaard et al., 2012). Since the technologies leading to their successful and widespread deployment have not yet been fully developed, it is understandable that their use in large-scale manufacturing of devices has not yet been realized. Nevertheless, one of the major benefits of organic electronics is the promise of very low cost circuits serving a diversity of custom as well as low cost needs. Provided sufficiently high performance can overcome the compromises that are inherent in continuous processing environments, R2R and other web-based fabrication technologies may yet become a mainstay in the manufacture of organic electronics (Forrest, 2004).

## 5.8 Packaging

The final step in the fabrication of an electronic device or circuit is its packaging. This has several purposes: the package protects the device from degradation due to environmental exposure, it can be sufficiently large and robust to make handling of the electronics contained within it manageable, and it enables connections to an external circuit. The vulnerability of organic materials to degradation when exposed to oxygen (particularly in the presence of light) and moisture makes some form of packaging imperative. Packaging of flexible electronics (requiring flexible packages) presents particular challenges.

For rigid displays used in many smartphones (see Fig. 5.88), the device is deposited onto a glass substrate. It is then sealed in an ultrahigh purity N<sub>2</sub> environment by a metal (or glass) lid to the substrate using a bead of epoxy that is cured by brief exposure to UV light. Alternatively, a cold-weld bond or solder seal is used.

The lid often contains a thin film desiccant such as the hygroscopic compounds BaO or CaO, or a high surface area *zeolite* that is deposited onto its inner

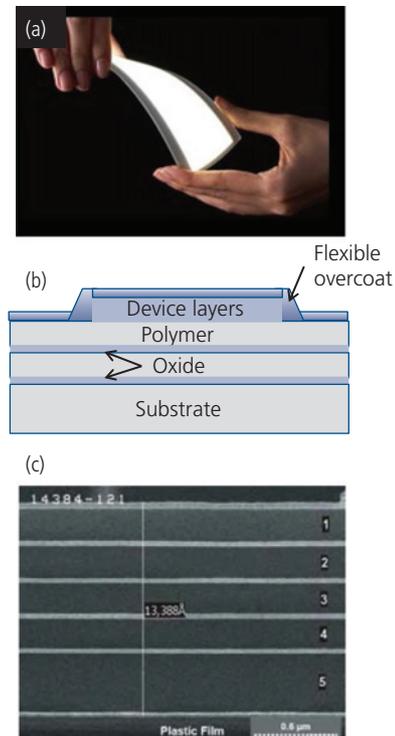

**Figure 5.88** Packaged OLED for lighting, showing its various functional layers and two possible emitting surfaces. An epoxy seal is placed around the package periphery, sealing the organic materials within.

surface. The desiccant scavenges the residual moisture that is captured in the package during sealing. Accommodation must also be made to provide electrical access to the device via contacts pre-patterned onto the substrate surface. The contacts must not be shorted nor interrupted by the seal, nor can they introduce leaks into the package interior. A moisture indicator that changes color (e.g.  $\text{CoCl}_2$ ) or transparency (Ca) when it is saturated with water can also be deposited inside the lid as a test of package integrity. This latter step is useful in diagnosing the integrity of the sealing strategy employed.

Packaging devices on flexible substrates provides a far greater challenge than on rigid media (Logothetidis, 2008). Metal foils can provide robust, impermeable flexible substrates. However, they must be coated with a planarizing polymer to overcoat surface irregularities absent in plastic or glass foils. On the other hand, plastic substrates are permeable to moisture and oxygen, presenting only a weak barrier to these contaminants that lead to irreversible degradation of device performance. For this reason, multi-layer coatings shown in Fig. 5.89 that alternate between a plastic and an inorganic oxide layer have been developed for organic electronic applications. Plasma deposition of oxides such as alumina ( $\text{Al}_2\text{O}_3$ ),  $\text{AlO}_x\text{N}_y$ ,  $\text{SiO}_x\text{N}_y$ , or  $\text{SiO}_2$  are typically interleaved with spin- or vapor-deposited parylene, PET, or other acrylate (Affinito et al., 1996, Dennler et al., 2006). The inorganic and organic layers are typically only a few tens, and a few hundreds of nanometers thick, respectively. If the encapsulated device emits or absorbs light, the laminate must be transparent.

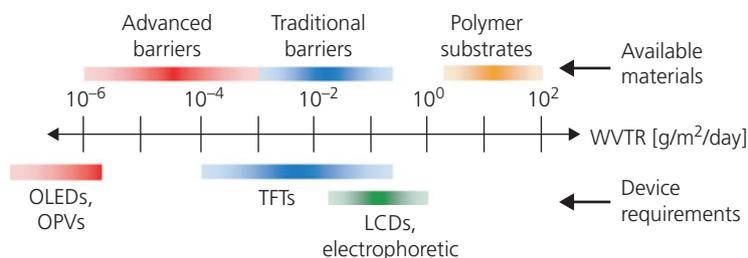

Such laminates have very low moisture permeation rates that are limited by the density and size of defects on the substrate. These defects are responsible for pinholes in the inorganic layers. The layer

**Figure 5.89** (a) Flexible OLED lighting panel demonstrator fabricated by Konica-Minolta; (b) Schematic of a flexible (plastic) package on a substrate comprising two dyads of a polymer/oxide barrier layer, and a flexible encapsulating coating. (c) Transmission electron micrograph of the cross-section of a 5 dyad barrier layer on a plastic substrate. The total barrier layer thickness (vertical line) is  $1.34 \mu\text{m}$ . The layers are produced by Vitex Systems (Lewis, 2006).

permeabilities themselves are no different than for thicker films, which is generally too high to result in device lifetimes greater than a few hundred to a thousand hours. However, when placed in lamellar form such as in Fig. 5.89b and c, the pinholes are non-uniformly distributed at low density in each of the inorganic layers. A water molecule that enters the plastic substrate will meander within the plane of a polymer layer until it finds a pinhole that allows it to cross into the next layer in the laminate. Hence, penetration of moisture into the device volume is retarded simply due to the longer path a water molecule must travel to reach it (Graff et al., 2004). In Table 5.6, we show the *water vapor transmission rate* (WVTR) vs. number of pairs of a  $0.34 \mu\text{m}$  thick PMMA/ $0.037 \mu\text{m}$  thick sputter-deposited  $\text{AlO}_x$  layer on a  $177.7 \mu\text{m}$  thick PET substrate. This organic/inorganic pair is known as a *dyad*.

The permeation rates for several substrates as well as the expectations for various device applications are shown in Fig. 5.90. The display industry standard for an acceptable level of water permeation is

**Figure 5.90** Flexible package types (top) and requirements needed to be met by several different device types leading to their acceptable operational lifetimes (bottom) vs. water vapor transmission rate. Advanced barriers are multilayer structures as in Fig. 5.89, traditional barriers are single layer structures. LCDs and electrophoretic displays are not organic electronics-based, and thus are less susceptible to water damage. After Lewis (2006).

**Table 5.6** Water vapor transmission rate (WVTR) vs. lamellar substrate structure on PET<sup>a</sup> (Graff et al., 2004).

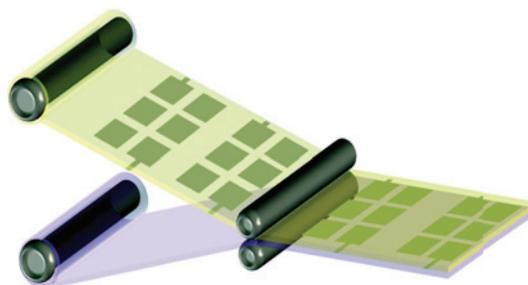

No. of dyads <sup>b</sup>	WVTR (g/m <sup>2</sup> /day)
0	4.7
1	0.07
2	<0.005
3	<0.005
4	<0.005
5	~10 <sup>-6</sup>

<sup>a</sup> PET substrate thickness = 1.77  $\mu\text{m}$ .

<sup>b</sup> The dyads comprise 0.34  $\mu\text{m}$  PMMA/0.037  $\mu\text{m}$  AlO<sub>x</sub>.

WVTR < 10<sup>-6</sup> g/m<sup>2</sup>/day, which is met when five or more dyads are employed. Unfortunately, the substrate fabrication process can be expensive, ultimately making the use of metal foil or thin glass substrates preferable.

To complete the flexible electronics packaging, a thin and highly flexible cover is required. While a flexible glass or metal foil lid can be sealed to the flexible substrate similar to the method used in rigid substrate encapsulation, a bilayer of two foils bonded together by an adhesive significantly limits the package flexibility. Alternatively, a laminate consisting of alternating layers of an oxide and a thin polymer can result in a barrier with properties similar to an analogously prepared substrate in Fig. 5.89b. When the top of the device is coated with a multilayer film, there is no need for epoxy or solder sealing the edge of the package. There is also no space within the package between the device and its sealant. Thus, the entire packaging process can be carried out in the same system used to grow the device itself without exposing the sensitive electronic layers to exogenous contamination. Of course, deposition conditions must not result in device degradation, and accommodation

**Figure 5.91** Schematic of R2R organic electronic encapsulation via lamination between rollers in a continuous web process. The electronic circuits are patterned on the underside of the top layer, and are combined by pressure lamination with a flexible encapsulating “lid” deployed from the lower roller. Both the substrate and lid materials must provide a barrier against atmospheric contaminants. The seal can consist of an adhesive, or a cold-weld bond between metal tracks on the substrate and lid.

must still be made to bring the electrical contacts to a region outside of the device volume.

Finally, packaging and encapsulation on flexible (or rigid) substrates can be made compatible with web processing. A conceptual diagram of a web-based device lamination system included at the end of a R2R fabrication sequence is illustrated in Fig. 5.91. As with all process steps, R2R packaging must be carried out in a contaminant-free and controlled environment to ensure that no impurities are captured within the package volume.

## 5.9 Summing up

In this chapter, we learned about the “how to” of organic electronics: that is, how to take a material from its crude source to a large scale electronic device created on a continuous web, ultimately leading to potentially low cost and unique optoelectronic applications inaccessible to other electronic technologies. There are many steps from synthesizing the source material to its application.

It starts with refinement of the crude material, to the growth of thin films with precisely controlled morphologies. Indeed, there has yet to be an instance in electronic or photonic technology where purity of the source materials could be sacrificed without making unacceptable compromises in device performance and lifetime. In this regard, organics are no different.

Once the layers are deposited in the desired scheme, the devices must be patterned and ultimately packaged. One of the most captivating attractions of organic electronics is their enablement of large devices such as displays, lighting, solar cells and complex circuits adapted for biological monitoring. Hence, they often must be lightweight, conformal and flexible. While these attributes offer many unique possibilities for applications not served by conventional inorganic semiconductor electronics, they nevertheless present complicated challenges to materials and device engineers. We have seen that organics can be deposited on sharply curved substrates, resulting in detector focal plane arrays that mimic the form and function of the human eye. We have also shown that the similarity of materials used in graphical and document printing, and those used in organic electronics enable similar and potentially very low cost patterning technologies such as inkjet, gravure and offset printing.

While this chapter covered many of the materials preparation, deposition and processing aspects common to all device types, the topics covered represent only a small fraction of all the techniques available. In fact, a unique feature of organic semiconductors is that they have encouraged the development of an extraordinarily wide range of processes from purification to printing. Hopefully, this chapter has provided the foundational knowledge that will be expanded in subsequent chapters when discussing specific details of devices in the remainder of this book.

Covering all aspects of this broad field would itself be the subject of an entire book; hence this chapter is meant only as an introduction. The reader is encouraged to learn more about materials growth and device fabrication processes by referring to the extensive literature devoted to the subject. Several references included in *Further reading* can serve as a starting point for exploration of the materials science and device engineering of organic semiconductors.

### Problems

1. Zone refining is an iterative process. It involves a thermal scan across a material ingot and removing the contaminated section at the end of a scan, and then starting over until the desired purity is reached.
  - (a) Starting with Eq. 5.3 for the change in impurity concentration at location  $x$ , derive the concentrations after a single pass given by Eqs. 5.5 and 5.6.
  - (b) Similarly, in the limit of an infinite number of scans (i.e.  $n \rightarrow \infty$ ), show that the impurity concentration is given by Eqs. 5.7–5.9.
2. Ultracentrifugation separates a mixture of particles according to their densities, radii, etc. along a vial containing a fluid of varying density along its length,  $L$ .
  - (a) Derive Eq. 5.13 for the radius of a fraction of a population at position  $z$  along a vial.
  - (b) If the initial distribution of radii of nanoparticles of constant density in a colloid is a Gaussian of width  $\sigma_i$ , with a mean radius of  $\langle R \rangle$ , plot  $R(z)$  after centrifugation time,  $t$ , for a rotational angular velocity  $\omega$  using a centrifuge of radius,  $r$ . Assume a linear density gradient of the solvent from  $\rho_{top}$  at the top, to  $\rho_{bot}$  at the bottom of the vial.
  - (c) Estimate the maximum time of centrifugation needed to obtain a reasonable separation of the population.
3. Derive Eq. 5.34 for the thickness of a spun-on film.
4. Patterning of displays employs vacuum thermal evaporation (VTE) through a shadow mask. Assume that a shadow mask of thickness,  $d_M$ , with a square opening of side  $a$ , is used in a VTE deposition system. Furthermore, assume a source-to-substrate distance of  $D$ .
  - (a) Derive an expression that describes the peripheral shape of the deposit based on all parameters in Fig. 5.59a.

- (b) What is the relationship between the pattern width,  $w$ , vs.  $a$ ,  $D$ ,  $d_M$  and the mask-to-substrate distance  $d_{M-S}$  (as measured from the side of the mask facing the substrate). Plot  $w/a$  vs.  $D$  for  $d_M = 20 \mu\text{m} = a/2$ .
- (c) What shape of mask opening would provide the smallest pattern?
- (d) What do you think is the smallest feature size obtainable with a practical VTE deposition apparatus? How does this compare to the highest resolution smart phone pixel size?
5. Estimate the force required to pattern contacts across an entire Gen 8 substrate using
- (a) A hard stamp via the subtractive cold-weld process. Assume that the contacts occupy 80% of the substrate area (a number typical of a high resolution display).
- (b) A soft stamp via the additive process.
- (c) Do the same calculations in (a) and (b) for a R2R system where the pressure is applied between 20 cm diameter rollers, assuming a rigid glass substrate and a contact area equal to 1% of the roller circumference.
6. Calculate the approximate melting temperature of an anthracene dimer using the atom-atom potential method, assuming that the anthracene molecules are facially stacked directly on top of each other. Can this material be evaporated without decomposition (determined by the bond energy of a benzene ring)?
7. Assume that the rate-limiting step in a web process is determined by the organic film printing rate by OVJP of  $1 \mu\text{g/s}$  of Alq<sub>3</sub>. The process step consists of writing a continuous,  $40 \mu\text{m}$  wide stripe of material that is  $300 \text{ nm}$  thick using a single  $300 \mu\text{m}$  long by  $20 \mu\text{m}$  wide nozzle.
- (a) What is the nozzle-to-substrate separation ( $s$ ) that must be maintained to provide a deposit whose half width is equal to the target half-width?
- (b) What is the web printing rate limitation by this step in meters per second?
- (c) What control mechanism would you use to maintain a constant  $s$  to within  $\pm 2 \mu\text{m}$ ? Provide details of estimated response time limits of the mechanism.
8. One limitation of OVPD is that in depositing materials with significantly different sublimation and decomposition temperatures, the reactor walls must be maintained at a temperature sufficient to prevent deposition of the less volatile material, while it is kept low enough to prevent decomposition of the lower temperature material. One means to prevent decomposition is to limit the collisions of a molecule travelling along the reactor axis from having too many collisions with the hot walls.
- (a) Derive an approximate expression for the number of collisions ( $N$ ) a molecule will have from the point of injection along the axis of a reactor tube of length  $L$  and radius  $r$ . Here, we assume a  $\text{N}_2$  carrier gas velocity,  $v$ , pressure,  $P$ , and reactor temperature,  $T$ . A molecule of mass  $M$  is entrained (at low Reynold's number,  $Re$ ) in the carrier gas having reached terminal velocity.
- (b) Assuming  $L = 1 \text{ m}$  long reactor tube with radius  $r = 10 \text{ cm}$ ,  $P = 0.1 \text{ torr}$ ,  $T = 350^\circ\text{C}$ , and a flow rate of  $10 \text{ sccm}$ , calculate  $Re$ . Is the flow laminar or turbulent?

- (c) Assuming the same conditions as in (b) for a low concentration of Alq<sub>3</sub> molecules injected into the gas stream, calculate  $N$ .
- (d) If the reactor temperature is raised to  $500^\circ\text{C}$  (approximately  $50^\circ\text{C}$  higher than the decomposition temperature of Alq<sub>3</sub>), estimate the probability for its decomposition prior to exiting the tube. Can you suggest a means to decrease the probability of decomposition?

# Organic light emitters

---

*“What we have here is a new form of light!”*

**Sherwin Seligsohn, visionary co-founder of Universal Display Corporation  
on his first sight of emission from an OLED**

Where would organic electronics be without the organic light emitting device, or OLED? It is hard to say. Certainly, it would remain a topic of fascination and interest to physicists, chemists, and materials scientists. The unique properties of organics are just too tempting to be ignored by the scientific community. This has been the case for at least the last 70 years. But my guess is that only a relatively small group of scientists and some engineers would be engaged in organic electronics scientific discoveries and applications, compared to the enormous cohort that works on this topic today, and whose careers depend on its success. This transformation was brought about by the invention of a relatively high efficiency, green bilayer diode, first named an organic electroluminescent device (OED), but then renamed the more pronounceable and now ubiquitously termed OLED. The success of OLEDs has led to a massive global industry in information displays, and an emerging industry in lighting. Organic light emitting devices (or equivalently, organic light emitting diodes) are rapidly overcoming competition from liquid crystal displays (LCDs) due to their unparalleled attributes, from their simplicity, to brilliant emission colors, and finally to their very high efficiency. And the many attractive features of OLED lighting, such as ultrahigh efficiency and color-tunable light emitting panels that can possibly be produced at exceptionally low cost, give every indication that OLEDs will soon find a major role in lighting our homes and businesses.

OLEDs are electroluminescent sources, in that current injection from the cathode and anode contacts generates an exciton on the emissive molecules within the structure, which then radiate with up to 100% internal quantum efficiency. The chapter begins with a brief discussion of the applications and basic operating principles of the OLED that is treated from an historical perspective. When was electroluminescence first discovered, and when was a device introduced that suggested this might actually be a practical source of light? Next, we discuss basic, modern OLED structures and techniques for quantifying their performance in their two main application spaces: displays and lighting. Indeed, how we think about color, lighting and efficiency are considerably different for these two applications.

The discussions of OLED characteristics rely heavily on all of the fundamental aspects of organic optical and electronic properties described in Chapters 3 and 4. As such, the discussion on OLEDs first presents principles, and then provides example devices and their operation based on those principles. This organization provides for a somewhat iterative treatment: devices introduced early in the chapter to demonstrate an architecture or principle will sometimes reappear later when a deeper look is warranted to understand an underlying physical mechanism of a class of materials or device structures. It is hoped that this revisiting of concepts throughout the chapter will provide the reader with a deeper appreciation of how multiple problems are solved in light emitting devices, sometimes using a single structure or material.

OLEDs fall into two different categories: somewhat low efficiency fluorescent devices and up to 100% efficient phosphorescent devices. Excitation of the fluorophores or phosphors depends on the spins of the injected electrons. We discuss the statistics of singlet and triplet formation, and the resulting efficiency of OLEDs using these chromophores.

Almost all efficient OLEDs use a doped emission zone, where energy transfer from the host, or charge trapping by the dopant, localizes the excited state on the luminescent dopant molecule. It has been found that doped OLEDs, where the chromophore concentration is generally less than 10% (with low doping if the OLED is fluorescent, and higher doping if it is a phosphorescent device), also have longer operational lifetimes than OLEDs with “neat” emission zones containing only the luminescent molecules themselves. Furthermore, as we have seen in Chapter 4, doping the charge conducting regions with electron donating or accepting molecules can reduce series resistance. Hence, conductivity-doped OLEDs tend to have lower operating voltages (leading to higher power efficiencies) and again, longer lifetimes, than devices lacking this type of doping.

The remainder of the discussion on OLEDs treats practical realizations and problems encountered by devices designed specifically for display and lighting applications. We will show examples of the countless clever ways that technologists have found to optimize the emission color, efficiency and lifetime of OLEDs used in a variety of environments, some benign and others quite harsh. Of particular importance is optical outcoupling: when grown on a conventional glass substrate, only ~20% of the emitted light reaches the viewer. An obvious way to improve OLED efficiency, therefore, is to improve outcoupling from the glass substrate. This sounds simple, but in fact it can be very difficult to extract a large fraction of the trapped light with simple, low cost solutions.

We complete our discussion by addressing a central concern of all organic devices: their reliability. Atoms comprising organic compounds are covalently bonded, and hence the stability of the molecules is ultimately limited by the weakest chemical bonds. Finding means to improve molecular robustness and stable device architectures has been a major focus of contemporary OLED engineering. This is a particularly challenging problem to address for high energy (i.e. blue) emitters, where the photon energy can exceed the bond energy of many compounds. To understand the limitations to device reliability, therefore, we must develop an understanding of the physics of failure: what are the fundamental mechanisms that lead to luminance loss in OLEDs, particularly in the blue part of the spectrum? Of course, there are failure mechanisms that are not fundamental but are equally difficult to eliminate, such as contact and layer delamination, impurity incorporation, attack by the ambient, and so on. All of these factors are discussed in the latter sections of this chapter.

Finally, we close with a discussion of organic semiconductor lasers. There remains the open question of whether or not electrically (rather than optically) pumped organic lasers are possible. We discuss the basic principles of organic semiconductor lasers, and the challenges faced in electrical pumping. We will show that its achievement remains a daunting challenge that has yet to be met in spite of numerous attempts at doing so.

Organic light emission is indeed an exciting topic. This chapter serves to provide both the fundamental as well as practical aspects of organic light emitters, with the hope of giving the reader the necessary tools to both understand and innovate in this fast moving field that is of both scientific and commercial interest.

## 6.1 OLED basics

An organic light emitting device (OLED) is a thin film structure deposited on a supporting substrate that emits light via the process of *electroluminescence* (EL). The emission results from the radiative recombination of electrons and holes injected from anode and cathode contacts located on opposite sides of the organic emissive medium. Hence, an OLED operates by *bipolar injection*. The color of the light is determined by the excitonic energy of the emitting molecule, and hence the device can be designed to radiate across a wide spectral range, from the infrared to the ultraviolet. Emission can occur via either a fluorescent or phosphorescent process. Due to their ultrahigh efficiencies,

the range of possible emission colors achieved by modification of the chemical structure of the emissive molecule (i.e. the *lumophore*), and their potentially low cost, OLEDs are finding widespread use in mobile displays such as smart phones, computer tablets and laptops, as well as in wall-mounted and roll-up televisions (Tsujimura, 2012). Their high efficiencies and color tunability have also led to applications in solid-state lighting in the interiors of residences and businesses (Kassakian, 2013).

Practical applications almost universally employ thin film (~100 nm total), multilayer small molecular weight structures. As we have seen in Chapter 5, this choice is driven by the ability to produce highly

purified source materials, a key criterion to achieve long device operational lifetimes. Furthermore, the ability to grow multiple layer structures with each layer optimized for a particular purpose (e.g. charge conduction, light emission, etc.) is also an essential ingredient for achieving the highest performance. The ease of deposition without concern for compatibility of the chemistry of a layer with others in the stack makes small molecules most suitable for OLED applications.

In Chapter 5 we showed that small molecular weight thin films are primarily deposited by vacuum thermal evaporation, and patterned into the desired structures (e.g. pixelated displays) using shadow masks. There are other potential technologies that can be employed to grow the OLED structure, including organic vapor phase deposition (OVPD), and various printing technologies such as organic vapor jet and ink jet printing. The OLED can be deposited on a variety of substrates, including glass, plastic or metal foils, or on semiconductors serving as the transistor driving circuits. Since OLEDs comprise amorphous organic thin films, there is no requirement for lattice matching with the substrate. This is a major differentiating characteristic of OLEDs with other LED technologies based on the InGaN or InGaP materials systems, where epitaxial growth is an essential ingredient for high performance. This feature provides extraordinary flexibility in the choice of materials used to form the OLED stack.

The high resolution patterning of the OLED film during deposition permits devices emitting in different spectral ranges to reside in close proximity on the same substrate. Hence, integration of a very high density of red, green and blue pixel triads onto a very large area substrate all deposited in a single growth cycle results in low cost production of displays with millions of pixels. Again, this is different than what can be achieved using LEDs where red, green and blue emitters must all be separately attached onto a substrate; a prohibitively costly process that prevents their use in high information content, large area displays.

We have seen that most organic semiconductors are dyes similar to those used as pigments in fabrics, in inkjet printed documents, or as paints. These synthetic processes often lend themselves to production in large batches at low cost. This feature, however, does not readily translate to electronic materials that are carefully optimized to precisely achieve a desired emission color through chemical modifications that are not always easy or efficient to synthetically access. Further, they need to be tailored for deposition within a narrow range of conditions that are compatible with other materials deposited in complex, multilayer device structures. Ultrahigh purity required for long device lifetime, and to avoid exciton quenching or

charge recombination at defects, can involve time consuming and costly synthesis. Hence, while OLEDs have the *potential* for being inexpensive, as of this writing they have not shown a clear cost advantage over the incumbent LCD technology.

The organic materials and the processes used in their synthesis or deposition are environmentally friendly when compared to many other illumination or display technologies. The very low toxicity of most organic thin films, the absence of hazardous metals such as Hg or As found in fluorescent or LED lighting, and the very low energy expense incurred during production due to the low sublimation temperatures of organics, leads to cost advantages and a reduced environmental impact in their production. Since displays and lighting fixtures are very large area devices with widespread consumer applications, minimizing the environmental impact of their production, use and disposal at the end of their life cycle are essential to their broad adoption by the public.

OLEDs possess several distinctive features that open up applications that other illumination technologies cannot access. For example, the OLED can be made fully transparent such that when it is turned off, it can serve as a window on buildings or in head-up displays in automobiles, aircraft, etc. Due to their high efficiency, they can achieve high intensity without significant heating above ambient temperature. Since the device itself can be arbitrarily shaped if placed on a flexible substrate, it can be used as a lighting fixture without requiring an expensive or bulky luminaire used contain and shape the output of conventional lighting sources. Their very low operating voltages (2–10 V) also reduce power consumption. This makes them compatible with low voltage driver circuits in power-constrained mobile applications.

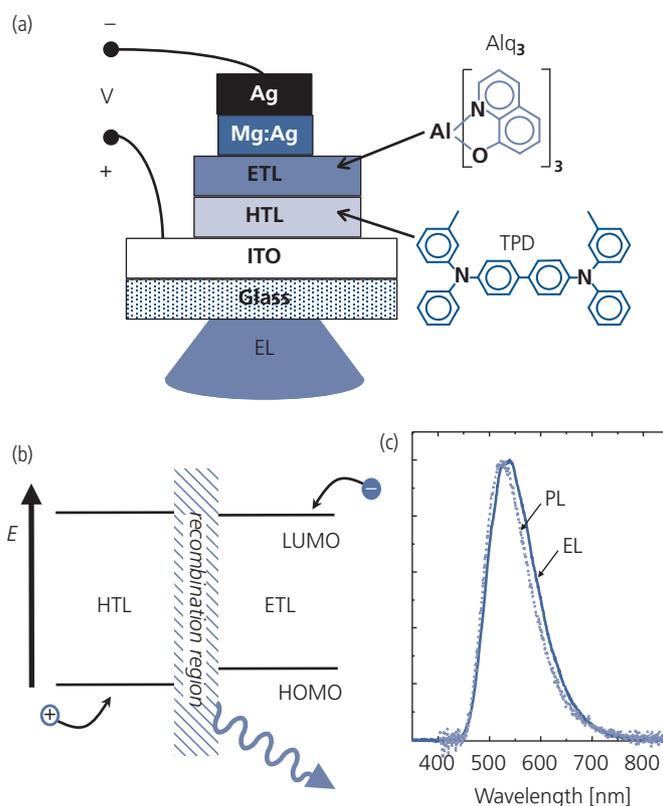

The list of advantages and opportunities afforded by OLEDs is long and growing every day, which helps to explain their popularity with the public. First and foremost, however, OLEDs provide an extraordinarily attractive display technology owing to their brilliant emission colors, very high on/off contrast ratio, ability to be shaped for a particular aesthetic or practical purpose, and even rolled into compact holders and stowed away when not in use. Singlehandedly, OLEDs have provided impetus for driving the robust research and commercialization of many other synergistic organic electronic device technologies to be discussed in subsequent chapters. A few images of OLED displays and lighting fixtures are shown in Figs. 6.1 and 6.2, respectively. While they do seem to represent “a new form of light” suggested by the epigram to this chapter, they are really only a new means for emitting light that opens up an unprecedented array of opportunities for their use.

**Figure 6.3** Bilayer small molecule OLED. (a) The bilayer structure introduced by Tang and VanSlyke (1987). The molecules shown are used for electron transport and fluorescent emission,  $\text{Alq}_3$ , and hole transport, TPD. (b) Energy level diagram of the OLED forming a type II heterojunction. The recombination region leading to light emission is at the interface between the electron (ETL) and hole transport (HTL) layers. (c) Electroluminescent (EL) and solution photoluminescent (PL) spectra from the OLED and a film of  $\text{Alq}_3$ , respectively.

The bilayer, thin film OLED structure similar to that in Fig. 6.3a, was introduced by Tang and VanSlyke (1987). The OLED comprises a type II, staggered heterojunction (HJ) formed between an electron transport layer (ETL) and a hole transport layer (HTL). Both the ETL and HTL thicknesses are only a few tens of nanometers thick, resulting in a total device thickness (not counting the substrate) of  $\sim 100$  nm. The charge transport layers are sandwiched between a low work function, electron-injecting cathode, and a high work function, transparent anode typically consisting of ITO. The HOMO–LUMO offset energies of the HJ in Fig. 6.3b result in current rectification. Interestingly, the EL spectrum of the OLED is nearly identical to the solution photoluminescence (PL) spectrum of the emissive  $\text{Alq}_3$  molecule, with only slight shifts due to dielectric polarization in the solid vs. the solution (Fig. 6.3c). This is in striking contrast with covalently bonded inorganic semiconductors where the PL spectra of the constituent atoms (e.g. Si atoms) bear little resemblance to that of the solid.

OLED light emission is based on the four-step process shown in Fig. 6.4 for a three-layer device

consisting of a light emission layer (EML) sandwiched between an ETL and an HTL. (1) Charges are injected from opposing contacts, and (2) subsequently localize on the emissive molecules in the EML. Next, (3) a hole on the HOMO and an electron on the LUMO form a bound exciton. Finally, (4) radiative recombination of the exciton emits light that emerges via the transparent anode, through the substrate, and toward the viewer. The bimolecular recombination region extends only a few nanometers into the ETL. Efficient operation requires the emissive molecule to have a high fluorescence quantum yield. The luminescent molecule determines the emission color. With only minor variations of the ligand structure, efficient emission from the deep blue to the near infrared (NIR) has been achieved, thereby enabling full color displays with large color gamuts, and white light emitting fixtures with a range of color temperatures and pleasing colors.

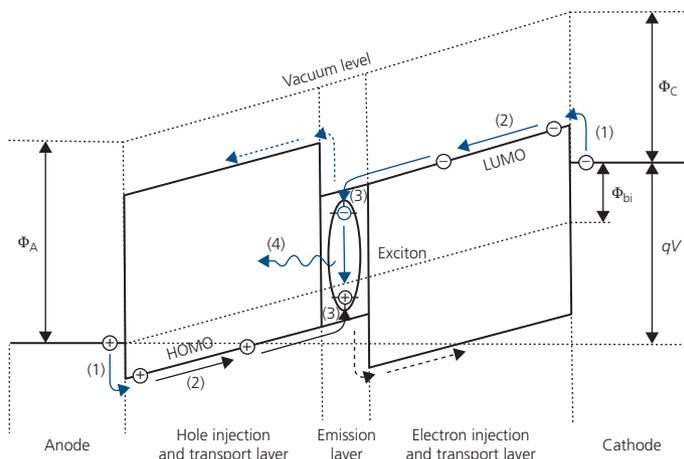

We will show in subsequent sections that the functions of light emission, and charge transport can be independently optimized in separate layers to deliver

higher device performance than the original bilayer design in Fig. 6.3a.

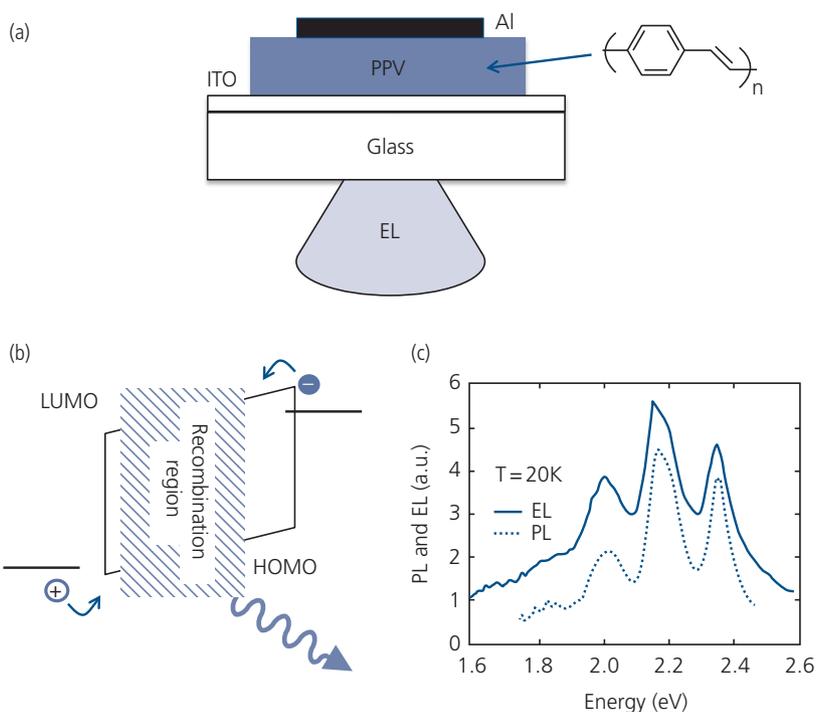

The device in Fig. 6.3 is known as an *electrofluorescent OLED*. We show in Section 6.3 that significantly higher efficiencies can be obtained via phosphorescent emission in *electrophosphorescent OLEDs* (Baldo et al., 1998).

Polymer OLEDs also support bipolar injection. When originally introduced, they consisted of only a single multifunctional layer, as shown in Fig. 6.5 (Burroughes et al., 1990). The device consists of a light emitting polymer, PPV, sandwiched between low and

high work function contacts (Al and ITO, respectively). Electrons and holes are both transported by the polymer, and the rectifying characteristics of the device are due to the Schottky barriers at one or both of the contacts, as inferred from the energy level diagram in Fig. 6.5b. In the zone where the overlap between their concentrations is highest, the polarons relax onto a polymer unit to form an exciton that eventually fluoresces via radiative recombination. Electroluminescent and PL spectra for a PPV device are shown in Fig. 6.5c. Similar to small molecule bilayer OLEDs, the two

**Figure 6.4** Electroluminescence generation process in an OLED (Brütting and Frischeisen, 2012).

**Figure 6.5** (a) Single layer polymer OLED with the molecular formula of the PPV active region shown. (b) Energy level diagram of the polymer OLED. (c) Low temperature photoluminescence and electroluminescence spectra of a PPV film and OLED, respectively. The spectra are obtained at low temperature to increase efficiency from its value at room temperature; (c) is from Swanson et al. (1993).

spectra are nearly identical, indicating that EL is due to exciton recombination following molecular excitation from the injected electron and hole polarons.

Unlike small molecule OLEDs, the polymer device does not have an emission region that confines electrons and holes, resulting in a spatially diffuse emission zone. Thus, the efficiency is low unless doped, multiple layer structures are used to separately optimize charge conduction and light emission. Hence, the seemingly simple single layer design in Fig. 6.5 is deceiving: to achieve very high performance, increased complexity in molecular design is required.

## 6.2 Design and characterization of electroluminescent devices

In this section we describe the elements of OLED design and operating characteristics. We will describe common approaches to designing OLED structures that go well beyond the original bilayer and single layer structures discussed in the previous section. Then we discuss methods for quantifying and measuring device properties such as quantum efficiency and power efficiency. Accurate measurement and understanding of performance parameters are key to providing valid comparisons between results obtained in different laboratories, and are detailed in Section 6.2.4.

### 6.2.1 Efficiency

We use two efficiencies to describe the OLED emission characteristics: the *external electroluminescent quantum efficiency*,  $\eta_{ext}$  (also written *EQE*) and the *power efficiency*,  $\eta_P$  (or *PE*). The external quantum efficiency is the ratio of the number of photons emitted from the OLED to the number of electrons injected. It is the product of the efficiencies of several processes that contribute to light emission, as follows:

$$\eta_{ext} = \eta_{int}\eta_{out} = \gamma\chi_{ST}\eta_{PL}\eta_{out}. \quad (6.1)$$

Here,  $\eta_{int}$  is the *internal electroluminescence quantum efficiency*, which is the ratio of the number of photons generated to the number of injected electrons. It is expressed as a number  $\leq 1$  or as a percentage. This efficiency includes photons emitted by the active region of the device but that may not emerge from the OLED structure into the viewing direction due to internal absorption and reflection from optical interfaces within the multilayer stack. Then,  $\eta_{out}$  is the *outcoupling efficiency*, equal to the ratio of photons that are coupled into air modes and hence can be viewed, to the total number of photons emitted. Outcoupling efficiencies of  $\eta_{out} \sim 20\%$  are typical of OLEDs emitting through a glass substrate. Methods for increasing  $\eta_{out}$  beyond 20% are the topic of Section 6.6.

Other contributions to  $\eta_{ext}$  include the electroluminescent specific losses,  $\gamma$ , due to such factors as imperfect balance of electrons and holes in the emission zone, recombination via charge traps, etc. Also,  $\eta_{PL}$  is the photoluminescence efficiency or quantum yield of the molecule or molecular mixture in the emission zone. For electrofluorescent devices,  $\eta_{PL}$  is the fluorescent efficiency, and for electrophosphorescent devices, it is the phosphorescent efficiency of the luminescent molecule, or lumophore.

Finally,  $\chi_{ST}$  is the *spin formation ratio*, that is, it is the ratio of luminescent states generated for each electron-hole pair injected into the EML. Given completely random formation of singlets and triplets due to pairing of uncorrelated spins of injected electrons and holes, spin formation statistics imply that only one in four of such pairings result in the formation of a singlet exciton that emits by the process of fluorescence. In this case, fluorescent devices have  $\chi_{ST} = 1/4$ . On the other hand, triplets are generated with a 75% probability since the three lowest energy triplet ( $T_1$ ) states can be formed compared to one  $S_1$  singlet. In electrophosphorescent devices, spin-orbit coupling that leads to a radiative triplet state also leads to efficient intersystem crossing from  $S_1$  to  $T_1$  (see Section 3.7). Hence, in electrophosphorescent devices,  $\chi_{ST} = 1$ . For similar reasons, devices based on *thermally activated delayed fluorescence* can also reach  $\chi_{ST} = 1$ . The determination of spin statistics in both polymer and small molecule systems will be discussed in Section 6.3.1.

The power efficiency is the ratio of the output optical power to the electrical input power, and has units of [W/W] or [%]. This is calculated using

$$\eta_P = \eta_{ext} \frac{P_{EL}}{jV} = \eta_{ext} \frac{hc}{qV\langle\lambda_{em}\rangle}, \quad (6.2)$$

where  $j$  is the OLED injection current density at voltage,  $V$ ,  $P_{EL}$  is the total emitted electroluminescent power density,  $h$  is Planck's constant,  $c$  is the speed of light in vacuum,  $q$  is the electronic charge, and  $\langle\lambda_{em}\rangle$  is the mean emission wavelength given by

$$\langle\lambda_{em}\rangle = \frac{\int_0^{\infty} \lambda \phi_{em}(\lambda) d\lambda_{em}}{\int_0^{\infty} \phi_{em}(\lambda) d\lambda_{em}}, \quad (6.3)$$

where  $\phi_{em}(\lambda)$  is the flux emitted between  $\lambda$  and  $\lambda + d\lambda$ .

### 6.2.2 OLED architectures

From Eq. 6.1, we see that the highest efficiencies are obtained for unity charge balance in the emission zone ( $\gamma = 1$ ), and by employing phosphorescent

molecules ( $\chi_{ST} = 1$ ) with quantum yields  $\phi_p = 1$ . Further, OLED efficiencies are greatly improved using schemes that result in efficient outcoupling of light from the device active regions and emitting surfaces. Finally, the highest power efficiency requires devices that operate at very low voltage, that is, they have a minimal series resistance,  $R_S$ .

OLED structures that optimize all of these separate efficiency factors can be quite complex. We show for example in Fig. 6.6 many of the layers employed in the highest efficiency top and bottom emitting OLEDs. A particular OLED may not require all of the layers shown; these structures simply define the possible layers that *can* be included. Whereas bottom emitting devices are used in lighting and laboratory demonstrations, top emitters are commonly used in displays where the substrate might be covered with opaque circuit elements used to address the individual pixels. The primary difference between bottom and top emitting OLEDs is that the transparent and opaque contacts are reversed. While this is apparently a simple modification, transparent materials with low work functions necessary for efficient electron injection are not available. There are three remedies for this situation. The first is to invert the stacking order in the top emitting device such that hole transport and injection layers are on the top of the stack adjacent to the anode. A second is to use the stacking order in Fig. 6.6, but employ conditions during the deposition of the transparent contact deposition that introduce damage, and hence deep levels that reduce the barrier

to electron injection (see Section 4.6) (Parthasarathy et al., 1998).

A third option is to maintain the stacking order in Fig. 6.6b, but use a thin, semitransparent, low work function metal cathode. The thickness must be considerably less than the penetration depth of the optical electric field,  $F$ , into the metal. The penetration depth, or *optical skin depth*,  $\delta$ , is obtained from a solution to Maxwell's equations for an oscillating electric field at frequency,  $\omega$ :

$$\nabla^2 F = i\omega\mu_r\mu_0\sigma F. \quad (6.4)$$

Here,  $\mu_r$  and  $\mu_0$  are the relative and the vacuum permeabilities, respectively, and  $\sigma$  is the conductivity of the metal. If a plane wave is incident in the  $\hat{x}$ -direction with initial field amplitude,  $F_0$ , this has solutions:

$$F_z = F_{0z}e^{-\tau x}, \quad (6.5)$$

where

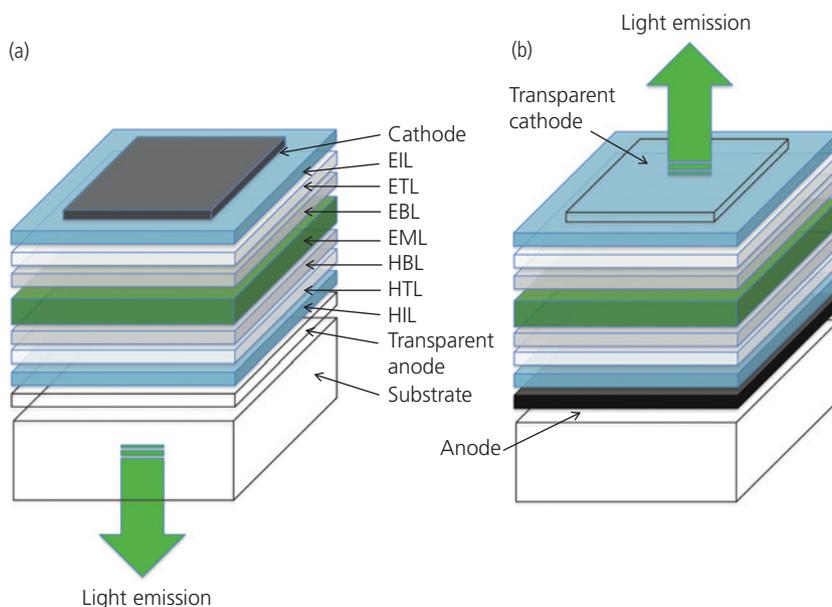

$$\tau = (1+i)\sqrt{\omega\mu_r\mu_0\sigma/2} = (1+i)/\delta. \quad (6.6)$$

Thus, Eq. 6.5 becomes

$$F_z = F_{0z}e^{-x/\delta}e^{-ix/\delta}. \quad (6.7)$$

Hence the skin depth is the attenuation length of the field given by

$$\delta = \sqrt{\frac{2}{\omega\mu_r\mu_0\sigma}}. \quad (6.8)$$

**Figure 6.6** Layer structures for (a) bottom emitting and (b) top emitting OLEDs.

In Table 6.1 we show the skin depth in the green spectral region at a wavelength of  $\lambda = 550 \text{ nm}$  ( $\omega = 3.42 \times 10^{15} \text{ s}^{-1}$ ) for several different metals at room temperature. The skin depth is only a few nanometers, hence in using thin metals there is a trade-off between contact resistance and transparency. Nevertheless, many top emitting OLEDs employ this approach due to its simplicity.

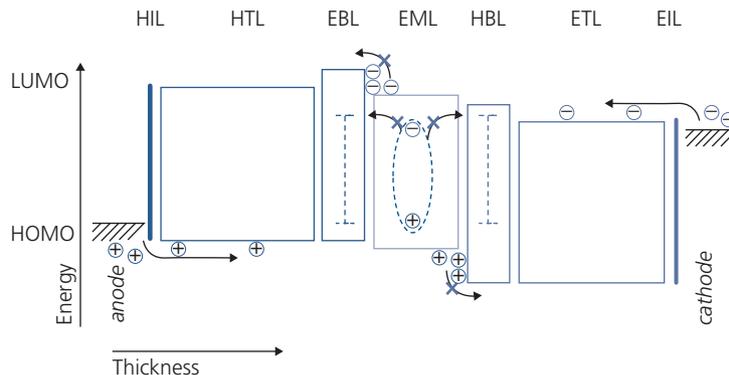

Finally, both the cathode and anode can be made transparent, thus rendering the entire OLED transparent (Bulovic et al., 1996). As we have seen in Figs. 6.1 and 6.2, transparency provides unique opportunities for OLEDs that are finding applications in both lighting and displays.

We can understand the functionality of each of the layers using the corresponding energy level diagram shown in Fig. 6.7, which is more complex than the basic structure in Fig. 6.4. This diagram reflects the energy levels under forward bias of a high performance OLED, where the tilt in the bands that results from applying a negative potential at the cathode for electron injection is not shown. We also neglect the presence of dipole layers at interfaces between different organic layers (see Chapter 4). We now identify and describe the individual purposes of each of the layers.

**Table 6.1** Conductivities and skin depths (at  $\lambda = 550 \text{ nm}$ ) of selected low work function metals

Metal	$\sigma$ ( $10^6 \text{ S/m}$ )	$\delta$ (nm)
Ag	63.0	2.7
Au	45.2	3.2
Al	37.7	3.5
Ca	29.8	3.9
Mg	22.6	4.5

- HIL and EIL: The *hole* and *electron injection layers* at the anode and cathode interfaces, respectively, reduce the charge injection barriers from the adjacent contacts, increasing the charge injection efficiency. Often these layers have their frontier orbitals (i.e. the HOMO of the HIL and the LUMO of the EIL) intermediate between the contact and that of the next layer in the stack (e.g. the HTL or ETL) to “broaden” the energy step between the contact and the subsequent layer. This reduces the internal field opposing charge injection. The injection layer can be doped to increase conductivity, and hence reduce layer internal resistance while also lowering the energy barrier. These layers are typically very thin ( $<10 \text{ nm}$ ) since their only purpose is to improve injection from the contacts.
- HTL and ETL: As above, these are the hole and electron transport layers. They preferentially transport charges due to their high mobilities for the particular carrier, and their energy level alignment with the corresponding contact. Often, the HTL and ETL are doped to increase their conductivities. Increased conductivity thus decreases device operating voltage, and hence increases its power efficiency, see Eq. 6.2. They are thicker than the HIL and EIL (typically  $10\text{--}50 \text{ nm}$ ) to provide “bulk” to the device that can eliminate shorts across the OLED layer stack.
- HBL and EBL: The *hole* and *electron blocking layers* are used to confine holes and electrons in the EML. From Eq. 6.1, the external efficiency is proportional to the *charge balance factor*. This accounts for electroluminescent specific losses;  $\gamma$  is the ratio of electrons to holes within the emission zone. If the LUMO of the HBL is too low to block electrons, then the emission zone will be electron deficient and  $\gamma$

**Figure 6.7** Forward biased energy level diagram of a multilayer OLED ignoring the presence of interface dipole layers. Tilting of the levels under an electric field, and dipole layers at heterointerfaces have been omitted. Charge and recombination processes are schematically illustrated. Exciton levels are shown by dashed lines (Reineke et al., 2013).

will decrease. Similarly, if the HOMO of the HTL lies above that of the HOMO of the EML, then holes injected from the anode will traverse the EML without recombination, and thus the electron population will exceed that of holes, once again resulting in a decrease in  $\gamma$ . The purpose of the HBL and EBL is to decrease the probability of escape of these carriers from the emission zone by having a shallow LUMO or deep HOMO respectively, relative to that of the EML. The HBL should be transparent to electron transport to avoid increasing series resistance, and hence its LUMO should align with that of ETL. Similarly, the HOMO of the EBL should align with that of the HTL to avoid energy barriers to hole injection. These layers should also be as thin as possible (5 – 10 nm) to minimize OLED series resistance.

Another essential function of the HBL and EBL is exciton blocking. Indeed, the HBL was first introduced as an exciton blocker in phosphorescent OLEDs (or PHOLEDs) (O'Brien et al., 1999). The long triplet lifetime can often lead to exciton diffusion lengths in excess of that for singlets (Section 3.9). Hence, to prevent triplet migration out of the EML where they are quenched at the cathode metal, an exciton blocking layer whose triplet energy is larger than that of triplets in the EML is employed. The large triplet energy of the blockers (indicated by the vertical dashed lines in the EBL and HBL in Fig. 6.7) discourages energy transfer, thereby confining excitons within the EML where the radiative recombination probability is highest.

- **EML:** This is the *emission layer*. It comprises a host material that can transport charges of one or both polarities, doped with the lumophore (i.e. a phosphor or fluorophore). A host that transports both electrons and holes is *ambipolar*. If the host transports only one charge effectively due to asymmetric charge mobilities, then the dopant is needed to transport the counter charge. In this instance, the dopant must be at sufficiently high concentrations to provide an adequate conductivity. Asymmetries in charge conductivity result in pile-up of one of the two carriers near an injecting interface. This, in turn, results in a high density of excitons near that interface where exciton–exciton or exciton–polaron annihilation becomes significant as the current density is increased (see Section 6.3.5). To achieve high OLED brightness, the electron and hole distributions within the EML should be as uniform as possible by balancing the mobilities. Furthermore, the EML

should be sufficiently thick to avoid high exciton densities that encourage annihilation, yet should be thin enough to allow for low voltage operation. The design of the EML, therefore, requires trade-offs in several materials and electronic properties.

### 6.2.3 Quantifying OLED performance

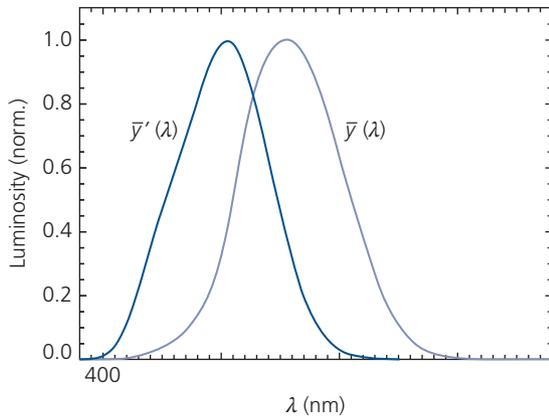

We now turn to the topic of understanding and quantifying OLED performance. This requires a knowledge of how we perceive color. Then we quantify the basic quantities of luminescence and efficiency for both displays and lighting; measurements that must be done with precision if we are to compare the performance of materials and devices emitting in different spectral ranges, and produced in different laboratories. The methods discussed in this section follow accepted procedures, with some of the essential details found elsewhere (Forrest et al., 2003).

#### 6.2.3.1 Radiometry and photometry: color perception and efficiency in OLED displays

The color perception and efficiency of displays are intimately linked to the response of the human eye, but also to more readily quantifiable characteristics such as the quantum and power efficiencies. This has led to the development of two systems for quantifying the performance of light emitters. *Radiometric properties* are electromagnetic performance metrics of the OLED that are measured using calibrated photodetectors, spectrometers, and so forth. *Photometric properties* are perceptual quantities, such as the perceived color or brightness of the source. Ultimately both the photometric and radiometric properties are required to fully understand OLED performance.

Radiometric properties are defined based on total power input into the device (i.e.  $jV$ ) vs. power emitted (see Eq. 6.2). Photometric properties, on the other hand, are based on the responsivity to light power of the human eye. This is known as the *luminosity function*,  $\bar{y}(\lambda)$  shown in Fig. 6.8. In fact, two functions are shown,  $\bar{y}(\lambda)$ , which is the response of the eye in normal daylight conditions, known as the *photopic response*, and  $\bar{y}'(\lambda)$  for nighttime vision, called the *scotopic response*.

These luminosity functions are based on the 1931 *Commission Internationale d'Eclairage* (CIE) standards. As we will see below, the CIE has provided a quantitative correlation between the perception of color due to the response of the three color-sensitive cone cells in the retina, and the spectrum of a particular color source.

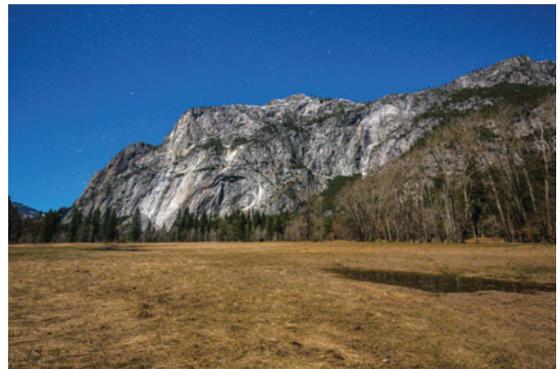

**Figure 6.8** 1931 CIE luminosity functions for photopic ( $\bar{y}(\lambda)$ ) and scotopic ( $\bar{y}'(\lambda)$ ) vision.

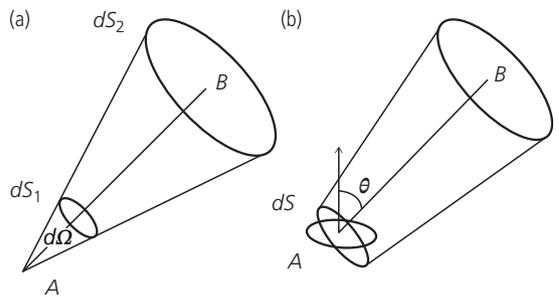

Photopic vision engages three color-sensitive cones with peak sensitivities at wavelengths of  $\lambda = 420$  nm (blue), 534 nm (blue-green), and 564 nm (yellow-green). By combining the response of all three cones at light of intensities  $>10^{-3}$  cd/m<sup>2</sup>, full color sensitivity is achieved. The photometric unit used to quantify the perceived *luminous intensity* emitted per solid angle is the candela (cd). The luminosity function in Fig. 6.8 has a maximum of 683 lm/W at  $\lambda = 555$  nm, where the perceived *luminous flux* has units of lumens (lm).

In very dim light ( $<10^{-3}$  cd/m<sup>2</sup>), the response of the eye is dominated by excitation of the rod cells that transfer the luminosity signal to the cones. In this process, color information is lost, and the peak sensitivity is blue shifted to  $\lambda = 505$  nm. Thus, in dim light the image lacks color and is represented by an average luminosity across the visible spectrum. A dramatic demonstration of photopic and scotopic vision is simulated in Fig. 6.9, which is the same image of a winter scene taken in moonlight; the top image shows the grayscale appearance of this scene perceived by an observer with dark-adapted, scotopic vision. Only the relative luminosities of the image elements provide contrast. The actual colors of the scene as recorded by the camera (which does not have the brightness-dependent limitations of the human eye) are shown in the lower image. As expected, the sky is blue due to Rayleigh scattering of the moonlight, the meadow grass is yellow, and the trees are green. This is a low contrast version of the scene perceived during daylight due to our photopic capabilities. For displays and lighting, the intensity ranges from a few tens of cd/m<sup>2</sup> to several thousand cd/m<sup>2</sup>, and hence only the photopic response needs to be considered.

We can appreciate the relationship between the photometric properties of luminous flux and the

**Figure 6.9** Photographs of an identical scene that (top) simulates scotopic (luminosity) and (bottom) photopic (color) perception of the human eye. The images were taken on a moonlit night in winter in Yosemite National Park, California.

**Figure 6.10** Geometries used in calculating (a) luminous flux and (b) luminance.

luminous intensity using the diagram in Fig. 6.10. Consider a point source located at point A in Fig. 6.10a. Then the luminous flux ( $\Phi$ ) through incremental area  $dS_1$  that subtends a solid angle,  $d\Omega$ , is the same as the flux through area  $dS_2$ , since it occupies the same solid angle as  $dS_1$ . Thus, the luminous intensity is

$$L_\Omega = \frac{d\Phi}{d\Omega} \tag{6.9}$$

An actual light source is not a point source, but rather can be considered to be comprised of numerous point

sources occupying an incremental area at position A in Fig. 6.10b. The luminance is thus the luminous intensity per unit solid angle per area. It depends on the angle ( $\theta$ ) of the source area,  $dS$ , relative to the observer at point B. From the diagram we find that the luminance that gives the perceived brightness of the source is

$$L = \frac{dL_\Omega}{dS \cos\theta} = \frac{d\Phi}{dS d\Omega \cos\theta}. \quad (6.10)$$

As noted above, the units of luminance are [ $\text{cd}/\text{m}^2$ ] or [nits]; hence [ $\text{candela}$ ] = [ $\text{lumen}/\text{steradian}$ ].

The amount of flux that is incident on a secondary surface is called the *illuminance*. Correspondingly, the flux that exits that surface is the *luminous exitance*. This is a quantity that characterizes the brightness of an object, and is useful for quantifying the results of illumination of a volume by a white light source. Illuminance has the units of lux, where  $1 \text{ lux} = 1 \text{ lm}/\text{m}^2$ . The relationship between luminous flux and illuminance is understood from Fig. 6.11. If the area illuminated is  $dS$ , then the amount of light exiting from surface B due to a source of area  $\Delta S$  at point A is the illuminance (or luminous flux density). From inspection of Fig. 6.11, this is given by

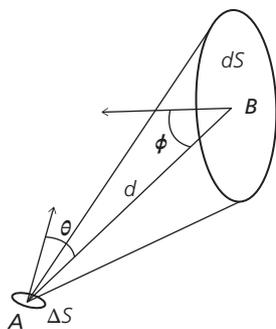

$$E = \frac{d\Phi}{dS} = \frac{L \Delta S \cos\theta \cos\phi}{d^2} \quad (6.11)$$

where  $d$  is the distance between the source and the illuminated surface.

Finally, a source that has a constant luminance in all directions has an angular luminance intensity that follows a cosine dependence, that is,

$$L_\Omega(\theta) = L \cos\theta \cdot dS d\Omega. \quad (6.12)$$

This dependence defines a *Lambertian source*, which, for example, can be achieved using a perfectly light diffusing surface. Often an OLED is assumed to be a Lambertian source, although this is generally incorrect since such devices are microcavity emitters, as discussed in Section 6.6.

**Figure 6.11** Relationship between luminance and illuminance.

The radiometric equivalents (along with their symbols and [units]) of the quantities of luminous flux, luminance, luminous intensity, and illuminance or exitance (if incident or emitted, respectively) are *radiant flux* ( $\Phi_e$ , [W]), *radiance* ( $L_e$ , [ $\text{W}/\text{m}^2\text{sr}$ ]), *radiant intensity* ( $I_e$ , [ $\text{W}/\text{sr}$ ]), *irradiance* or *radiant exitance* ( $E_e$ ,  $M_e$ , [ $\text{W}/\text{m}^2$ ]) if incident or emitted, respectively.

The photometric efficiencies of the OLED are defined as the *luminous efficiency* and the *luminous power efficiency* (also known as the *efficacy*). These are analogous to the radiometric units of external quantum efficiency and power efficiency in Eqs. 6.1 and 6.2, respectively. The luminous efficiency ( $\eta_L$ ) is equal to the luminance output divided by the current density,  $j$ :

$$\eta_L = \frac{L}{j}, \quad (6.13)$$

and has units of [ $\text{cd}/\text{A}$ ]. Likewise, the luminous power efficiency is the luminous power emitted to the total electrical power input into the device:

$$\eta_{LP} = \frac{\Phi}{jV\Delta S} = \frac{E}{jV}. \quad (6.14)$$

A summary of the relationships between photometric and radiometric quantities and their units is provided in Table 6.2.

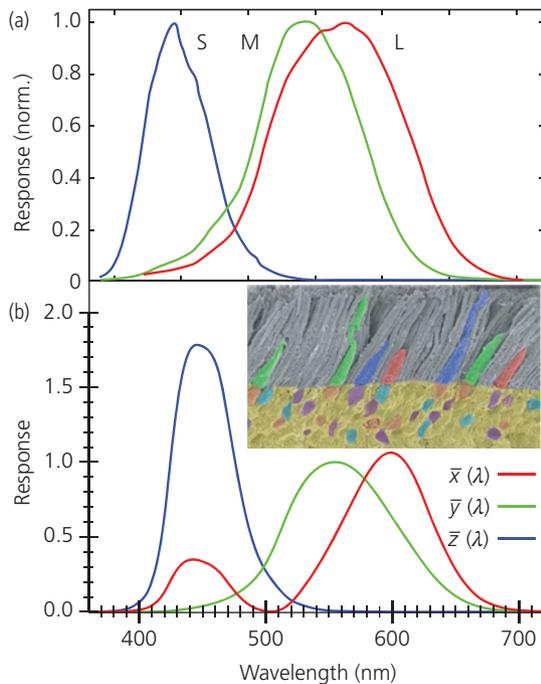

Photometric units are strongly dependent on the spectral content of the emitted light, and hence small differences in the spectrum of a source can result in significant differences in the luminous and luminous power efficiencies. Hence, for direct comparisons of device performance that are not dependent on the sensitivity of the eye to a particular spectrum, photometric quantities are more reliable and revealing of the device characteristics. Hence, photometric units find their greatest use in quantifying the *appearance* of a light source, rather than in its fundamental emission properties.

### 6.2.3.2 Chromaticity

The biological origin of the photopic response arises from excitation of three color-sensitive cone cells in the retina. Their individual spectral responses are shown in Fig. 6.12a. The responses extend from the deep red at a wavelength of  $\sim 550\text{--}650 \text{ nm}$  for the long wavelength (L) sensitive cells (see inset, Fig. 6.12b), to a peak at  $\sim 530\text{--}540 \text{ nm}$  for the middle wavelength (M), and  $420\text{--}440 \text{ nm}$  for the short wavelength (S) cones. These responses have been mapped into the *color matching functions*,  $\bar{x}(\lambda)$ ,  $\bar{y}(\lambda)$ , and  $\bar{z}(\lambda)$ , based on the 1931 CIE standards in Fig. 6.12b. The color matching functions are useful in quantifying the spectrum of an illumination source to determine the perceived

**Table 6.2** Radiometric and photometric units for quantifying properties of illumination sources

Radiometric units				Photometric units			
Quantity	Symbol	Expression	Unit	Quantity	Symbol	Expression	Unit
Radiant flux	$\Phi_e$		W	Luminance flux	$\Phi$		lm
External quantum efficiency	$\eta_{ext}$	$\eta_{int}\eta_{out}$	%	Luminous efficiency	$\eta_L$	$\frac{L}{j}$	cd/A
Power efficiency	$\eta_P$	$\frac{1}{jV} \frac{d\Phi_e}{dS} = \frac{E_e}{jV}$	%, or W/W	Luminous power efficiency	$\eta_{LP}$	$\frac{1}{jV} \frac{d\Phi}{dS} = \frac{E}{jV}$	lm/W
Radiant intensity	$I_e$	$\frac{d\Phi_e}{d\Omega}$	W/sr	Luminance intensity	$L_\Omega$	$\frac{d\Phi}{d\Omega}$	lm/sr
Radiance	$L_e$	$\frac{d\Phi_e}{dS d\Omega \cos\theta}$	W/sr-m <sup>2</sup>	Luminance	$L$	$\frac{d\Phi}{dS d\Omega \cos\theta}$	cd/m <sup>2</sup> = lm/sr-m <sup>2</sup>
Irradiance	$E_e$	$\frac{d\Phi_e}{dS}$	W/m <sup>2</sup>	Illuminance	$E$	$\frac{d\Phi}{dS}$	lm/m <sup>2</sup> = lux
Radiant exitance	$M_e$	$\frac{d\Phi_e}{dS}$	W/m <sup>2</sup>	Luminous exitance	$M$	$\frac{d\Phi}{dS}$	lm/m <sup>2</sup>

**Figure 6.12** (a) Human eye response of the short (S), middle (M), and long (L) wavelength cone cells. (b) 1931 CIE color matching functions,  $\bar{x}(\lambda)$ ,  $\bar{y}(\lambda)$ , and  $\bar{z}(\lambda)$ . Inset: Micrograph of color sensing cone cells (colors indicate their respective wavelength sensitivities) and rod cells (gray) that are sensitive only to luminosity.

color response. The photopic luminosity response curve in Fig. 6.8 is the same as the color matching function,  $\bar{y}(\lambda)$  in Fig. 6.12b. The sensation, or perception of color is not directly related to the actual source color, which is often a combination of hues. Based on the responses of a population of test subjects who were asked to distinguish between a standard series

of sample colors, a *Standard Colorimetric Observer* was used to define the *tristimulus values*,  $X$ ,  $Y$ , and  $Z$ , for a source with radiance,  $L_e(\lambda)$ , as follows:

$$X = \int_{380}^{780} L_e(\lambda) \bar{x}(\lambda) d\lambda, \quad (6.15a)$$

$$Y = \int_{380}^{780} L_e(\lambda) \bar{y}(\lambda) d\lambda, \quad (6.15b)$$

and

$$Z = \int_{380}^{780} L_e(\lambda) \bar{z}(\lambda) d\lambda. \quad (6.15c)$$

The Standard Colorimetric Observer is also known as a 2° Standard Observer since during the tests it was assumed that the color sensitive cone cells were located within a 2° arc defining the fovea, the most sensitive region of the retina. The  $X$ ,  $Y$ , and  $Z$  values are used to define the 1931 CIE XYZ color space that is shown in Fig. 6.13. This color space assigns a coordinate pair,  $(x, y)$ , to every color in the visible spectrum, which are related to  $X$ ,  $Y$ , and  $Z$  by

$$x = \frac{X}{X + Y + Z}, \quad (6.16a)$$

$$y = \frac{Y}{X + Y + Z}, \quad (6.16b)$$

and

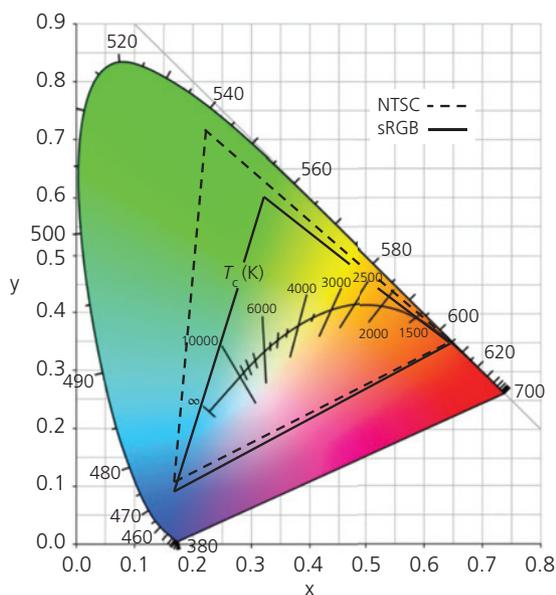

$$z = \frac{Z}{X + Y + Z} = 1 - x - y. \quad (6.16c)$$

Since  $z$  depends on  $x$  and  $y$ , only the latter two coordinates are required to fully define a perceived color. While several other color matching functions and color spaces have been defined, the 1931 CIE XYZ color space is convenient and straightforward for defining the properties of OLEDs and other standard illumination sources, since  $Y$  defines the total luminance of the source. The coordinates  $(x, y, Y)$  provide both the color and the luminosity, fully defining the properties of the source. This triad of coordinates is called the 1931 CIE  $xyY$  color space. Transformation between  $xyY$  and XYZ, and other color spaces is straightforward, and hence we will only use the 1931 CIE  $xyY$  standard in the following discussion.

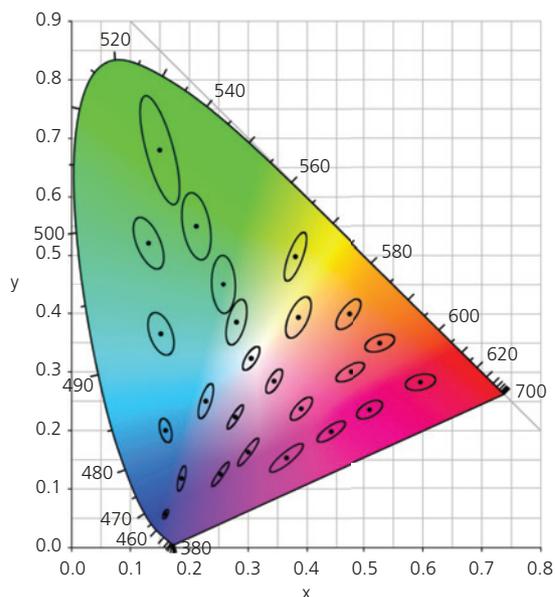

The visible color space shown in Fig. 6.13 represents the total *color gamut* that can be perceived by the Standard Colorimetric Observer. Saturated (pure) colors whose wavelengths (in nanometers) are found along the curved, outer arc of the color space is the *color locus*, and color mixtures are found within the interior of the color space. The inner arc shows the Planckian locus of white points, with each point along the arc corresponding to a *color temperature* listed (in Kelvin) adjacent to the locus. The lines of constant color temperature are shown intersecting the arc. The triangles enclose the space contained within two common color gamuts, one corresponding to super red, green, blue (sRGB) used as a photographic standard, and the other to the National Television

Standards Committee (NTSC) used as a video display standard. If the R, G, and B color sources (e.g. pixels in a display) are located at the vertices of the color gamut triangle, then mixtures of these primary colors can produce any color enclosed within that triangle. The color obtained by adjusting the relative luminosities of the sub-pixel triad then results in a total pixel chromaticity defined by coordinates  $(x, y)$ . Colors outside of the perimeter of the triangle are inaccessible to the light source, and hence cannot be produced. No three color sources (e.g. R, G, and B pixels in a display) can be positioned to cover the entire color space perceived by the eye. Nevertheless, larger color gamuts enclosed by particular sub-pixel triads result in a broader range of accessible display colors.

When designing illumination sources, it is reasonable to ask how sensitive the human eye is in distinguishing between colors with different coordinates in the chromaticity diagram. This question was answered in a painstaking experiment by MacAdam (1942) whereby subjects were asked to match two colors at a fixed luminosity that were viewed through an apparatus that constrained the viewing angle to  $2^\circ$  within the range of foveal vision. The experiment extended over 25,000 color-matching trials across the entire color gamut. This resulted in 25 ellipses drawn to demark the standard deviation in chromaticity that could not be distinguished by an observer. These so-called *MacAdam ellipses*, drawn 10 times their actual

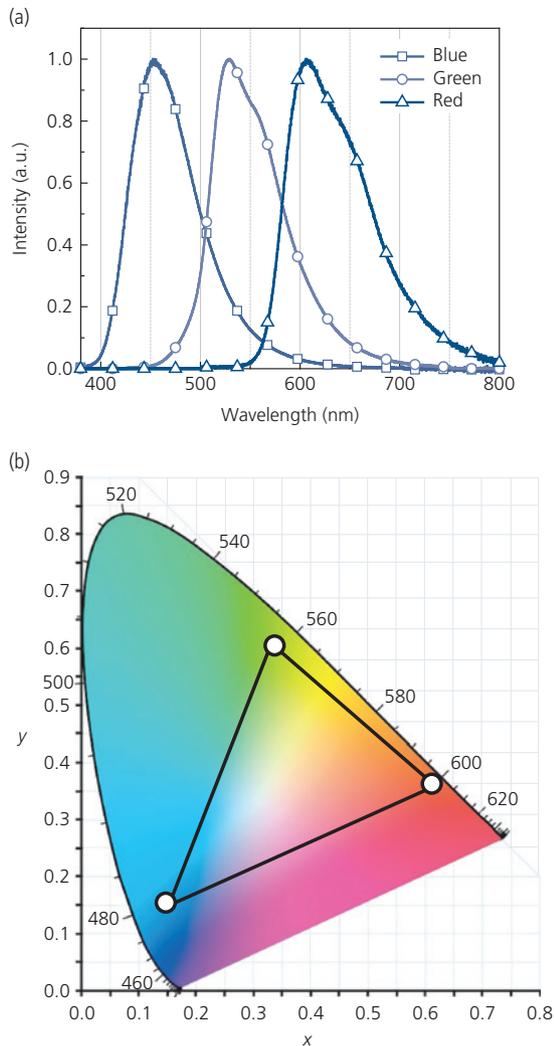

**Figure 6.13** 1931 CIE  $xyY$  color space showing the white locus and the color gamuts for sRGB (solid triangle) and NTSC (dashed triangle) displays.

**Figure 6.14** 1931 CIE chromaticity chart showing the 25 MacAdam ellipses at several color locations. The ellipses are drawn 10 times their actual size.

sizes, are shown in Fig. 6.14. Interestingly, there is no single transformation that can bring these ellipses into equal-sized circles, indicating that the perception of color is a nonlinear function of the spectral content of the source. Furthermore, it is apparent from Fig. 6.14 that color acuity is highest for blue, less so for red, and not nearly so high in the green. This provides an explanation why apparently saturated display colors can be obtained using a gamut that extends nearly to the color locus in red and blue, yet does not extend far toward the limb at  $\lambda = 520$  nm (at coordinates of (0.07, 0.83)).

An example color gamut that results from emission from three PHOLEDs emitting in the red, green and blue spectral regions is shown in Fig. 6.15. The

**Figure 6.15** (a) Emission spectra from three phosphorescent OLEDs. (b) The color gamut (triangle) due to emission from the three OLEDs in (a). Open circles indicate the color coordinates for each for the three OLEDs.

phosphors used are the blue emitting  $\text{Ir}(\text{pmp})_3$ , the green emitting  $\text{Ir}(\text{ppy})_2(\text{acac})$ , and the red emitting PQIr. The intensity spectra in Fig. 6.15a must be converted to luminance to determine the color coordinates of each device, denoted by the open circles in Fig. 6.15b. The resulting color gamut is enclosed by the triangle. The gamut is smaller than required by sRGB standards (Fig. 6.13), largely due to the slightly red-shifted and spectrally broad green PHOLED sub-pixel.

### 6.2.3.3 White light

Thus far we have concentrated on quantifying color perception primarily for displays. Another application of OLEDs is in the generation of white light for illumination. The method for characterizing the appearance of white illumination sources is considerably different than that required for information displays, yet ultimately it, too, relies on the nature of human vision and its range of color perception bounded by the chromaticity diagram in Fig. 6.13. The primary difference between a white light source and one that emits a particular hue is the way that objects appear when illuminated by the source. Do the colors look natural as they would under sunlight, or does the source give an unnatural coloration to the objects, yet when directly viewed it nevertheless looks satisfactorily white?

There are two quantities that are used to characterize illumination source color quality: the *color rendering index* (CRI) and the *correlated color temperature* (CCT). The CRI quantifies how close a color source matches a black body radiator at a particular temperature. The rationale for this quantity is that we assume that solar radiation follows that of a Planckian black body at temperature  $T$ . Then the spectral radiance,  $B(\lambda, T)$ , follows Planck's law:

$$B(\lambda, T) = \frac{2hc^2}{\lambda^5} \frac{1}{\exp(hc/\lambda k_B T) - 1}. \quad (6.17)$$

With the exception of spectral loss due to absorption by water and other gases in the atmosphere, the sun is indeed an ideal black body radiator with a surface temperature of 5780 K. However, its apparent color temperature varies throughout the day, shifting to the red in the morning and evening (with an apparently lower temperature of  $\sim 5000$  K), and becoming bluish-white at mid-day (with a much higher temperature of  $\sim 6000$  K). Perceptually, we consider bluish casts to be "cool white" with color temperatures  $>5000$  K, and redder hues are "warm white" with temperatures between 2700 K and 3000 K (see

Fig. 6.16). Of course, this convention is opposite to the temperature trends predicted by Eq. 6.17.

The CRI is the degree to which the spectrum of the test illumination source differs from that of a black body of a specified temperature. Hence, to quantify a white light source, we need to know its temperature. The Planckian locus indicating the color coordinates of black bodies radiating at a particular temperature is shown by the arc in Fig. 6.13 with lines of constant color temperature as noted. A white light source, other than an incandescent bulb, does not have a perfect black body spectrum. Hence, for white light sources such as OLEDs we define the CCT as the black body temperature that most closely resembles the test source. The 1960 CIE color space shown in Fig. 6.17 is commonly used to determine the CCT of a particular illumination source (i.e. an *illuminant*). The

**Figure 6.16** Examples of white LED sources of different color temperatures. From Novalite.com ([http://www.nova-lite.com/index.php?route=module/kbm/article&kbm\\_article\\_id=7](http://www.nova-lite.com/index.php?route=module/kbm/article&kbm_article_id=7))

color temperatures are shown as well as the isotherms perpendicular to the Planckian locus, whose lengths define the chromaticity range over which meaningful comparison with a black body can be made.

This white color space is often defined in terms of the coordinates  $(u, v)$ . Via a simple transformation,  $(u, v)$  can be converted to the 1931 CIE coordinates  $(x, y)$  using

$$u = \frac{4x}{-2x + 12y + 3} \quad (6.18a)$$

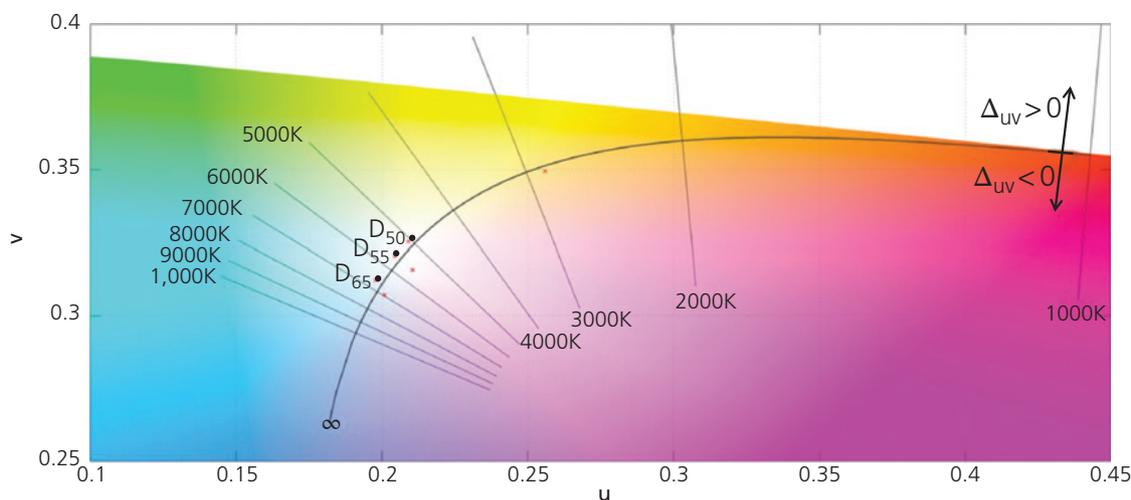

and

$$v = \frac{6y}{-2x + 12y + 3}. \quad (6.18b)$$

Deviations from a black body lie above or below the locus at distance  $\Delta_{uv}$ , shown in Fig. 6.17. Comparison of the illuminant spectrum and a black body is considered meaningful when  $\Delta_{uv} \leq 5.4 \times 10^{-3}$ . In this case, the CRI obtained for the source will also be accurately defined since its spectrum will approximate that of a black body.

Now the *equal energy point* ( $E$ ) corresponds to a spectrum that has equal energy at all visible wavelengths. This point is at  $(x, y) = (0.33, 0.33)$ , or according to Eq. 6.18,  $(u, v) = (0.209, 0.315)$ .

Once the CCT of the illuminant is determined, the CRI is found by comparing the color coordinates of the reflected light from eight standard *test color samples* (TCS) under the test source, compared to a reference black body at the same color temperature. The TCS in Fig. 6.18 range from light grayish red (TCS01)

**Figure 6.17** A segment of the 1960 CIE color space used to characterize white light sources. The Planckian locus is shown by the arc, with color temperatures indicated along with CCT isotherms oriented perpendicular to the arc. Differences of a source to the Planckian locus are positive ( $\Delta_{uv} > 0$ ) above the arc, and  $\Delta_{uv} < 0$  below the arc. Also standard daylight illuminants from CCT = 6500 K to 5000 K (corresponding to  $D_{65}$  and  $D_{50}$ , respectively) are shown.

**Figure 6.18** Test color samples (or patches) used for determining the color rendering index.

to light reddish purple (TCS08). The specific CRI, or  $R_i$ , is found from the reflectance deviations by calculating their Euclidean distances,  $\Delta E_i$ , between the test  $(u_t, v_t)$ , and the reference white point  $(u_r, v_r)$  coordinates. A commonly used reference is the  $D_{65}$  illuminant in Fig. 6.17. From the tristimulus values we define the 1964 CIE color space:

$$W^* = 23\sqrt[3]{Y} - 17, \quad (6.19a)$$

$$U^* = 13W^*(u_t - u_r), \quad (6.19b)$$

and

$$V^* = 13W^*(v_t - v_r). \quad (6.19c)$$

This differs from the 1960 CIE color space used for determining  $u, v$  in that it has information about the luminosity of the source ( $Y$ ), which is found in the coordinate,  $W^*$ . Thus, the 1960 CIE space is used to determine CCT, whereas the 1964 CIE standard (also known as CIE UVW) is useful for determining the CRI.

To find  $R_i$ , we determine the differences,  $\Delta U_i^*$ ,  $\Delta V_i^*$ , and  $\Delta W_i^*$  between the CCT of the source and the chromaticity coordinates from the  $i$ th TCS to obtain

$$\Delta E_i = \sqrt{(\Delta U_i^*)^2 + (\Delta V_i^*)^2 + (\Delta W_i^*)^2}. \quad (6.20)$$

Then the specific CRI is

$$R_i = 100 - 4.6\Delta E_i \quad (6.21)$$

and the general color rendering index,  $R_a$  (also known as simply CRI), is the mean of all eight  $R_i$ , viz.

$$CRI = \frac{1}{8} \sum_{i=1}^8 R_i. \quad (6.22)$$

From Eqs. 6.21 and 6.22, we see that CRI has a maximum value of 100, a value only achieved by a perfect black body where  $\Delta E_i = 0$ .

The acceptable CRI and CCT of a lighting source depend on the intended application. For general room illumination, CRI = 90 or higher is deemed acceptable, whereas for lighting industrial or utility areas, CRI = 80–85 are often used. Similarly, the color temperature chosen depends on the application. Room

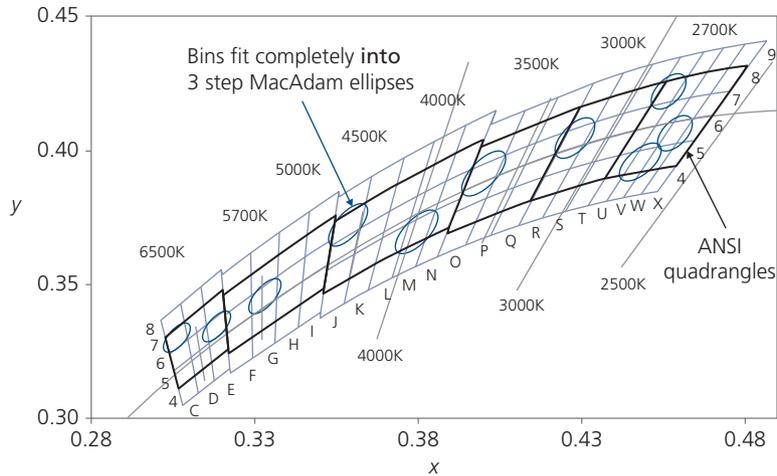

lighting typically employs “soft white” which is warm with a lower color temperature than outdoor lighting, where daylight CCTs of up to 6000 K are often found.

A characteristic of lighting is that there are inevitable differences in the color content of otherwise identical lighting sources that are manufactured at different times or fabrication facilities. To match these different illuminants, we must quantify the perceptual acuity of the observer: that is, we must determine the difference in color coordinates of a lighting source that can be perceived. This question is answered in the same manner that MacAdam quantified perceptual acuity in viewing hues at different locations in the 1931 CIE color space. In Fig. 6.19 we show the MacAdam ellipses drawn along the Planckian locus in the 1931 CIE color space. The ellipses represent three times the standard deviation for perceptual distinction between two lighting sources. The black quadrangles provide so-called “seven-step bins” established by the *American National Standards Institute* (ANSI) in which similar illuminants can be grouped without undue variation between sources in a given bin. However, higher uniformity lighting sources are often placed into bins as small as two and three standard deviations (i.e. two step and three step bins) from the distinguishable limit. Three step bins used to group LED sources are shown in orange.

## 6.2.4 Measuring OLED performance

The accurate measurement of OLED efficiency is essential for comparing device performances achieved in different laboratories. Also, the procedure for measuring efficiency is different for display and lighting sources. For displays, only photons emitted into the half space in front of the display (i.e. in the viewing direction) are counted, whereas for general lighting, photons emitted in all directions add to the illumination intensity.

If the OLED emission is Lambertian, one simply measures the device performance using a commercial luminance meter. The meter collects light emitted from a fixed diameter spot on the display surface, into a specified (small) solid angle about the

**Figure 6.19** MacAdam “ellipses” along the Planckian locus. The ellipses are bounds to areas three times the standard deviation at the perceptual limit to distinguish between white sources, and hence are known as three step ellipses. The black boxes are the ANSI C78.377 standard for variations of an acceptable lighting source at a particular CCT, and the light blue boxes show bins used to group illuminants whose CCT and CRI fit within approximately a three step ellipse.

surface normal. From the intensity, the instrument calculates a value of the surface luminance,  $L$ , in  $\text{cd}/\text{m}^2$ , or nits. The meter uses a calibrated photodiode to detect the light, and the conversion of the diode photoresponse into a luminance value is done by the instrument itself, with the implicit assumption that the emission pattern is Lambertian, and that the meter is oriented perpendicular to the emitting surface. The recorded luminance then allows for a calculation of the luminous efficiency  $\eta_L$  ( $\text{cd}/\text{A}$ ) using the drive current density,  $j_{\text{OLED}} = I_{\text{OLED}}/A$ , where  $A$  is the area and  $I_{\text{OLED}}$  is the OLED current. Given the voltage at which  $\eta_L$  is measured, it is then straightforward to obtain  $\eta_P$  (see Table 6.2). While simple, this method is vulnerable to inaccuracies, and hence should be used only for characterizing the performance of an actual display.

A direct and accurate means for measuring external quantum efficiency employs a calibrated photodetector used in a measurement setup requiring a minimal amount of correction for losses due to lenses, overfilling of the detector active area with light, conversion between lumens to percent, etc. The generally broad spectral emission of OLEDs, however, will introduce errors in measurement if the wavelength dependence of the photodetector is itself ignored. The wavelength dependence of the photodiode *responsivity* between wavelengths  $\lambda$  and  $\lambda + d\lambda$  is  $R(\lambda) = I_{\text{det}}(\lambda)/f(\lambda)P_{\text{OLED}}(\lambda)$ , where  $I_{\text{det}}(\lambda)$  is the incremental photocurrent generated in the photodetector by the incident power,  $P_{\text{OLED}}(\lambda)$ , emitted at center wavelength,  $\lambda$ , and  $f(\lambda) \leq 1$  is the ratio of light emitted to that coupled into the

detector. The external OLED quantum efficiency is, therefore,

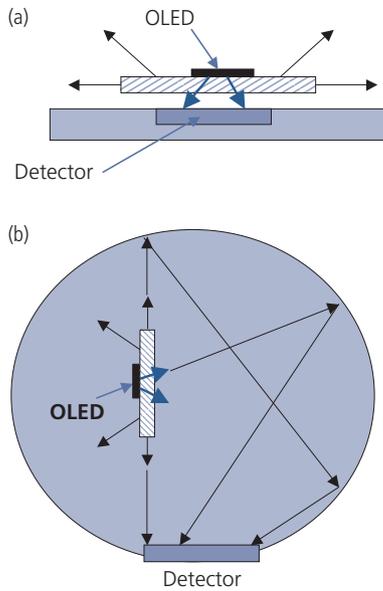

$$\eta_{\text{ext}} = \frac{q \int \lambda I_{\text{det}}(\lambda) d\lambda}{hc f_{\text{OLED}} \int R(\lambda) d\lambda}. \quad (6.23)$$

Since the OLED may exhibit microcavity effects that result in a non-Lambertian angular dependence of the emission intensity on wavelength (Greenham et al., 1994, Bulovic et al., 1998a, Kim et al., 2000), accurate measurement requires the use of large aperture light collection optics. Often, the detector sensitivity is quoted in terms of its own external quantum efficiency,  $\eta_{\text{det}}$ . This is simply related to the detector responsivity via  $\eta_{\text{det}} = hcR(\lambda)/q\lambda$ . Then, Eq. 6.23 can be rewritten as

$$\eta_{\text{ext}} = \frac{\int \lambda I_{\text{det}}(\lambda) d\lambda}{f_{\text{OLED}} \int \lambda \eta_{\text{det}}(\lambda) d\lambda}. \quad (6.24)$$

As defined, the quantum efficiency is simply a ratio that, if multiplied by 100%, can be stated as a percentage. For “engineering” display applications,  $\eta_{\text{ext}}$  is typically quoted independent of the emission wavelength, as in Eqs. 6.23 and 6.24.

From the foregoing, the optimum measurement geometry has a coupling factor,  $f$ , as close to unity as possible. A particularly accurate and convenient configuration for such a measurement is shown in Fig. 6.20a. The primary objective is to detect every

**Figure 6.20** Efficiency measurement configurations for an OLED for (a) displays where the OLED is placed directly on the surface of a detector, and (b) lighting where the OLED is inserted into an integrating sphere (Forrest et al., 2003).

photon emitted into the forward direction using a calibrated detector, such that  $f \sim 1$  is independent of  $\lambda$ . This can be achieved by using a detector whose area is considerably larger than that of the OLED (a condition known as “underfilling” of the detector active area), and then placing the OLED very close to the detector without any intervening optics (Burrows et al., 1996). It is also necessary to mask trapped photons that may emerge from the substrate edges. Coating the edges with black paint or wax, or by ensuring that the detector is considerably smaller than the OLED substrate can accomplish this objective (Adachi et al., 2001a).

A common method for measuring internal quantum efficiency is to place the OLED into an integrating sphere containing a calibrated detector, and then measuring all photons output from the device (Fig. 6.20b) (Gong et al., 2002). Several sources of inaccuracy need to be considered. (i) The response of the photodiode is generally not uniform over the broad spectral output of an OLED. As in the case of the external efficiency measurement, the spectral response of the photodiode must be calibrated across the entire OLED emission spectrum to accurately obtain the efficiency from the photocurrent. (ii) All significant sources of internal loss in the structure, such as reabsorption in the organic films, total internal reflection (TIR) at the substrate/air interface, propagation and other losses in the transparent anode,

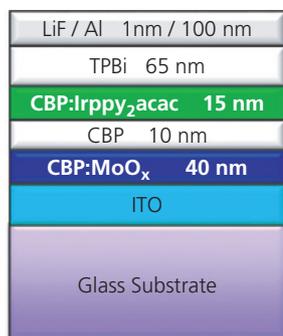

surface plasmon polaritons, free carrier absorption, and other effects associated with contacts (see Section 6.6). Due to the uncertainties inherent in these estimates, the internal quantum efficiency can contain significant systematic errors (Bulovic et al., 1998a, Kim et al., 2000). (iii) Losses due to shadowing by the probes and other fixtures (e.g. the baffle used to prevent direct irradiation of the detector) within the sphere, and less than unity reflectivity from the interior surface of the sphere, must be “backed out” of the measurement. (iv) Losses due to reabsorption of rays traversing the sphere by the OLED itself.

The internal efficiency can be several times greater than the external efficiency, since the integrating sphere captures nearly all the photons emitted in the device active region and that are subsequently emitted into all directions, not just in the forward viewing direction (Gong et al., 2002).

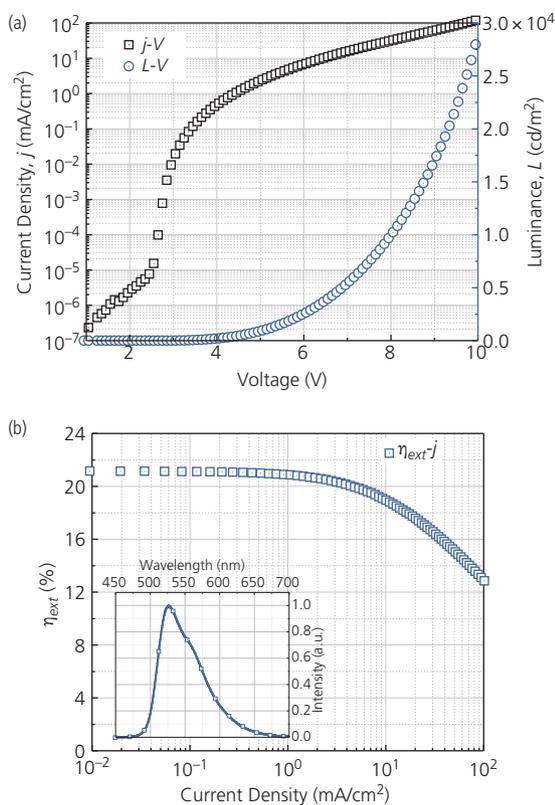

Using an integrating sphere is *not* a measurement of the display-relevant (forward emitted) *external* quantum efficiency; the source of some confusion in the literature. To measure the forward-viewing external quantum efficiency in an integrating sphere requires that the edge-emitted light be prevented from reaching the detector. The integrating sphere measurement is useful for assessing the OLEDs for lighting since the source is typically attached to a fixture (also known as a *luminaire*) that directs photons emitted in all directions into the space being illuminated.

Once the external efficiency is measured as a function of  $I_{OLED}$  and  $V$ , and the device emission spectrum is also determined using calibrated detectors. These measurements allow for calculation of  $L$ ,  $\eta_{L}$ , and  $\eta_p$ . Doing this process in “reverse order” (i.e. deriving the radiometric from the photometric parameters) requires that the output emission pattern, meter calibrations and other geometric factors are accurately known. Deviations from Lambertian emission of most OLEDs (Tokito et al., 1997) can lead to significant errors, and hence direct measurements of the photometric characteristics are the most reliable.

To fully characterize the OLED, therefore, three groups of data are required: the current-voltage characteristics, the external quantum efficiency-current characteristics, and the emission spectrum. An example data set for the PHOLED structure in Fig. 6.21 is shown in Fig. 6.22. The  $j$ - $V$  characteristics at  $j > 0.01$  mA/cm<sup>2</sup> in Fig. 6.22a are consistent with space charge limited transport (see Section 4.4.2) showing a power-law behavior of  $j \sim V^m$ . Below 1.5 V, the characteristics are approximately Ohmic. The onset of substantial

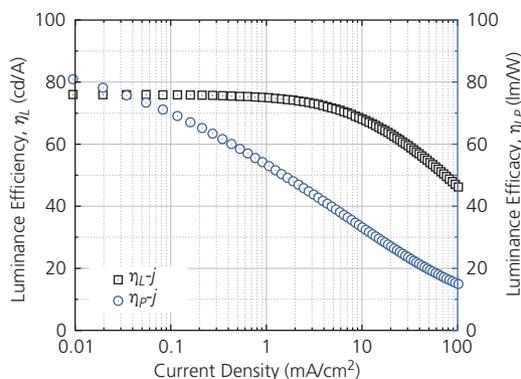

**Figure 6.21** Structure of the PHOLED used in Figs. 6.22 and 6.23. Materials are: cathode: LiF/Al; exciton blocking layer: TPBi; emission layer: CBP doped with 10 vol.% Ir(ppy)<sub>2</sub>acac; hole injection layer: CBP doped with MoO<sub>x</sub>; anode: ITO.

**Figure 6.22** (a) Current density–voltage and luminance–voltage characteristics and (b) external quantum efficiency vs.  $j$  of the device in Fig. 6.21. The emission spectrum is shown in the inset.

luminance occurs at approximately  $0.1 \mu\text{A}/\text{cm}^2$  at 4V, reaching  $3 \times 10^4 \text{ cd}/\text{m}^2$  at 10 V.

The external quantum efficiency is provided in Fig. 6.22b. Here,  $\eta_{\text{ext}} = 21\%$  is approximately constant up to  $j = 1 \text{ mA}/\text{cm}^2$ , and then begins to decrease

**Figure 6.23** Luminance efficiency and efficacy vs. current for the device in Fig. 6.21.

rapidly as current (and brightness) is further increased. We show in Section 6.6 that the external quantum efficiency of 21% corresponds to an internal quantum efficiency,  $\eta_{\text{int}} \sim 100\%$ , which is expected for high performance PHOLEDs. Furthermore, in Section 6.3.5 we show that the roll-off at high current is a result of triplet annihilation. The inset, Fig. 6.22b, provides the last piece of information needed to fully quantify the performance of the OLED—the emission spectrum. This is due to triplet emission from Ir(ppy)<sub>2</sub>acac with a peak at  $\lambda = 525 \text{ nm}$ , with one vibronic overtone observed at  $\lambda = 560 \text{ nm}$ .

From the data in Fig. 6.22, we arrive at the luminance efficiency and the luminance power efficiency shown in Fig. 6.23. To obtain  $\eta_L$ , we use both  $\eta_{\text{ext}}$  and the spectral luminance in the inset, Fig. 6.22b, as discussed in Section 6.2.3.1. Similar to  $\eta_{\text{ext}}$ , the  $\eta_L$  is constant at  $75 \text{ cd}/\text{A}$  until roll-off is reached at  $j \sim 10 \text{ mA}/\text{cm}^2$ .

Finally, the efficacy is obtained from Eq. 6.14 along with the voltage obtained from the  $j$ -V characteristics in Fig. 6.20a. Here,  $\eta_{\text{LP}}$  decreases monotonically from  $80 \text{ lm}/\text{W}$  at  $10 \mu\text{A}/\text{cm}^2$ , to  $20 \text{ lm}/\text{W}$  at  $100 \text{ mA}/\text{cm}^2$  due to the monotonic increase in OLED voltage. Efficacy is most useful when comparing white light sources. When combined with the device CRI and CCT, it provides an important quantity in evaluating the properties of the illuminant. It is far less useful for characterizing the actual efficiency performance of monochromatic devices such as the green PHOLED in Fig. 6.21. In this case, the radiometric quantity of power efficiency is more useful.

### 6.3 Electroluminescent processes

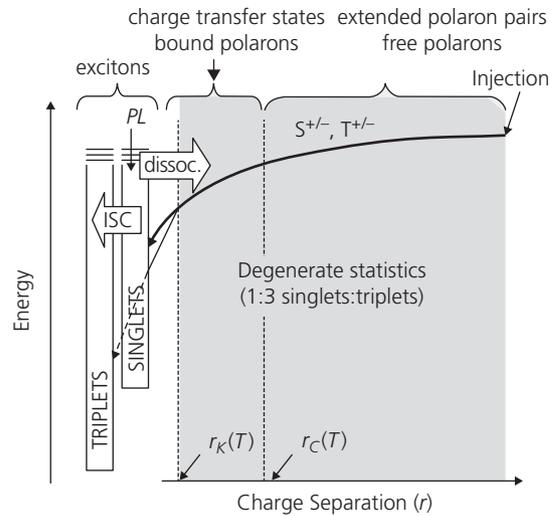

There are two spin-dependent mechanisms for OLED emission: fluorescence due to radiative recombination

of electrically generated singlet states, and phosphorescence due to triplet-mediated emission. The efficiency of the device is dependent on which of these two processes are responsible for controlling the emission. In Section 6.2.1 we showed that the maximum OLED internal quantum efficiency is determined by the spin statistical splitting of the injected charges. Random statistics (i.e. the spin of the injected electron and hole are uncorrelated) suggest that the spin formation ratio in Eq. 6.1 is  $\chi_{ST} = 25\%$  for singlets and  $\chi_{ST} = 75\%$  for triplets due to the multiplicities of these two spin manifolds (Chapter 3). In the following section we describe the spin formation process, and means for measuring  $\chi_{ST}$ . We show that in almost all materials, random statistics appear to govern the spin formation ratio. This will be followed in subsequent sections by a discussion of the luminescence processes that ensue once the excitons are formed in their various spin manifolds.

### 6.3.1 Spin statistics

The exciton formation process following the injection of uncorrelated spins from the cathode and anode results in subsequent formation of a precursor electron-hole *polaron pair* (PP). This transfers to an even lower energy *charge transfer* (CT) state on adjacent molecules. At this point, the spins are completely uncorrelated and hence must form according to the 1:3 singlet:triplet statistical ratio. The bimolecular pair then scatters onto a single molecule to form the exciton that subsequently recombines.

The energetic landscape traversed from free charges to excitons is shown in Fig. 6.24. The process begins by injection of charge from the anode and cathode, whose collective spin symmetries randomly form either a singlet or triplet polaron pair (denoted  $S^{+/-}$ ,  $T^{+/-}$ , respectively). Once the polarons approach to within a capture radius where the Coulomb energy is equal to the thermal energy,  $r_c(T) = q^2/4\pi\epsilon_r\epsilon_0k_B T$ , either a singlet or triplet CT state ( ${}^1CT$ ,  ${}^3CT$ , respectively) is formed. Here,  $\epsilon_r$  is the material dielectric constant and  $\epsilon_0$  is the permittivity of free space. The CT state relaxes to an exciton of radius  $r_K(T)$ . That is, the polaron-pair collapses from the point at which the two charges are nearly free at  $r_c$  (corresponding to the *charge separated state*), to where the oppositely charged polarons locate on nearest neighbors, and the exchange energy is large (at separation,  $r_K$ ). At this point, the degeneracy is lifted and the spin symmetry no longer changes unless there is strong spin-orbit coupling due, for example, by a heavy metal atom within the molecular complex. Prior to

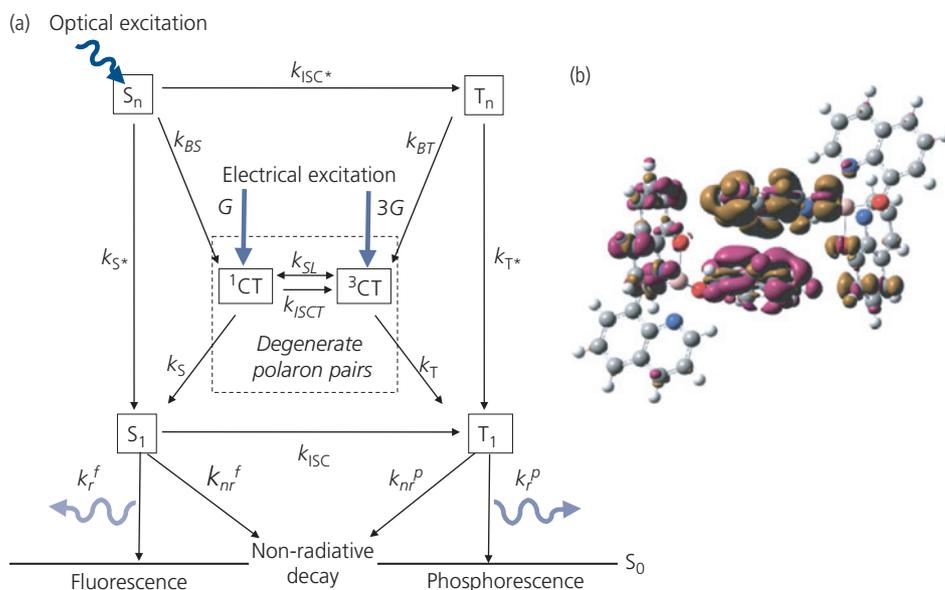

**Figure 6.24** Free polaron-to-exciton formation process. The free polarons are injected from contacts, randomly forming a singlet and/or triplet polaron pair ( $S^{+/-}$ ,  $T^{+/-}$ , respectively). When the polarons are within a capture radius,  $r_c$  a CT state is formed. When the electron and hole of the CT state approach at distance  $r_K$ , a bound singlet or triplet forms, depending on the spin symmetry of the original polaron pairs. Here, *dissoc.* = exciton dissociation, *ISC* = intersystem crossing (Segal et al., 2003).

reaching radius  $r_K$ , there can be mixing at rate  $k_{SL}$  between polarons in the charge separated state due to spin-lattice relaxation, or the presence of spin-orbit or hyperfine coupling discussed in Section 3.7 (McClure, 1949, 1952).

Figure 6.25a illustrates the rates governing the generation of excitons from the precursor CT states. Triplet,  ${}^3CT$ , states are statistically generated at three times ( $3G$ ) the probability of singlet,  ${}^1CT$ , states ( $G$ ). Once formed, the CT states bind into either singlet or triplet excitons at rates  $k_S$  or  $k_T$ , respectively. However, if the *spin exchange energies* between CT or exciton singlets and triplets ( $\Delta E_{CT}$  or  $\Delta E_{EX}$ ) are small (i.e. on the order of or less than the thermal energy,  $k_B T$ ), intersystem crossing between spin manifolds at rates  $k_{ISC}$ ,  $k_{ISC^*}$ , and  $k_{ISC}$  can result in exciton spin distributions that differ from the statistical 1:3 ratio. That is, if  $k_{ISC}$  is higher than the exciton formation rates,  $k_S$  and  $k_T$ , then the spin statistical splitting can deviate from 1:3 singlets-to-triplets. This situation occurs for nearly degenerate singlet and triplet polaron-pair (i.e. CT) states.

The CT state formed on a pair of adjacent Alq<sub>3</sub> molecules is shown in Fig. 6.25b. Here, CT formation leads to substantial overlap of the polaron wavefunctions, ensuring efficient exciton formation that occurs via the hop of one of the charges from one molecule to its neighbor. We have seen that both Miller-Abrahams

**Figure 6.25** (a) Detailed exciton formation process via both optical and electrical excitation. Energies involved in triplet and singlet exciton formation are implied by vertical distances in the diagram. Here,  $G$  is the electrical-to-exciton generation probability. Once formed, CT states bind into either singlets ( $S$ ) or triplet ( $T$ ) excitons at rates  $k_S$  or  $k_T$ , respectively. The intersystem crossing between spin manifolds occurs at rates  $k_{ISCT}$ ,  $k_{ISC}$ , and  $k_{ISC^*}$  for CT, upper manifold singlet ( $S^*$ ) and triplet ( $T^*$ ) states, and lowest energy ( $S$ ,  $T$ ) excitons, respectively. Radiative ( $k_r^f$ ,  $k_r^p$ ) and non-radiative ( $k_{nr}^f$ ,  $k_{nr}^p$ ) rates from fluorescent (superscript  $f$ ) or phosphorescent ( $p$ ) states are shown. (b) Polaron pair charge distributions on two adjacent Alq<sub>3</sub> molecules. The negative polaron distribution (orange) is primarily on the molecule on the right, and the hole distribution (red) is on the left (Segal et al., 2007).

and Marcus transfer theories (Section 4.3.2) predict that the probability for hopping decays exponentially with intermolecular distance. That is, the hopping rate follows  $k_{fi} \sim \exp(-2\gamma a) \exp\left(\frac{E_f - E_i}{k_B T}\right)$  for a final state energy  $E_f < E_i$ . On the other hand, if  $E_i < E_f$ , then  $k_{fi} = 0$ . Here,  $\gamma$  is the hopping parameter and is related to the tunneling distance between the donor and acceptor molecules spaced at distance,  $a$ . The hopping rate is thus highly sensitive to the intermolecular spacing, yet the long-range Coulombic attraction between the electron and hole results in a near unity probability for the formation of a bound exciton once the charges are located on neighboring molecules.

The several routes affecting exciton formation statistics are shown schematically in Fig. 6.26. As noted, it is safe to assume that uncorrelated spins of the precursor electron-hole polaron pair combine according to the singlet-triplet statistical ratio of 1:3 as shown in Fig. 6.26a. These subsequently form singlet and triplet CT states ( $^1CT$  and  $^3CT$ ) in the same ratio. If the exchange energy splitting is higher than a few  $k_B T$  (Kadashchuk et al., 2004), or if the rate of singlet exciton formation,  $k_S$ , is greater than for triplets,  $k_T$ , it is likely that this ratio will be preserved, and the ultimate ratio of singlet ( $S^*$ ) to triplet ( $T^*$ ) excited states will also be 1:3. The resulting emission is thus almost entirely

due to singlet recombination ( $S^* \rightarrow S_0$ ) via fluorescence occurring within 1-10 ns of exciton generation.

When there is strong spin-orbit coupling ( $L \cdot S$ ), the spins within the exciton manifold are mixed, resulting in rapid intersystem crossing,  $k_{ISC}$ , prior to recombination. As shown in Chapter 3, the spin-orbit interaction strength scales as  $Z^4$ , where  $Z$  is the atomic number (cf. Eq. 3.175). Hence, incorporation of heavy metal atoms has been shown to be effective in increasing  $k_{ISC}$  well above  $k_S$ . For these systems, the singlets rapidly transfer to the triplet manifold, and the spin selection rule that ordinarily forbids radiative recombination to the ground state following  $T^* \rightarrow S_0$  is allowed, also due to the strong  $L \cdot S$  coupling. In these instances, the emission is via triplets and is known as phosphorescence. The natural triplet lifetime is typically from 500 ns to 100  $\mu$ s (Baldo et al., 1998, Baldo et al., 1999a). This situation is depicted in Fig. 6.26b.

In some special cases, the exchange energy of the CT state manifold may be less than, or on the order of the thermal energy, leading to spin mixing prior to exciton formation (see Fig. 6.26c). This leads to a departure from the statistical spin ratio. The relative population of singlets and triplets depends on the ratio of their relative formation rates,  $k_S/k_T$ . Typically,  $k_S \gg k_T$ , leading to a disproportionate fraction of

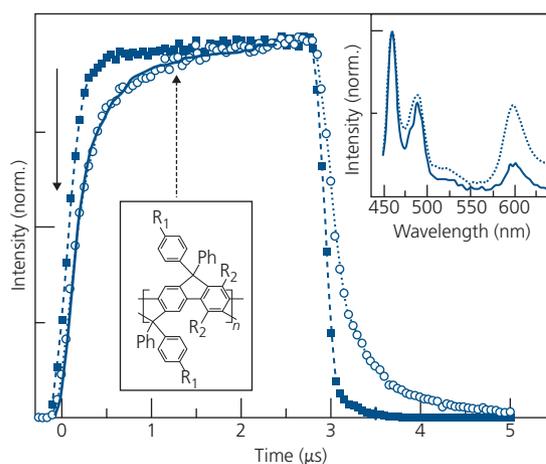

**Figure 6.26** Exciton formation processes starting with a free electron–hole polaron pair. The random generation statistics imply that singlet and triplet CT states are generated (G) in a ratio of 1:3. (a) CT states form singlet and triplets without mixing, resulting in a 1:3 excited state singlet ( $S^*$ ) and triplet ( $T^*$ ) exciton ratio. Without mixing, fluorescence (fl) is dominantly observed. (b) Fast intersystem crossing at rate  $k_{ISC}$  due to enhanced spin–orbit coupling ( $L \cdot S$ ) results in predominantly phosphorescent (ph) emission. (c) Rapid mixing of spins between CT states at rate  $k_{ISC-CT}$  in the absence of ISC results in fl emission. (d) If the exchange energy splitting between singlet and triplet is small, then thermally activated intersystem crossing at rate  $k_{ISC-th}$  between the  $T^*$  and  $S^*$  is possible, resulting in delayed fluorescence. After Reineke and Baldo (2012).

singlets. In the absence of spin–orbit coupling, this process ultimately leads only to fluorescent OLED emission.

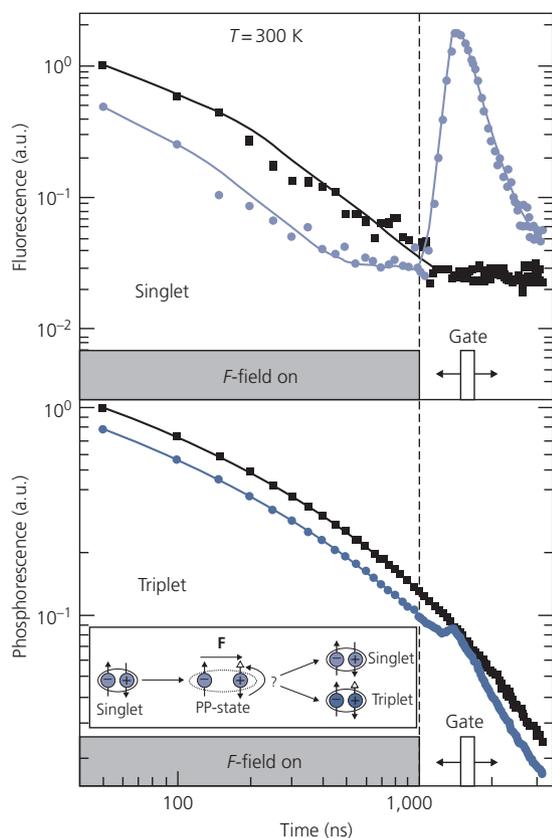

Finally, we consider a case analogous to a small CT state exchange energy: that corresponding to a small exchange energy in the final exciton state, shown in Fig. 6.26d. The triplets can rapidly transfer to the singlet manifold via thermal excitation, thus leading to a disproportionately large singlet population, even though the initial formation statistics are still one in four. The singlet undergoes radiative recombination at a timescale of a few nanoseconds, but with the system achieving an internal quantum efficiency greater than 25%. This process is known as *thermally activated delayed fluorescence* (TADF, see Section 3.7.5). It has been exploited in OLEDs to deliver high efficiencies, approaching 100%, and is the topic of Section 6.3.4.

The following question remains: do spin statistics change in the transition from  $PP \rightarrow CT \rightarrow S, T$ ? This question was addressed by electric field polarization of the  $PP$  state during formation to determine if the ratio of  $S$  to  $T$  changes over time (Reufer et al., 2005). A ladder-type polymer, poly(*p*-phenylene) or PhLPPP (see lower inset, Fig. 6.27) slightly contaminated by  $\sim 0.1\%$  Pd atoms during synthesis yields both fluorescent and phosphorescent PL. Phosphorescence is made possible by spin–orbit coupling due to the Pd impurities. The separate luminescent processes are resolved in the transient EL spectra of OLEDs fabricated

**Figure 6.27** Singlet (filled symbols) and triplet (open symbols) EL response of the ladder-type polymer, PhLPPP whose molecular structural formula is shown in the lower inset. The arrows indicate the times that the two spectra in the upper inset are recorded. The  $S$  emission has a peak at a wavelength of 480 nm, and  $T$  emission is at 600 nm (Reufer et al., 2005). M., Spin-conserving carrier recombination in conjugated polymers. Copyright 2005.

using this compound. The phosphorescent lifetime puts a lower limit to the triplet formation time of  $k_T^{-1} > 100\text{ns}$ , which is primarily due to triplet diffusion to the widely separated Pd sites. That is, the phosphorescent and fluorescent signals occur on significantly

**Figure 6.28** Fluorescent (top) and phosphorescent (bottom) emission transients in the absence (black symbols) and presence (color symbols) of an electric field. The electric field separates the exciton state into a weakly interacting polaron pair, and then the field is switched off after 1  $\mu$ s to determine if the spin state of the singlet has changed. The process of singlet polarization and recombination is illustrated in the inset, bottom panel (Reufer et al., 2005).

different times scales (Fig. 6.27, upper inset). As expected for singlet and triplet splitting, phosphorescence is at lower energy, and hence at a longer wavelength than fluorescence.

To determine the strength of singlet–triplet mixing in the PP state, the samples were illuminated under reverse bias. A strong electric field (>1 MV/cm) physically separates (via polarization) the singlet into a PP (inset, Fig. 6.28) where the charges are held for the duration of the voltage pulse. In this state, the orbital overlap is minimal, preventing exchange interactions. After a delay greater than 100 ns (the triplet formation time), the field is turned off, and the PP is allowed to once more form an exciton. Essentially, this experiment allows for singlet state production, and then reverses the process by an applied field. Lastly, the field is removed and recombination occurs once again. Once the field is turned off, there is a burst of

fluorescence and phosphorescence, as shown in the delayed emission in Fig. 6.28.

The fluorescence signal is 1000 times stronger than that of phosphorescence. Indeed, there is almost no detectable phosphorescence even at 4 K, although the PP state is maintained for 10 times longer than the triplet formation time. It is, therefore, concluded that spin mixing is absent in the PP state and the statistical 1:3 singlet:triplet formation ratio in this conjugated polymer is preserved over the timescale of the F-field delay.

We note that degeneracy of the singlet and triplet CT manifolds might upset the perfect statistical balance, depending on the ratio  $k_S/k_T$  as in Fig. 6.26 (Difley et al., 2008). Indeed, it has been shown that CT spin state formation in degenerate systems can be controlled by CT formation at material interfaces in an extrafluorescent OLED, resulting in an apparent increase in the singlet emission efficiency (Segal et al., 2007). While the experiment in Fig. 6.28 suggests that the formation statistics do not change over time, direct and accurate measurement of these statistics has been challenging (Baldo et al., 1999b, Cao et al., 1999, Kim et al., 2000, Wilson et al., 2001, Segal et al., 2003). The primary assumption of most such measurements is that the singlet fraction can be determined from the relationship between the EL and PL efficiencies in Eq. 6.1. Hence, once the EL efficiency in the OLED is measured, it would appear to be a simple matter of independently determining the PL efficiency, the losses specific to EL emission, and the outcoupling efficiency. From this, it is straightforward to calculate the exciton formation ratio,  $\chi_{ST}$ . The accurate measurement of these several parameters within an OLED structure, however, can lead to significant inaccuracies. Also, effects such as exciton annihilation where two singlets combine to form one singlet or triplet, or similarly where two triplets can annihilate to form one triplet or singlet, can also be active under high electrical injection conditions. Many of these processes are dependent on factors including device structure, voltage, current and temperature. Hence, measurement of the spin formation statistics has often been the subject of controversy. Nevertheless, its accurate determination is necessary to understand the exciton formation process under electrical injection.

The greatest accuracy is achieved by reducing the number of absolute measurements of the parameters in Eq. 6.1. Then,  $\chi_{ST}$  can be obtained by measuring the ratio of the EL to PL efficiencies for an OLED in a single experimental configuration (Segal et al., 2003). We now outline an approach that has been used to

successfully determine  $\chi_{ST}$  for both polymeric and small molecular weight materials.

In fluorescent materials, almost 100% of the species generated on optical excitation are singlets (although this too can lead to  $\sim 1$ –5% error, see Section 6.8). Hence, the PL efficiency of a sample provides a reference from which we obtain  $\chi_{ST}$  from  $\eta_{ext}$ . The PL power emitted by an OLED is given by (Segal et al., 2003)

$$P_{PL} = \frac{hc}{\langle \lambda_{em} \rangle} \eta_{out} \phi_{ph} \frac{k_r}{k_r + k_{nr} + k_Q}, \quad (6.25)$$

where  $k_r$ ,  $k_{nr}$ , and  $k_Q$  are the radiative, non-radiative, and electric field quenching rates, respectively,  $\langle \lambda_{em} \rangle$  is given by Eq. 6.3, and  $\phi_{ph}$  is the photon flux *absorbed* by the film. Here, we assume that the PL power is measured in the presence of an electric field across the same OLED structure used to determine its external quantum efficiency, and hence we cannot ignore the current injection-specific losses,  $\gamma_L$ , due, for example, to ionization, quenching at defects, etc. Also, the ratio of rates in Eq. 6.25 is the emission efficiency. Thus,  $k_r \eta_{out} \phi_{ph} / (k_r + k_{nr} + k_Q)$  is the photoluminescent flux outcoupled from the device (which depends on the thin film structure) and into the detector, which is a function of the experimental setup.

Under weak reverse bias where  $k_Q \ll (k_r + k_{nr})$ , an OLED under illumination, generates a photocurrent,  $j_{ph}$ . This is proportional to the optical pump intensity, that is,

$$j_{ph} = q \phi_{ph} \frac{k_Q}{k_r + k_{nr} + k_Q} \approx q \phi_{ph} \frac{k_Q}{k_r + k_{nr}}. \quad (6.26)$$

The difference in PL efficiency in the presence and absence of an electric field gives

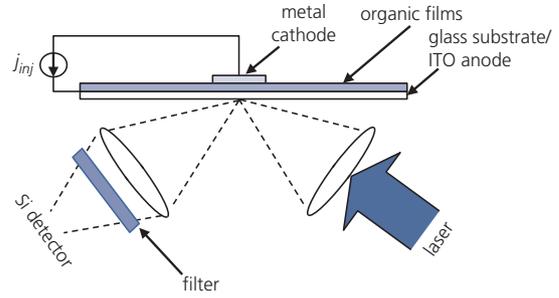

$$\begin{aligned} \Delta P_{PL} &= P_{PL}(k_Q) - P_{PL}(k_Q = 0) \\ &\approx -\frac{hc}{\langle \lambda_{em} \rangle} \eta_{out} \eta_{PL} \phi_{ph} \frac{k_Q}{k_r + k_{nr}}, \end{aligned} \quad (6.27)$$

where the PL efficiency in the low field limit is  $\eta_{PL} = k_r / (k_r + k_{nr})$ . Combining Eqs. 6.26 and 6.27 yields:

$$\eta_{out} \eta_{PL} \approx -\frac{q \langle \lambda_{em} \rangle}{hc} \frac{\Delta P_{PL}}{j_{ph}}. \quad (6.28)$$

Thus, by measuring the *change* in photoluminescent power efficiency and the photocurrent, we obtain the product of the PL and optical coupling efficiencies. The EL efficiency measured under forward bias is, from Eq. 6.2,

$$\eta_{ext} = \frac{hc}{q \langle \lambda_{em} \rangle} \frac{P_{EL}}{j_{OLED}}. \quad (6.29)$$

**Figure 6.29** Experimental setup used in the measurement of OLED PL and EL using a single optical system for both (Segal et al., 2003).

Then, from Eq. 6.1 we arrive at the spin statistics using

$$\gamma \chi_{ST} = \frac{\eta_{ext}}{\eta_{PL} \eta_{out}} = -\left( \frac{P_{EL}}{\Delta P_{PL}} \right) \frac{j_{ph}}{j_{OLED}}. \quad (6.30)$$

If the PL and EL optical powers are measured in the same experimental configuration, then the coupling efficiency to the detector remains unchanged for the measurement of both quantities, removing a significant potential source of error. Figure 6.29 shows such an experimental setup whereby the OLED PL is obtained by pumping with a laser source, while its EL is independently obtained by electrical injection. For both experiments, a single optical system comprising a lens and a filter to remove the laser emission is used.

From Eq. 6.30, the only uncertainty remaining is the determination of EL-specific losses,  $\gamma$ . The primary source of loss is imperfect charge balance in the OLED EML. As discussed in Section 6.2.1, employing blocking layers, particularly at the cathode side of the EML, can ensure unity charge balance. Another source of loss is triplet–polaron annihilation (TPA); this can be reduced or nearly eliminated by measuring the EL intensity at low current densities before there is any evidence of roll-off, as in Fig. 6.22 at  $j > 2$  mA/cm<sup>2</sup>. If TPA is insignificant,  $\eta_{ext}$  vs.  $j_{OLED}$  should be constant over the range of currents used.

It is also important to eliminate recombination of counter charges at traps. That is, a charge injected into the EML may become trapped and then non-radiatively recombine with its opposite at a defect. There are several means to eliminate this source of error. Since the trap density should be far lower than the dopant density within the EML, traps would be expected to fill at high currents. That is, the losses via traps will saturate, leading to an increase in  $\eta_{ext}$  with  $j_{OLED}$ , although the current may be sufficiently high to introduce annihilation, as above. Furthermore, since traps lie within the energy gap of the guest and/or

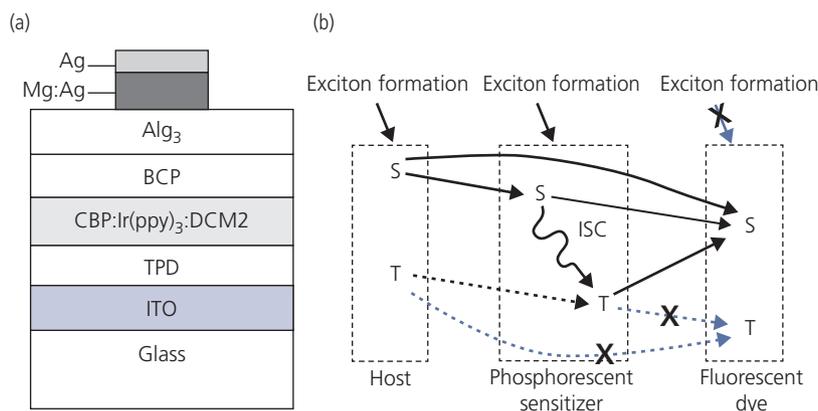

host in the EML, their contributions to losses should be temperature dependent. Hence, as  $T$  is reduced, traps may become more or less active, depending on their energy levels. Models for these various effects have been developed and provide a reasonable approach to limiting potential errors. Employing this analysis, it has been found the singlet fraction in the archetype fluorescent small molecule Alq<sub>3</sub>, and the polymer MEH-PPV is, to within experimental error, 25% (Baldo et al., 1999b, Segal et al., 2003).

Another means to measure spin statistics is to use a structure where exciton transfer to a fluorescent dopant from a fluorescent host (the subject of the measurement) occurs in the presence or absence of a phosphorescent “sensitizing” molecule. The fluorescent dopant in the absence of the phosphor emits only via singlet recombination. The phosphor sensitizer doped into the host harvests both singlets and triplets in the host, followed by conversion of singlets to the radiative triplet manifold via ISC. If a fluorescent guest is also doped in the same region as the phosphor, the sensitizer can transfer its excitation to the guest which is now capable of emitting at 100% efficiency from both host singlets and triplets (see Fig. 6.30). The phosphor sensitizer is chosen to ensure rapid Förster transfer to the fluorescent dopant. Hence, measurement of the relative intensity of the fluorophore-only device to that employing both the phosphor and the fluorophore provides the ratio of singlets to the total number of excitons generated in the host, thus providing a direct and uncomplicated measurement of  $\chi_{ST}$ .

A schematic of a device that exploits the sequential transfer of excitons from host to phosphor to fluorophore, is shown in Fig. 6.30a. This process is known

as *phosphor sensitized fluorescence*. It was first proposed by Förster (1959), and is used in OLEDs to generate 100% internal quantum efficiency via the use of fluorescent dyes (Baldo et al., 2000b). This process results in the transfer of all electrically excited excitons (regardless of spin) in a host by a high energy phosphor, to a fluorescent dopant where they can radiatively recombine at the wavelength determined by the fluorophores. In Fig. 6.30, the blue fluorescent CBP host (emitting with a peak wavelength of  $\lambda = 400$  nm) and the green Ir(ppy)<sub>3</sub> phosphor is combined in the EML with the red fluorescent dye DCM2. DCM2 absorbs in the green and emits at wavelengths between  $\lambda = 570$  nm and 650 nm. The ETL is Alq<sub>3</sub>, the hole and exciton blocking layer is BCP, and the HTL is TPD.

The transfer process in the phosphor sensitized fluorescent OLED is shown in Fig. 6.30b. Both singlets and triplets are generated on the host, and subsequently transferred to the phosphor whose S and T energies are lower than that of the host. Singlets transfer via the Förster process, whereas triplets transfer via exchange, or Dexter interactions. Hence, the concentration of the phosphor dopant must be sufficiently high to allow for direct contact between the host donor and phosphor acceptor molecules, which typically ranges from 8% to 10%. The phosphor is co-doped with the fluorescent “target” molecular species. The transfer from phosphor to the dopant is again via the Förster mechanism. Hence, the fluorophore concentration must be sufficiently high to allow for efficient Förster transfer but low enough ( $\leq 1\%$ ) to discourage direct Dexter transfer of triplets from the host to the fluorophore (Baldo et al., 2000b, D’Andrade et al., 2001).

**Figure 6.30** Measuring spin formation statistics in CBP. (a) An OLED with an emission zone employing a CBP fluorescent host, doped either with 0.2% of the fluorescent molecule DCM2, or with 8% Ir(ppy)<sub>3</sub> + 0.2% DCM2. (b) Exciton formation pathways via electrical injection are shown, as well as energy transfer pathways for both the singlet (S) and triplet (T) manifolds. The relative energies are indicated by vertical displacements of S and T.

To quantify  $\chi_{ST}$  in the device in Fig. 6.30, we rewrite Eq. 6.1 for the external EL quantum efficiency as

$$\eta_{ext} = \left[ \chi_S \eta_{PL}^f \eta_S + \chi_T \eta_{PL}^p \eta_T \right] \gamma \eta_{out}. \quad (6.31)$$

Here,  $\chi_T = (1 - \chi_S)$  is the fraction of triplets and  $\chi_S$  is the singlet fraction. Also,  $\eta_{PL}^f$  and  $\eta_{PL}^p$  are the PL efficiencies of fluorescence and phosphorescence of the acceptor,  $\eta_S$  and  $\eta_T$  are the transfer efficiencies of singlet and triplet excitons from donor to acceptor.

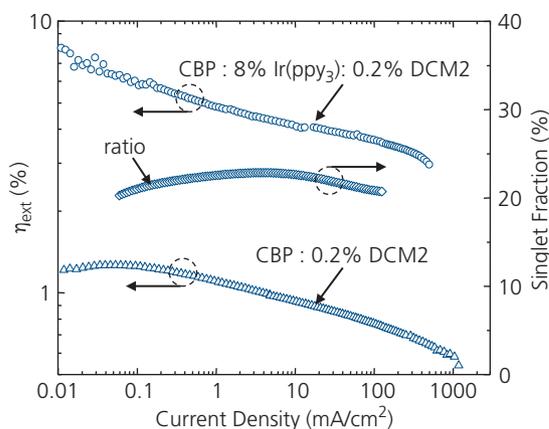

By quantitatively comparing the EL efficiencies ( $\eta_{ext}^f$  and  $\eta_{ext}^p$ ) of separate devices employing either the fluorescent or phosphorescent dye, we can use Eq. 6.31 to determine  $\chi_S$  and  $\chi_T$  provided that  $\gamma$  and  $\eta_{out}$  are identical in both devices. As noted above, this can be a source of error since it relies on an identical setup for both experiments, and the outcoupling efficiencies of both devices must also be the same. This latter requirement can be particularly challenging since the layer structures of fluorescent and phosphorescent OLEDs are inherently different, leading to differences in the optical field within the OLEDs.

If all singlets are transferred (i.e.  $\eta_S = \eta_T \sim 1$ ), we can obtain  $\chi_S$  from the ratio of fluorescent and phosphorescent efficiencies to obtain (Baldo et al., 1999b)

$$\chi_S = \frac{\eta_T}{\left( \frac{\eta_{ext}^p}{\eta_{ext}^f} \cdot \frac{\eta_{PL}^f}{\eta_{PL}^p} \right) - (1 - \eta_T)}. \quad (6.32)$$

Since the ratios reflect relative measurements, the only absolute measurement required is the triplet state transfer efficiency from the host to the phosphor (i.e.  $\eta_T$ ).

The efficiency of the phosphor sensitized fluorescent device in Fig. 6.30a is shown in Fig. 6.31. Here the sensitized device, consisting of CBP doped with 8 wt% Ir(ppy)<sub>3</sub> and 0.2% DCM2 has  $\eta_{ext} = 6\%$  at  $j = 0.1$  mA/cm<sup>2</sup>, decreasing to 3% at  $j = 500$  mA/cm<sup>2</sup>. The roll-off is due to *triplet-triplet annihilation* (TTA, see Section 6.3.5). For an analogous fluorescent device doped only with 0.2% DCM2, the efficiency is only 1.3% at  $j = 0.1$  mA/cm<sup>2</sup> which is characteristic of this particular compound. This decreases to 0.6% at 500 mA/cm<sup>2</sup> (D'Andrade et al., 2001). In the sensitized device, both triplets and singlets are harvested, whereas in the DCM2-only device, singlets are harvested. Hence, the ratio of these two efficiencies gives the singlet fraction of  $\chi_S = 1.3/6 = 0.22$ , independent of current density, assuming complete energy transfer. The energy transfer efficiency can also be obtained from the relative fluorescence and/or phosphorescence intensities in the emission spectra of the various devices. Should both spectral features coexist in a single device, their relative intensities can be used to

**Figure 6.31** External quantum efficiency vs. current density for the fluorescent as well as for the phosphor sensitized fluorescent OLEDs. The ratio of the quantum efficiencies between these two devices is a direct measurement of the singlet fraction (D'Andrade et al., 2001, Segal et al., 2003).

Reprinted figure with permission from Segal, M., Baldo, M. A., Holmes, R. J., Forrest, S. R. & Soos, Z. G. 2003. Excitonic singlet-triplet ratios in molecular and polymeric organic materials. *Phys. Rev. B*, 68, 075211 Copyright 2003 by the American Physical Society.

infer  $\eta_S/\eta_T$ . The singlet fraction obtained from phosphor sensitized fluorescence is consistent with the results obtained using the PL/EL experiments applied to MEH-PPV and Alq<sub>3</sub> in Fig. 6.29.

Hence, we have seen that fluorescent OLEDs based on small molecules (CBP and Alq<sub>3</sub>) and polymers (MEH-PPV) have a singlet-triplet production ratio of 1:3. Indeed, there do not appear to be convincing examples where that ratio is violated in other fluorescent systems, although other measurement approaches have led to a diversity of singlet fractions, ranging from 15% to 60% (Cao et al., 1999, Wilson et al., 2001, Wohlgenannt et al., 2001, Wohlgenannt and Vardeny, 2003). These latter approaches, however, are subject to greater uncertainties than those described above, and hence are not considered further.

### 6.3.2 Fluorescent OLEDs

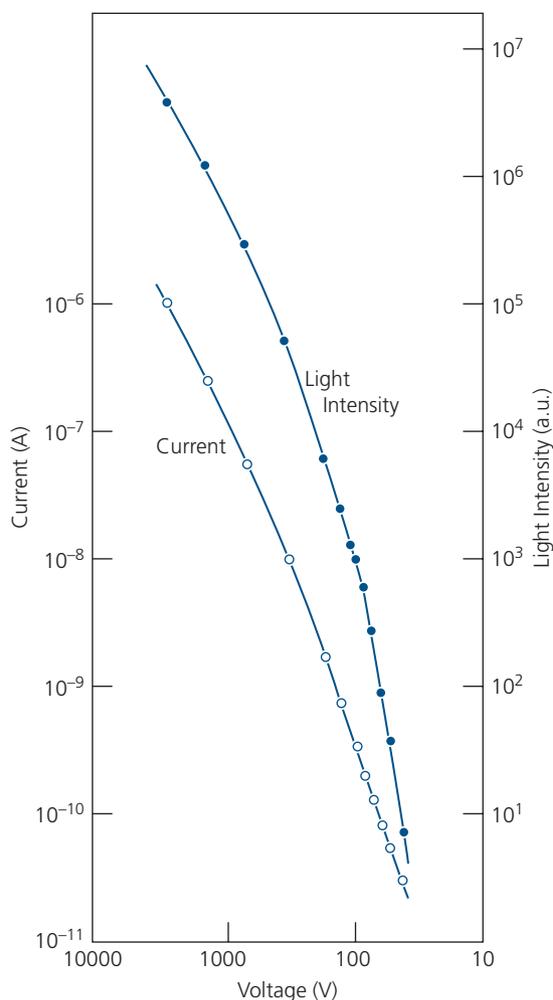

The first low voltage OLED was a bilayer fluorescent device based on small molecules (Tang and VanSlyke, 1987), followed three years later by a fluorescent polymer OLED (Burroughes et al., 1990). These technological breakthroughs were preceded by the observation of EL in a film of brilliant acridine orange E (II) (Bernanose and Vouaux, 1953, Bernanose, 1955), and later in a pure anthracene crystal, and one doped at 0.1 mol. % with tetracene (Pope et al., 1963). In the anthracene devices, contacts were made using silver paste, hence this device was capable of unipolar

charge injection that was space-charge limited, following  $j \sim V^{10}$ . At 400 V and at a large current density of  $100 \mu\text{A}/\text{cm}^2$ , anthracene luminescence in the undoped sample was observed, whereas tetracene fluorescence was observed in doped anthracene. Due to the very high currents and voltages necessary to observe weak EL from unipolar injection, the phenomenon was attributed to recombination following *impact ionization* of the anthracene molecules. The flood of electrons liberated on impact by high energy injected electrons recombine with holes left behind on the ionized molecules. Luminescence was achieved at even higher voltages (2000 V) applied to the acridine derivatives, and was likely due to similar field ionization effects.

Bimolecular recombination in a 1–5 mm thick anthracene crystal due to injection of electrons and holes from opposite electrolyte cathodes and anodes, respectively, resulted in emission of intense blue fluorescence (Helfrich and Schneider, 1965). The  $I$ - $V$  and luminance voltage characteristics are shown in Fig. 6.32. The light intensity was proportional to bipolar space charge limited current. It was estimated that the blue emission quantum efficiency due to bimolecular recombination was  $\sim 100\%$ . The internal resistance of the large anthracene crystals resulted in operating voltages  $>100$  V.

The demonstration of bipolar injection into an anthracene crystal arguably represents a structure similar to a polymer OLED (Helfrich and Schneider, 1965). However, anthracene has a much higher hole than electron mobility, thereby requiring very high voltage operation. Furthermore, OLEDs are thin film devices as opposed to free-standing single crystals. This is an important distinction, since an OLED is interesting primarily because it has the potential for large-scale integration in displays or lighting. The thin films can be applied over large surface area glass, plastic, metal or a range of other substrate materials that provide support as well as mechanical durability. This feature cannot be replicated by bulk crystals that are typically very small (a few cubic millimeters, see Chapter 2) and fragile.

A significant advance was, therefore, the demonstration of the bilayer OLED. The small molecular weight device used an aromatic diamine HTL (which is similar to the high hole mobility TPD molecule, shown in Fig. 6.3a) and an emissive electron transporting  $\text{Alq}_3$  layer sandwiched between a low work function  $\text{Mg:Ag}$  alloy cathode and an ITO anode (Tang and VanSlyke, 1987). Radiative recombination occurs on  $\text{Alq}_3$  with a PL quantum yield of  $\sim 30\%$  (Garbuzov et al., 1996) emitting intense green fluorescence at a peak wavelength of  $\lambda = 550$  nm. The entire device comprised

**Figure 6.32** Current and luminous intensity vs. voltage due to bimolecular recombination of electrons and holes in an anthracene single crystal (Helfrich and Schneider, 1965).

amorphous organic thin films deposited by vacuum thermal evaporation. In the first reported bilayer OLED, the external quantum efficiency was  $\sim 1\%$ . Importantly, the voltage needed to achieve an easily visible emission was only  $\sim 5$  V.

### 6.3.2.1 Exciton diffusion and confinement in multilayer small molecule OLEDs

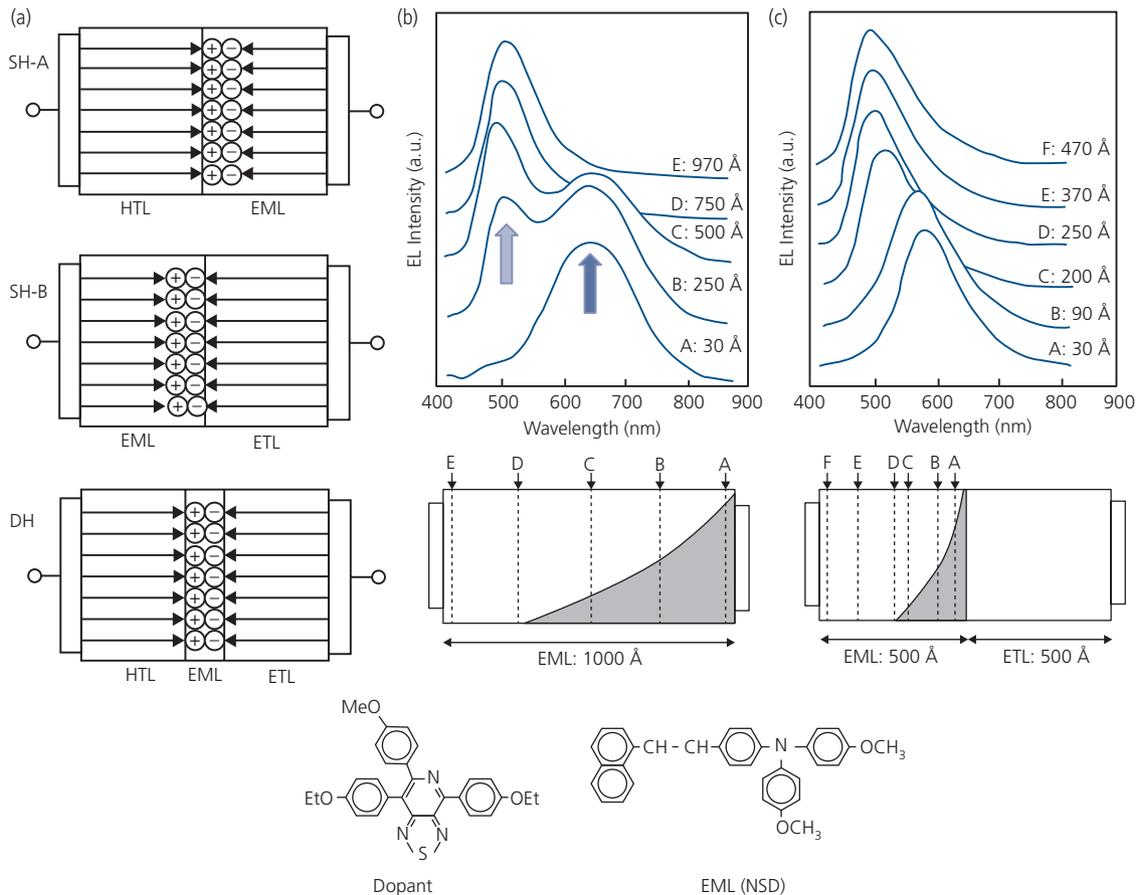

A disadvantage of the bilayer structure in Fig. 6.3 is that it requires individual layers to serve multiple purposes, for example, both light emission and charge conduction. Further, single layer or bilayer (single HJ) devices lack a region that confines a high density of excitons required for bright light emission. The exciton distribution in the bilayer device, nevertheless, is far more confined than in earlier, single layer structures.

The exciton density distribution, and its effects on the emission properties of OLEDs was first explored in the bilayer and triple layer devices shown in Fig. 6.33 (Adachi et al., 1991). The exciton density distribution was inferred by placing a 1 nm thick layer of the dopant, thiadiazole, that forms a charge transfer complex with the host (NSD) emitting at 630 nm (Fig. 6.33) at different distances from the contacts or HJs, and then measuring the emission from that fluorophore. The thiadiazole thus acts as a *sensor layer* whose emission is distinct from the layer in which it is embedded, and whose intensity is proportional to the local exciton concentration. Figure 6.33a shows a bilayer, single HJ OLED (SH-A) comprised of a TPD HTL and a naphthylstyrylamine derivative (NSD) EML that is preferentially electron conducting. The second device in Fig. 6.33a (SH-B)

replaces the HTL with a PBD ETL. Finally, the double heterostructure (DH) comprises a sandwich with the emitting layer placed between an independently optimized ETL and HTL. The cathodes consist of a low work function Mg-Ag contact, and the transparent anode was ITO (Adachi et al., 1990).

The exciton distribution obtained from the relative EL intensities of the thiadiazole and the transport layers in a single layer device in Fig. 6.33b is spread over 75 nm, with the peak nearest to the cathode due to the larger hole mobility of the NSD EML compared to electron mobility of the PBD ETL. The shape of the distribution is exponential due to the dependence of the exciton density ( $N(x)$ ) on its diffusion length ( $L_D$ ) given by

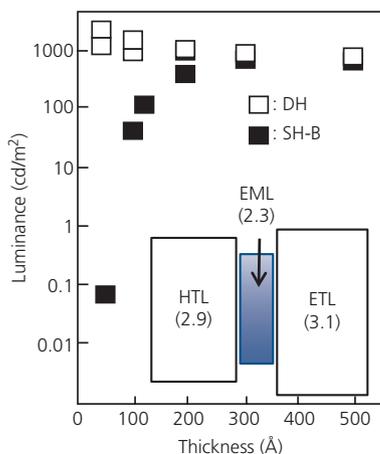

$$N(x) = N_0 \exp(-x/L_D). \quad (6.33)$$

**Figure 6.33** (a) Three devices used in determining the spatial extent of the exciton distribution in fluorescent OLEDs. SH-A is a bilayer device consisting of an electron conducting EML, SH-B consists of a hole conducting EML, and DH is a double heterostructure with the EML sandwiched between an HTL and ETL. (b) Emission from a series of single layer OLEDs comprising only the EML molecule, NSD. A 1 nm thick thiadiazole dopant slab is placed at varying distances (denoted A, B, C, D, E) from the Mg-Ag cathode. The light and dark blue arrows indicate the peak emission from the EML and dopant respectively. (c) As in (b) for SH-B OLEDs with the dopant placed at various distances from the EML/ETL interface. The dopant and the EML molecular structural formulae are shown at the bottom. After Adachi et al. (1991).

Here,  $N_0$  is the exciton density at the point of origin. The dopant emission dominates the spectrum at a distance of only 50 nm from the cathode, indicating that excitons generated beyond this point do not significantly contribute to the luminance. This broad distribution also results in a luminance that is  $10^4$ – $10^6$  times less than for SH-A and SH-B, respectively. The more confined distribution using a hole conducting EML is apparent for SH-B, as shown in Fig. 6.33c. Here, the exciton population extends only as far as 20 nm. The emission is almost entirely from the dopant at longer distances, and the device is far brighter than the single layer device. A similar result is obtained for SH-A, which is the most efficient of the several structures investigated.

These observations suggest that almost all excitons are generated within 5–10 nm of the charge transport/EML or injecting contact/EML interfaces in bilayer and single layer devices, respectively. This conclusion is supported by comparing the luminance of the DH and SH-B devices as functions of EML thickness in Fig. 6.34. Since excitons in the DH structure are confined by the larger energy gaps (and hence energy barriers) of the ETL and HTL layers in the EML, quenching is eliminated. Indeed, the lack of dependence of the luminance on layer thicknesses (in contrast to the strong dependence of the SH-B device) as small as 5 nm suggests that excitons are formed within only a few monolayers of the injecting interfaces. This is apparently the first example where a double heterostructure was used to achieve balanced

**Figure 6.34** Luminance of DH and SH-B devices vs. EML thickness. Inset: Relative energies (in parentheses) of the ETL, HTL and EML taken from the EL spectra of OLEDs. Since the HOMO and LUMO energies are unknown relative to vacuum, a space is left between each material indicating only the magnitude of the optical energy gaps (Adachi et al., 1990).

hole and electron injection (i.e. where  $\gamma \rightarrow 1$ ) where injected charges are confined by the energy barriers surrounding the EML (Adachi et al., 1990).

### 6.3.2.2 Energy transfer and luminescent layer doping in fluorescent OLEDs

An important advance toward high efficiency and long lifetime was achieved by doping the EML with a fluorescent acceptor guest molecule in a donor host (Tang et al., 1989). This separates charge conduction on the host from emission on the guest, thereby allowing for independent optimization of the materials to carry out their separate functions. The exciton can be formed on the conductive host molecule, in which case complete transfer to the guest is required, or it can form directly on the emissive guest molecule itself. Thus, there are three mechanisms for exciting the guest molecule:

- (i) *Fluorescence (or Förster) resonant energy transfer (FRET)*: This is the principal energy transfer mechanism in fluorescent guest–host OLED systems where the exciton is formed by recombination of the injected electron and hole on the host (donor), and then transferred to the guest (acceptor). As discussed in Section 3.8.1, FRET requires that the host molecule have a high radiative efficiency, and hence is active in the transfer of singlet excitons between fluorescent molecules. From Eqs. 3.233 and 3.234, the rate of energy transfer is given by

$$k_{ET} = \frac{1}{\tau_D} \left( \frac{R_0}{R_{DA}} \right)^6, \quad (6.34)$$

where  $\tau_D$  is the natural lifetime of the donor,  $R_{DA}$  is the distance between donor and acceptor molecule, and  $R_0$  is the Förster radius:

$$R_0^6 = A_\lambda \int \lambda^4 f_D(\lambda) a_A(\lambda) d\lambda. \quad (6.35)$$

Here,  $f_D(\lambda)$  is the emission spectrum of the donor,  $a_A(\lambda)$  is the absorption spectrum of the acceptor molecule, and  $A_\lambda$  is a constant. When  $R_0 = R_{DA}$ , the transfer efficiency is 50%. As in Chapter 3,  $R_0 = 3$ – $5$  nm is typical for many fluorescent guest–host systems. Since a common molecular dimension is  $\sim 1$  nm, concentrations of 1–3 wt% of the dopant are sufficient to achieve a very high FRET efficiency.

- (ii) *Exchange (or Dexter) energy transfer*: When the host exciton is non-emissive, direct contact between guest and host molecules allows for exchange energy transfer. This is not a useful process for

fluorescent molecules since such a high density of guest molecules ( $\sim 5\text{--}10$  wt%) leads to *concentration quenching* of the luminescence. This is due to intimate coupling between nearest neighbor molecules that opens up non-radiative recombination channels, such as phonon-assisted relaxation of the excited state. Also, at low doping, there is a reduced opportunity for excitons on adjacent excited molecules to annihilate; a phenomenon that becomes particularly pronounced at high intensities. However, transfer of the host triplet and singlet states to a triplet-emitting molecule such as a transition metal phosphorescent complex can occur by the spin-conserving Dexter mechanism (Baldo et al., 1998). In Section 6.3.3, we showed that the phosphor dopant concentration must be considerably higher than that used for fluorescent OLEDs to achieve high efficiency. Again, referring to Section 3.8.2, the exchange transfer rate is given by (Eqs. 3.242 and 3.243)

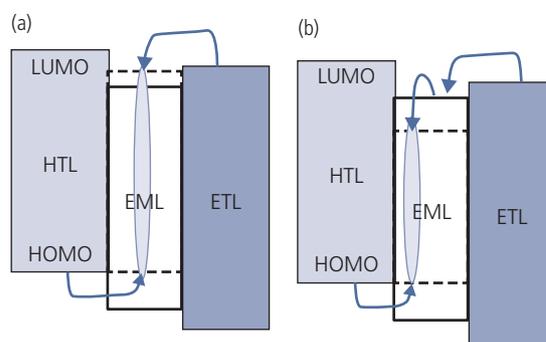

$$k_{ET} = \frac{2\pi}{\hbar} \Gamma^2 \int f_D(\lambda) \sigma_A(\lambda) d\lambda, \quad (6.36)$$

where the orbital overlap between donor and acceptor is given by

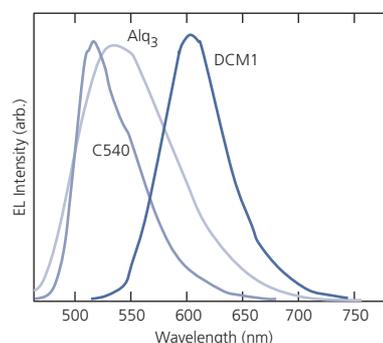

$$\Gamma^2 \propto \frac{q^2}{(4\pi\epsilon_0)^2 n_r R_{DA}^2} \exp(-2R_{DA}/L). \quad (6.37)$$

Here,  $L$  is the intermolecular spacing as determined by van der Waals forces of the molecules, and  $n_r$  is the refractive index. Hence, the rate of exciton transfer falls off exponentially with distance between guest and host.

- (iii) *Direct charge trapping on the dopant:* Direct charge injection onto the emissive guest molecule from the ETL and/or HTL can result in exciton formation that bypasses the host entirely. Similarly, the host molecule can be used to transport one of the charge carriers to the emitting guest molecule, taking advantage of the higher mobility of the host than the guest for that particular charge. Charge trapping is illustrated in Fig. 6.35. Trapping can excite either fluorescent or phosphorescent molecules since the processes are spin-independent. However, the exciton formation statistics are the same for direct charge trapping as for exchange and FRET processes. That is, 25% of excitons formed by trapping will be singlets, with the remainder being triplets. This excitation mechanism is particularly prevalent in blue emitting OLEDs and PHOLEDs, where the

**Figure 6.35** Two example direct trapping processes. (a) Electron and hole trapping from the LUMO of the ETL and the HOMO of the HTL onto the LUMO and HOMO levels of the dopant (dashed lines). (b) Trapping from the HOMO of the HTL to that of the dopant, and direct trapping from the host (solid line in the EML) LUMO to that of the guest.

**Figure 6.36** Spectra of C540 and DCM1 doped fluorescent OLEDs with an Alq<sub>3</sub> host compared with the emission spectrum of neat Alq<sub>3</sub> (Tang et al., 1989).

choice of high energy hosts that can efficiently exothermically transfer excited states from host to guest is limited (Holmes et al., 2003a).

Figure 6.36 shows the OLED EL spectra due to FRET in an EML comprising an electron conducting Alq<sub>3</sub> host doped with 1 mol. % of the green fluorophore, coumarin 540, or 0.25 mol. % of the red emitting, DCM1. The OLED emission from the doped devices is compared with that from an undoped Alq<sub>3</sub> EML. The EML is 60 nm thick, and is sandwiched between a Mg:Ag cathode and a 75 nm thick TAPC HTL on an ITO anode. The lack of Alq<sub>3</sub> emission from the DCM1 OLED indicates complete Förster energy transfer, even at only 0.25 mol. % dopant concentration. However, a small shoulder on the long wavelength edge of the coumarin 540 spectrum indicates residual Alq<sub>3</sub> emission. The higher energy of this dopant reduces the overlap between its emission spectrum and the absorption spectrum of the host,

thus making FRET somewhat less efficient than for the red-emitting device. However, both doped OLEDs have nearly twice the efficiency of the neat Alq<sub>3</sub> device. The higher efficiency is a consequence of the low doping of the fluorescent centers.

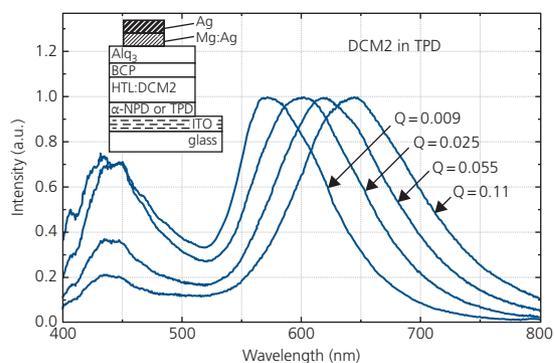

In a set of experiments analogous to those in Fig. 6.33, the doped devices were modified by inserting a thin (4 nm) doped DCM2 exciton sensing layer at various distances from the HTL/Alq<sub>3</sub> interface. The ratio of green emission intensity from Alq<sub>3</sub> to red emission from DCM1 is used to quantitatively determine the exciton diffusion length,  $L_D$ , from the interface using (Tang et al., 1989)

$$\eta_{\text{ext}}(\lambda) = (1 - \exp(-x/L_D))\eta_{\text{Alq}_3}(\lambda) + \exp(-x/L_D)\eta_{\text{DCM}_2}(\lambda). \quad (6.38)$$

Here,  $\eta_{\text{Alq}_3}$  and  $\eta_{\text{DCM}_2}$  are the external quantum efficiencies of the neat Alq<sub>3</sub> and the Alq<sub>3</sub>/DCM2 doped OLEDs, respectively. Using this procedure, an exciton diffusion length of 20 nm is obtained for Alq<sub>3</sub>. This is somewhat longer than obtained via more direct methods, where  $L_D \sim 8\text{--}15$  nm is typical of singlet excitons in several fluorescent materials (Wu et al., 2005, Lunt et al., 2009). The difference may be due to uncertainties in sensing layer thickness, exciton generation at sites near, but not at the HJ, charge trapping by the low energy LUMO or HOMO of the dopant compared to the host, or quenching at electrodes.

Doping of a luminescent molecule into a host can result in spectral shifts arising from the solid state solvation effect (SSSE, see Section 3.6.7). Here, the dipole field from a host molecule interacts with the dipole of the emitting molecular species, changing the local electric field. This results in a change in the relative stability of the ground and excited states, leading to a concomitant change in the exciton energy. Devices based on the dipolar fluorophore, DCM2 (with a dipole moment of  $p = 11$  D), exhibited a rigid red shift attributed to solvation of the dipolar DCM2 in the Alq<sub>3</sub> matrix ( $p = 5.5$  D) (Bulovic et al., 1998c). Since that early experiment, SSSE has been observed in numerous fluorescent systems (Green et al., 2013, Chang et al., 2015).

Color tuning of OLEDs via solvatochromism is shown in Fig. 6.37. The device in the inset consists of DCM2 mixed into the relatively non-polar TPD HTL ( $p = 1.5$  D). A rigid and dramatic bathochromic shift of 0.25 eV in the OLED EL spectra as the relative concentration of DCM2,  $Q$ , increases from 0.009 to 0.11 results from an increase in the average dipole moment of the binary mixture (Bulovic et al., 1999).

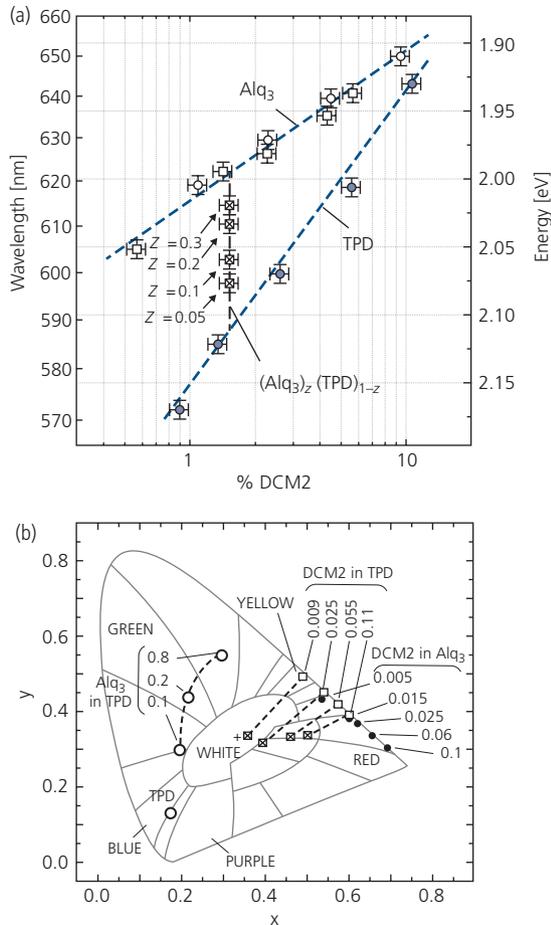

**Figure 6.37** Solid state solvation effect observed in the EL spectrum of an OLED with different fractions ( $Q$ ) of the red emitting fluorophore, DCM2 in TPD. The peak at 420 nm is due to TPD emission resulting in incomplete energy transfer to DCM2 (with peak emission at 575 nm) as  $Q$  is decreased (Bulovic et al., 1999).

Reprinted from Chemical Physics Letters, 308, Bulovic, V., Deshpande, R., Thompson, M. E. & Forrest, S. R., Tuning the color emission of thin film molecular organic light emitting devices by the solid state solvation effect, 317-322, 1999, with permission from Elsevier.

At the smallest concentrations, the mixture is only weakly polar due to the TPD, but as the DCM2 fraction increases, the emitting molecule is in an increasingly dipolar environment due to nearby DCM2 molecules.

Including Alq<sub>3</sub> as a second dipolar dopant into the EML increases the color tuning range. The peak emission wavelength as a function of both DCM2 and Alq<sub>3</sub> fraction ( $Z$ ) in TPD is shown in Fig. 6.38a. The spectral peak shifts from 570 nm at low DCM2 concentration in TPD, to as long as 650 nm for DCM2 in Alq<sub>3</sub>. In all devices, the DCM2 spectral shift was rigidochromic, that is, there was no apparent spectral broadening as the peak position changes. *Rigidochromism* is a distinguishing characteristic of SSSE.

Since Alq<sub>3</sub> emits in the green, and TPD in the blue, a large color gamut extending across a significant fraction of the visible spectrum (including the isochromic white point) is accessible by variations of concentration of the molecular constituents (see Fig. 6.38b). However, the quantum efficiency is also a function of DCM2 and Alq<sub>3</sub> concentrations. The peak  $\eta_{\text{ext}} = 0.7\%$  at  $j = 1$  mA/cm<sup>2</sup> and  $Z = 0.2$ , but falls to 0.2% at  $Z = 0.1$  for a DCM2 concentration of 1.5%. The loss in  $\eta_{\text{ext}}$  is due to the reduced Förster energy transfer efficiency from TPD to Alq<sub>3</sub> to DCM2 at low  $Z$  as the Förster radius becomes comparable to the molecular spacing. At higher Alq<sub>3</sub> and TPD concentrations than  $Z = 0.2$ , the reduced efficiency results from increased concentration quenching

**Figure 6.38** (a) Color tuning the OLED EL emission spectrum by varying the relative concentrations of DCM2 and Alq<sub>3</sub> in a TPD hole transport layer.  $Z$  is the Alq<sub>3</sub> fraction. The TPD is weakly polar. The wavelength can be tuned from 573 nm to 650 nm by the addition of the more polar DCM2 and Alq<sub>3</sub>. (b) Colors accessible as a function of the concentrations of the constituents. TPD emits in the blue, Alq<sub>3</sub> in the green and DCM2 in the red, availing a large color gamut to this ternary system. Filled circles = DCM2 in Alq<sub>3</sub>, open circles = TPD in Alq<sub>3</sub>, crossed squares = DCM2 in TPD. Numbers correspond to the dopant fraction (Bulovic et al., 1999).

Reprinted from Chemical Physics Letters, 308, Bulovic, V., Deshpande, R., Thompson, M. E. & Forrest, S. R., Tuning the color emission of thin film molecular organic light emitting devices by the solid state solvation effect., 317-322, 1999, with permission from Elsevier.

between host molecules. Hence, while SSSE can be useful in tuning the OLED color coordinates, it comes at the cost of reduced efficiency as the concentrations of dopant and hosts are adjusted to reach the desired emission color.

### 6.3.2.3 Small molecule fluorescent dopants and hosts

The variety of materials used in OLEDs, whether they are for injection, charge transport or emission, is enormous, and its proper treatment would consume a

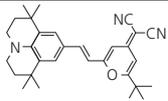

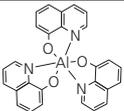

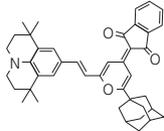

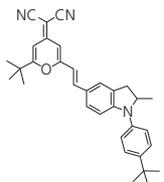

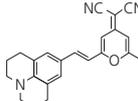

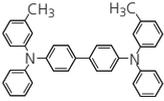

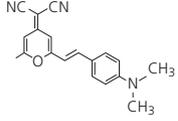

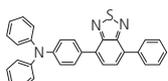

volume all by itself. Due to the advent of exceptionally high efficiency of PHOLEDs compared to their fluorescent analogues, work on fluorophore discovery has recently been almost entirely directed at blue emitting materials combinations whose operational lifetime still exceeds that of blue PHOLEDs. In this section, we will briefly highlight advances in red, green and blue fluorescent dopants and hosts. The purpose is to introduce representative materials and the challenges faced in finding practical materials for use in modern OLEDs. For a more comprehensive discussion, the reader is referred to the many review papers on this topic (Chen, 2004, Wen et al., 2005, Jeong et al., 2015, Jou et al., 2015).

Light emitting dopants must satisfy several conditions to be of interest. (i) They must emit with the desired color coordinates. For displays, the emission colors should be close to the coordinates required either for sRGB or NTSC standards in the red (R), green (G), and blue (B) (see Section 6.2). For lighting, the white isochromatic point can be accessed by three (or more) colors (R, G, B), or by only two colors at the end of a line extending from blue-green to yellow. There is little need, except for specialized purposes to develop OLEDs emitting at other color coordinates. (ii) Their luminance intensity must be sufficiently high for the intended application (typically at least 500 cd/m<sup>2</sup> for displays and 3000 cd/m<sup>2</sup> lighting). (iii) They must have high efficiency, and in particular their PL quantum yield must approach unity. (iv) They must be stable, leading to a long OLED operating lifetime.

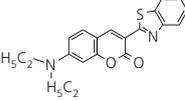

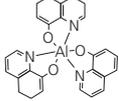

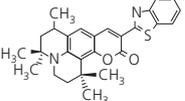

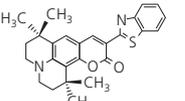

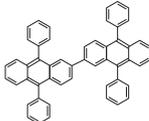

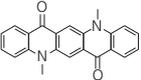

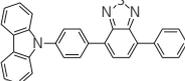

In Tables 6.3, 6.4, and 6.5, we list example dopant/host combinations employed in red, green, and blue fluorescent OLEDs, respectively. The materials included in these tables do not undergo TADF, a topic that is the subject of Section 6.3.4. However, devices with exceptionally high (>5%) fluorescent external quantum efficiencies may have some degree of delayed fluorescence, or they may preferentially align with their transition dipole moments (TDMs) parallel to the substrate plane, thus increasing the outcoupling efficiency,  $\eta_{out}$ , to greater than ~20% expected for OLEDs on flat glass substrates (Section 6.6.5). The external quantum efficiencies listed are generally < 5%, which is consistent with a maximum singlet spin formation ratio of  $\chi_S = 25\%$ .

With four exceptions (guest-host systems **5R**, **7R**, **10R**, **11R**, Table 6.3), all red emitting devices employ only Alq<sub>3</sub> as the electron conducting host material. The alternative host is rubrene doped with DBP (Okumoto et al., 2006a) and TPD doped with DCM2 (Bulovic et al., 1999). The latter device emits in the

orange due to incomplete energy transfer from the blue fluorescent TPD, thus allowing for dilution of the pure red emission of DCM2 by a small blue peak.

Interestingly, a high efficiency, orange-red device (**11R**) is obtained with a neat thiazole-containing moiety, TPA-BZP (Wang et al., 2016). This is probably enabled by the twist of the molecule of approximately 40–50° at each of the three single C–C bonds along the molecular longitudinal axis that sterically hinders the molecules from close packing in the solid state. The limited packing reduces concentration quenching often found in more planar molecular systems. A similar molecule (CzP-BZP) also shows very high efficiency green emission in an undoped EML (**7G**, Table 6.4). The non-planar motif is used in the design of blue emitting chromophores due to their tendency to exhibit red-shifted exciplex emission when closely packed.

It is notable that the difference in structures between the red and green emitting BZP molecules lies only in a single bond: the carbazole donor of the green emitting CzP-BZP that links the two phenyl groups is absent in TPA-BCP. This bond results in a shift in emission to well into the green. The strong donor character of the latter molecule creates a low energy CT state that is only weakly hybridized with the local, singlet exciton. This is in contrast to the reduced donor character of the carbazole group in CzP-BZP that results in a higher degree of singlet localization, thus lifting the energy of emission into the green. This pair of molecules is an example of how minor molecular structural modifications can result in significant changes in the donor or acceptor character and charge distributions, and consequently the excited state energies.

There are many other molecules that have been investigated for their saturated red emission. Most

notable are the metal-free phenyl porphyrin derivatives (Shen et al., 1997). A comprehensive description of many of these compounds is found elsewhere (Chen, 2004). They have not been included in Table 6.3 due to their low efficiencies (typically <1%), and hence are of limited technological significance.

Almost all efficient green fluorescent dopants are based on some variation of either coumarin or quinacridone. As in the case of red devices, the most commonly used host is Alq<sub>3</sub>. An exceptionally high efficiency is achieved by doping Coumarin 545T in TPBA (**4G**) (Okumoto et al., 2006b). It is unclear why this particular device has an external quantum efficiency of 9.3% that implies a singlet fraction > 25%.

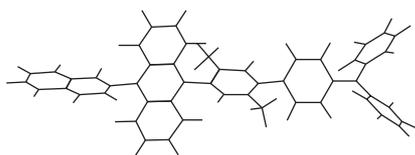

Indeed, assuming  $\eta_{\text{out}} \sim 20\%$ , an external quantum efficiency of  $\sim 5\%$  is the maximum value achievable for 100% singlet emission efficiency. Violation of spin statistics is unlikely, given that a similarly doped device employing Alq<sub>3</sub> as the host shows efficiency well below 5%. Two possibilities that would explain the high efficiency achieved with coumarin 545T/TPBA is preferential horizontal alignment of the excited state dipole moment relative to the substrate arising from the planarity of both dopant and host molecules, or additional emission via delayed fluorescence.

Table 6.5 lists several representative deep blue emitting fluorophores. Many approaches to blue

emission start by employing a small polycyclic aromatic hydrocarbon with high fluorescence efficiency in the blue, such as anthracene, pyrene, or fluorene. These planar emitting molecules have the advantage of being exceptionally thermally stable. Unfortunately, their planarity leads to a tendency to form extended  $\pi$ -stacks, and hence in the solid state they typically emit from low energy excimers. This results in undesirably broad and low efficiency emission shifted to the green or red. Hence, the design motif leading to efficient blue emission involves the addition of bulky side or end groups that are attached to the luminescent center along a conjugated molecular backbone. These groups twist out-of-plane to prevent close packing.

Examples of this molecular design strategy are the xylene- and dinaphthal-anthracenes (compounds **1B**, **2B**, Table 6.5) that connect bulky end groups via intermediate phenyl moieties. The twist along the backbone of TPAXAN shown in Fig. 6.39, is due to repulsion of electronic orbitals in neighboring molecular groups. A similarly sterically hindered design is employed for the dimethylphenyl dipyrene molecule, DMPP (**3B**). In that case the emitting pyrene moiety appears as end capping groups about a central phenyl ring. An alternative strategy to create steric hindrance is to use a *spiro* architecture such as the spirofluorene and similarly bulky molecules **4B** and **6B**, or to attach a very bulky end cap, such as the Si-based group in **5B**.

Blue luminance in the absence of a planar aromatic molecular core can be achieved by a dipolar molecule that contains both an electron donating (d) and accepting (a) group at opposite ends of its conjugated backbone, such as compound **9B**. This approach shifts the emission from the red to the green for the donor-acceptor species **11R** and **7G**. The challenge of employing d-a structures in the blue is that they form CT states as precursors to the emitting localized exciton (LE) state. The CT state has a low energy and hence may result in unacceptable red shifts in emission. Hence, **9B** consists of a very high energy, violet-emitting PPI donor group with a peak wavelength of  $\lambda_{\max} = 369$

**Figure 6.39** Three-dimensional (3D) molecular structure of TPAXAN (compound **1B**, Table 6.5) showing a pronounced twist of the groups attached to the C–C bonds along the molecular backbone. The twist is due to electronic repulsion between neighboring functional groups (Kim et al., 2013a).

nm attached to a triphenylamine (TPA) acceptor via a biphenyl moiety that introduces a twist between the TPA and PPI. This results in a partial decoupling of their electronic orbitals, red shifting the emission. OLEDs using **9B** reach 5% external efficiency in the deep blue at  $\lambda_{\max} = 438$  nm (Li et al., 2012).

Although blue emitting molecules are designed to sterically inhibit stacking, several unusually high external efficiencies  $> 5\%$  (e.g. **4B–8B**) suggest that these species orient with their planar emitting moieties parallel to the substrate plane, that is, the *transition dipole moment* (TDM) is oriented such that emission is principally at angles less than that which results in TIR in the substrate (approximately within a cone with half angle of  $20^\circ$ , see Section 6.6). Alternatively, the high energy of the singlet excited state may lead to additional delayed fluorescence from TTA.

Steric hindrance often eliminates the need for dilution in a wide energy gap host. Indeed, the very high energy of the blue singlet state significantly limits the choice of hosts that do not trap charges or excitons at lower lying energy states. Trapping siphons energy away from the emitting molecule, thus reducing efficiency. Hence, with only a few exceptions (**4B–6B**, **8B**, **10B**), blue fluorescent OLEDs do not employ a host molecule in the EML.

To confine the blue excitons within the EML, many devices include a blocking layer with a higher energy gap than the dopant (or host) in the EML. These layers can be occasionally found in green and red fluorescent OLEDs as well. As discussed throughout this chapter, the OLED comprises many layers ranging from charge transport and injection layers, to the guest–host emitting system, and blocking layers. The materials used for these purposes are highly diverse, with many different solutions applied to OLEDs emitting in different regions of the spectrum. Those interested in exploring this topic are referred to texts in *Further reading* to learn more about the challenges and solutions arrived at for achieving a diversity of high performance OLED structures. In particular, comprehensive treatments of charge transporting, blocking, and injecting materials can be found in O'Brien et al. (1998), Kulkarni et al. (2004), Shirota and Kageyama (2007), Gaspar and Plikarov (2015), Ho et al. (2015), and Jou et al. (2015).

#### 6.3.2.4 Fluorescent polymer OLEDs

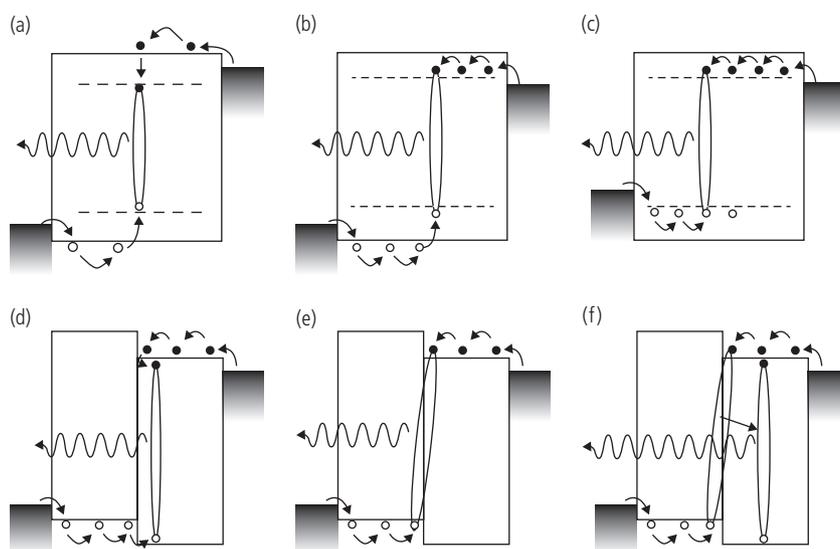

Polymer OLEDs were first demonstrated by spin coating a 70 nm thick film of PPV onto the surface of a glass substrate with a pre-deposited ITO anode (Burroughes et al., 1990). While this thin film device had a relatively low operating voltage of  $\sim 13$  V, the electric field required to produce measurable

luminescence was  $2 \times 10^6$  V/cm. This is three orders of magnitude higher than required in the anthracene single crystal EL device in Fig. 6.32, but only marginally higher than in the  $\text{Alq}_3$ -based bilayer device in Fig. 6.3. The PPV voltage, therefore, is low only due to the thinness of the PPV film. Due to the limited ability of PPV to conduct electrons whose mobility is considerably less than that of holes (Blom et al., 1996), and its low PL quantum yield of 8%, the external fluorescence quantum efficiency was only  $\sim 0.05\%$  for emission in the yellow-green spectral region with a peak at 2.2 eV ( $\sim 565$  nm wavelength).

In previous sections we have shown the benefits of using multilayer structures to achieve high performance. However, the challenges encountered in making devices comprising several solution-processed layers have given rise to strategies that circumvent this limitation. For example, blending a second polymer with improved electron conducting properties into an otherwise hole conducting emissive polymer layer, or using polymers that can support bipolar charge conducting via side chain or main chain functionalization, are two approaches to reducing the operating voltage. Significant early improvements were realized by employing more luminescent polymers with improved charge balance (i.e. where the electron and hole mobilities are approximately equal) compared to PPV-based devices. Improved charge injection is achieved by replacing the Al cathode (which forms an insulating oxide barrier) with Ca or Ba (Cao et al., 1999).

Many improvements have also been realized by employing multilayer structures along with the light emitting polymer blends that have both hole and electron conducting functionality. As discussed previously, charge injection and exciton formation can occur by numerous routes, even in simple two and three layer devices. Mechanisms for charge transport and exciton formation in single layer blend and bilayer polymer OLEDs are summarized in Fig. 6.40. In Fig. 6.40a, a large energy gap host polymer transports both electrons and holes that become trapped by the smaller energy gap, light emitting guest. A disadvantage of this structure is that the host is called upon to transport both charge carriers with nearly equal mobilities to avoid forming the emission zone near one of the contacts. This can lead to exciton quenching at the electrodes, and an emission zone position that is dependent on current and voltage. The shifting position of the emission zone results in a variable optical outcoupling efficiency, depending on the brightness.

Figure 6.40b partially resolves this problem by using the guest lumophore to conduct one of the charge carriers (electrons), with the host conducting the opposite charge (holes). Thus, the guest may be optimized for both its luminescence efficiency and its ability to conduct one of the two charges, while the host provides a high mobility medium for transport of the counter charge. Figure 6.40c has the same problems as Fig. 6.40a since the guest is responsible for both electron and hole conduction and exciton formation.

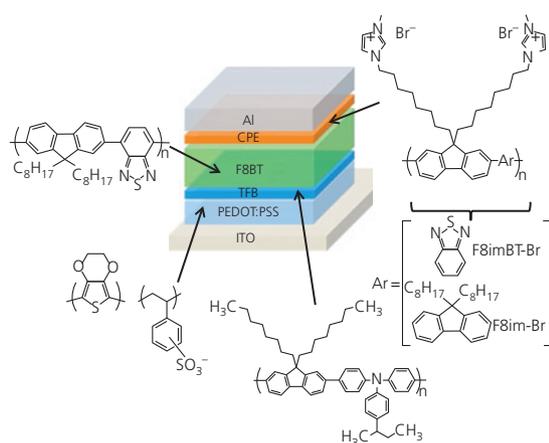

**Figure 6.40** Charge transport and exciton formation in single layer blend (a–c) and bilayer type II heterojunction (e–f) OLEDs. The dashed lines in a–f indicate the energy levels of the light emitting polymer species. The ellipses represent excitons (McNeill and Greenham, 2009).

Doping a luminescent guest within a “passive” host may result in higher luminance due to a reduction in concentration quenching, although a low guest–host blend ratio also decreases the conductivity, thereby increasing operating voltage.

Figures 6.40d–f show bilayer devices where the functionalities of the two materials forming the type II (staggered) HJ are separately optimized. Figure 6.40d represents a device in which excitons are formed in the high electron mobility layer due to leakage of holes from the opposite layer into the ETL/EML interface region. Of course, the opposite situation can also be engineered, where the EML is within the HTL. In Fig. 6.40e, emission is from an exciplex (i.e. a CT state) formed across the interface. This route dominates when the energy level offsets at either the HOMO or LUMO edges of the contacting semiconductors are too high to allow for leakage into the adjacent layer (Fig. 6.40d), thus preventing direct exciton formation. The final case, Fig. 6.40f shows the formation of a precursor CT state that subsequently transfers into one of the polymers to form a localized exciton. As in Fig. 6.40d, this structure relies on sufficiently small energy barriers ( $\sim k_B T$ ) at either the HOMO or LUMO energies to allow for charge hopping across the heterointerface at room temperature.

An efficient, green emitting multilayer polymer OLED comprising separate layers for hole injection, emission and electron injection is shown in Fig. 6.41. This  $\sim 130$  nm thick device is effectively a combination of strategies shown in Fig. 6.40a and d, where the 40 nm thick PEDOT:PSS/10–15 nm thick TFB layer delivers holes to the 70 nm thick ambipolar conducting and emitting F8BT EML, and electrons are transported to

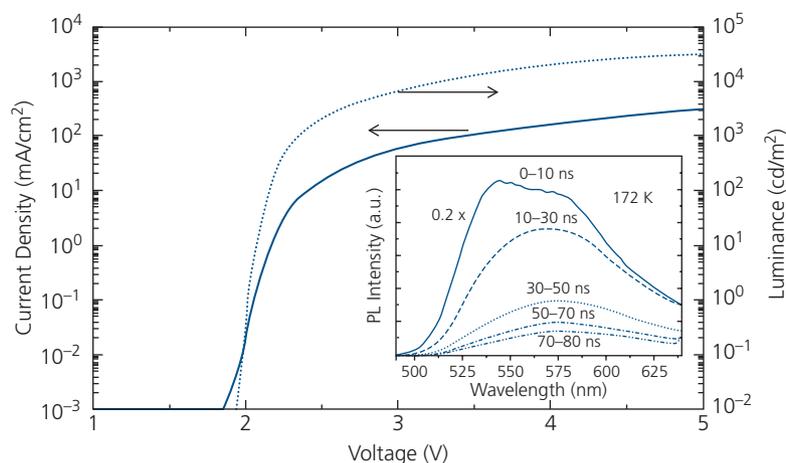

**Figure 6.41** Multilayer, green emitting fluorescent polymer OLED showing the structural formulae of polymers used in each layer. After Suh et al. (2015).

the EML by the  $\sim 10$  nm thick CPE EIL. The CPE comprises a poly[(9,9-bis(8'-(3''-methyl-1''-imidazolium)octyl)-2,7-fluorene)] brominated polyelectrolyte backbone functionalized by one of the two groups shown (2,7-(9,9-dioctylfluorene) in F8im-Br, and benzo(2,1,3)thiadiazol-4,8-diyl in F8imBT-Br). In spite of the presence of the ionic  $\text{Br}^-$  and imidazole cation, these devices showed surprisingly fast electroluminescent switching ( $< 10$   $\mu\text{s}$ ), along with a maximum  $\eta_{\text{ext}} = 5.1\%$ , and luminous efficiency of 10.8 cd/A at 100 cd/m<sup>2</sup> (for F8imBT-Br). The F8BT emits in the green with peak intensity at approximately 550 nm. Taken together, this multilayer structure shows a remarkable improvement in characteristics compared to single layer polymer OLEDs.

The TFB layer in the OLED is used as both an exciton and electron blocking layer. Its energy gap ( $> 3.0$  eV) is wider than that of F8BT ( $\sim 2.3$  eV), hence preventing excitons from diffusing to the PEDOT:PSS HIL where they are quenched. Also, electrons injected from the cathode stop at this interlayer (Kim et al., 2005). Due to these benefits, interlayers are now commonly employed in efficient polymer OLEDs.

Interestingly, TFB:F8BT OLEDs form type II HJs, resulting in exciplex emission, as illustrated in Fig. 6.40e. A characteristic of exciplex emission is that it is potentially “lossless,” that is, the exciplex is formed without encountering an energy barrier between the free polarons and the excited state (Morteani et al., 2003). This is apparent from the low ( $< 2\text{V}$ ) voltage needed at the onset of current and luminance in Fig. 6.42. The photon emission from F8BT is 2.29 eV (corresponding to  $\lambda_{\text{max}} = 538$  nm), which is below the threshold for luminance turn-on. The exciplex emits at 2.1 eV (580 nm), with a tail extending into the NIR at 1.8 eV (Fig. 6.42, inset), which is accessible at the low turn-on voltage observed. The “energy barrier free” exciplex emission occurs  $> 10$  ns after the onset of the exciton emission; a delay that arises from slow diffusion of the exciton and charges from the F8BT to the HJ.

Photon emission at applied voltages less than the band gap is a well-known phenomenon in inorganic light emitting diodes. This “sub-bandgap emission” is due to charge diffusion to and band-to-band recombination in the quasi-neutral regions adjacent to the p-n junction. Thus, weak emission can be observed with sufficiently sensitive detection equipment at an arbitrarily low voltage. Similarly, it has been shown that OLEDs can emit at well below the energy gap of the emitting material as a result of similar drift-diffusion driven by the built-in potential of the organic HJ (Engmann et al., 2019). A dramatic

**Figure 6.42** Current density and luminance vs. voltage characteristics of a TFB:F8BT OLED. The onset of both luminance and current is at  $\sim 1.9$  V. Inset: PL spectra of the active layer as a function of time delay from the optical pump pulse. The peak F8BT emission is at 538 nm, and the exciplex peak emerges after a short delay at 580 nm. After Morteani et al. (2003).

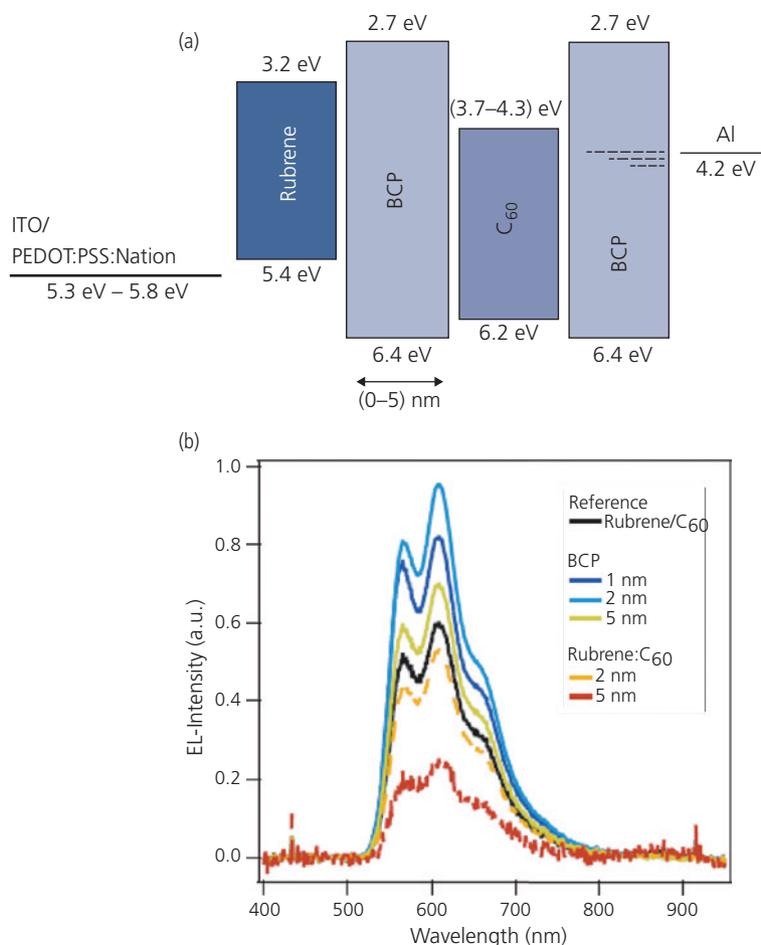

demonstration of emission at half the energy gap of rubrene is observed for OLEDs whose energy level diagrams are shown in Fig. 6.43a. The devices comprise a rubrene EML (with optical energy gap of 2.2 eV), and a  $C_{60}$  ETL. These are spaced apart by a wide energy gap layer of BCP whose thickness is varied from  $x = 0$  (no spacer) to 5 nm, or by a co-evaporated, blended region of rubrene and  $C_{60}$  (in a 1:1 ratio) that is either  $y = 2$  or 5 nm thick. The BCP spacer is used to prevent formation and recombination of low energy charge transfer states at the rubrene/ $C_{60}$  interface, while the blended device should enhance the formation of such states.

The  $j$ - $V$  characteristics show a rapid turn-on at  $< 1$  V for devices with spacers, and with a forward-biased ideality factor of  $n = 1.44$  for  $x > 0$  and 1.62 for  $x = 0$ , suggesting that a mixture of diffusion and recombination determines the current. The neat rubrene device has a turn-on at 2 V and  $n = 2$  indicative of pure recombination (see Section 4.5.2). The luminance intensity is observed to turn-on at approximately the same voltage of  $\sim 1$  V, independent of  $x$  or  $y$ . Remarkably, this is less than half of the energy gap of rubrene. The neat rubrene device, however, shows a luminance turn-on at 2.8 V. Importantly, the emission spectrum is the same for all devices tested, as shown in Fig. 6.43b.

Since rubrene has a triplet energy equal to  $\frac{1}{2}E_G$ , it is reasonable to expect that the device undergoes singlet fission into two triplet states (Section 3.10). This may account for the very low voltage (approximately 50% of the energy gap) turn-on of the emission. However, the lack of change of spectrum from that characteristic

of rubrene  $S_1 \rightarrow S_0$  transitions, coupled to the fact that the emission intensity *increases* by a factor of 3 by the interposition of a BCP interlayer, suggesting that singlet fission is not the source of the low voltage luminance turn-on. Furthermore, Auger recombination that involves the promotion of excited states to higher energies via bimolecular interactions, also cannot account for the increased efficiency. Auger processes require that two excitons combine to form a higher energy state, thus *decreasing* the efficiency by at least 50% (see Section 4.5.3). The lack of CT emission and the increase in efficiency achieved when the BCP layer is inserted at the HJ are both indications that the low voltage turn-on is not caused by the emission from these lower energy states. Indeed, the mixed rubrene:  $C_{60}$  interface devices should show very strong CT emission, yet they have efficiencies even lower than those of the conventional device with  $x = 0$ . Hence, we conclude that the sub-energy-gap emission is due to charge drift and diffusion at the HJ; a mechanism that is the same as that attributed to sub-bandgap emission in inorganic LEDs (Engmann et al., 2019).

As discussed in Chapter 5, the ability to form multi-layer structures using solution-based processes is somewhat limited since the solvent used in the deposition of one layer can degrade materials previously deposited in the device stack. In the device in Fig. 6.41, this problem is partially mitigated by using layers with orthogonal solvents (i.e. PEDOT:PSS uses an aqueous solvent, followed by TFB in a *p*-xylene solution). F8BT also uses *p*-xylene, and CPE is dissolved in 2-methoxyethanol, which is a non-orthogonal solvent that can attack the underlying

**Figure 6.43** (a) Energy level diagram of a rubrene/ $C_{60}$  OLED employing a  $x = 0\text{--}5$  nm thick BCP interface layer and a BCP exciton blocker. (b) Emission spectra for the devices in (a) (Engmann et al., 2019).

layers. To minimize layer interactions, they are hardened by baking prior to application of the subsequent layers. An alternative strategy to fabrication of multi-layer structures is to employ polymers that undergo cross-linking under ultraviolet radiation or at elevated temperatures (Sekine et al., 2014). This alters their solubility in solvents used in their deposition. In any case, fabrication of solution processed multi-layer structures with reproducible characteristics can present significant challenges in a high volume manufacturing environment (Ho et al., 2015).

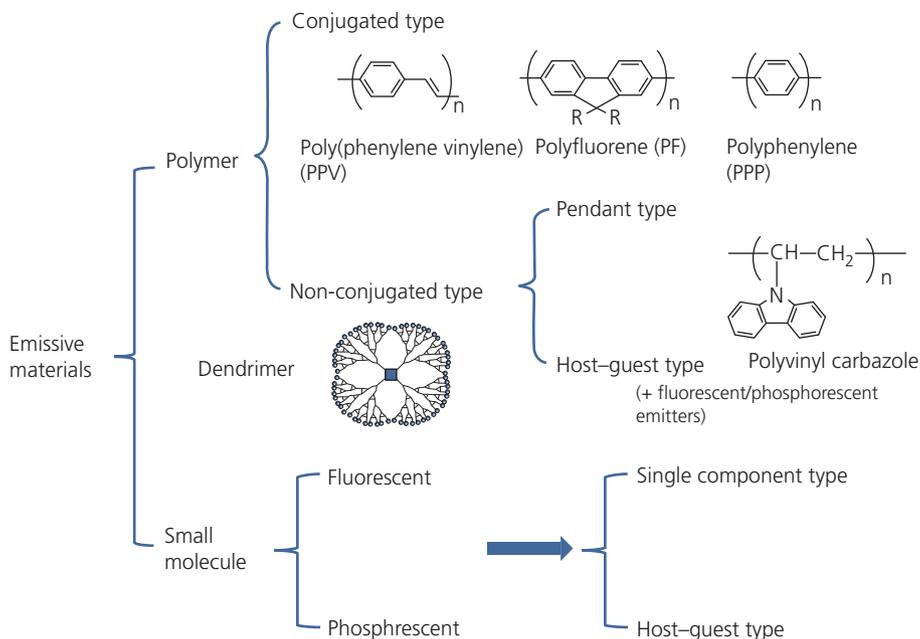

### 6.3.2.5 Materials for fluorescent polymer OLEDs

As in our treatment of small molecule materials, here we discuss only a few example polymer systems and the molecular design strategies leading to high performance devices. There are two primary routes to engineering high efficiency *light emitting polymers* (LEP) summarized in Fig. 6.44. The first is to use a

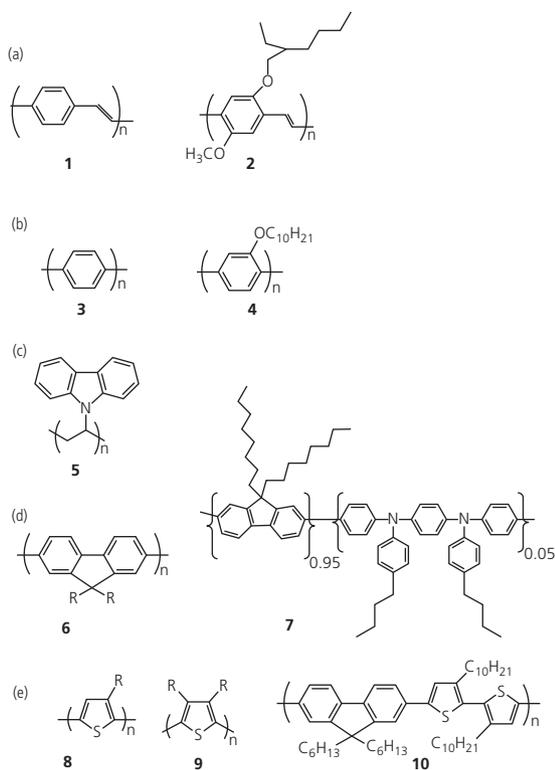

conjugated, emissive polymer that falls into one of several different classes exemplified by PPV, polyfluorene (PF), poly-*p*-phenylene (PPP), polyvinyl carbazole (PVK), and polythiophene (PT). Examples of these conjugated polymers are shown in Fig. 6.45.

*Copolymerization* is also used to achieve desired properties, as illustrated in Fig. 6.46. Starting with a conjugated backbone moiety such as a fluorine or PPP, fractions of electron and hole transporting units (e.g. benzothiophenes or amines) along with emitting centers such as small molecules or dendrimers are blended with, or copolymerized into the backbone. Thus, the molecular composition can be precisely controlled to achieve the optimized monomer ratios and sequences that combine multiple functionalities into a single molecular structure.

Conjugated polymers have the advantage of a simplified device structure that requires only a single, or at most two different materials (i.e. the emitting and

**Figure 6.44** Strategies for the design of light emitting polymers used in OLEDs. Adapted from Sekine et al. (2014).

(a) **1** PPV and **2** MEH-PPV; (b) **3** PPP and **4** MEH-PPP; (c) **5** PVK; (d) **6** PF and **7** (King et al., 2011); (e) **8**, **9** PT, with  $R$  = alkanes for increased solubility, and **10** (Perepichka et al., 2005).

charge transporting polymer and a blocking inter-layer). The emitting chromophores are often linked, or doped within the conjugated polymers backbone. To prevent emission or siphoning off of energy, the backbone units such as PF must be at higher energy than the emissive segments. Furthermore, using conjugated polymers requires that a single molecular species be both a good electron and hole conductor, and often it must also serve as an efficient emitting material. OLEDs following this approach often sacrifice efficiency for simplicity.

A second approach is to use pendant or side chain groups attached to a non-conjugated polymer backbone, or host-guest blends whose constituents are separately optimized to perform the charge transport and/or emissive functions. One example in Fig. 6.45 is PVK, where the emitting carbazole is pendant to a polyvinyl backbone. This separate functionalization is a potentially simpler route to synthesis and optimization.

Up to this point we have discussed strategies for achieving high efficacy fluorescent polymer OLEDs. Clearly, the scope for achieving the desired functionalities via molecular variation is enormous, and has been the subject of considerable research over many years. In Table 6.6 we provide a few illustrative examples of polymer OLED materials. The reader is once more directed to several reviews, and *Further reading* to obtain a comprehensive appreciation for this subject (Kulkarni et al., 2004,

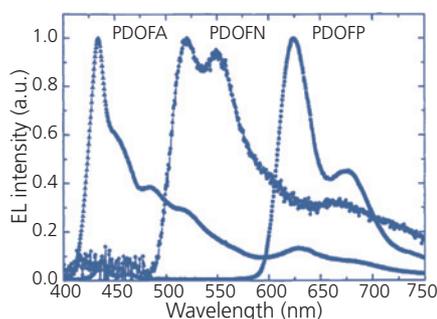

**Figure 6.46** Strategy for copolymerization to achieve high conductivity and emitting efficiency in a single polymer (Sekine et al., 2014).

Perepichka et al., 2005, Cheng et al., 2008, Gong, 2013, Ho et al., 2015).

In Table 6.6, we observe that almost all efficient systems (with the exception of **3O** and **9B**) comprise conjugated copolymers with a PVK core. Polyfluorene copolymerized with polyacene emitting groups with increasingly long conjugation lengths (and hence lower singlet energies) are exemplified by compounds **1R**, **4G**, and **7B**. The dependence of wavelength on polyacene molecular weight is shown by the spectra of these compounds in Fig. 6.47. These compounds are, in descending order of molecular weight, copolymers with pentacene, tetracene, and anthracene. The conjugation length of each successively larger polyacene group is increased, shifting the emission from the blue into the red. Hence, the peak wavelengths are  $\lambda_{\text{peak}} = 625$  nm for pentacene, to 525 nm for tetracene and 435 nm for anthracene (Tokito et al., 2001).

In the table we have not listed any thiophene-based compounds as those do not tend to have high efficiency. Furthermore, nearly all devices have a PEDOT:PSS hole injection layer, and **6G** and **9B** employ multiple hole injecting and electron blocking interlayers at the anode side. To avoid dissolution of the deposited layers, the hole transporting 2-NPD in **5G** is thermally cross-linked at 180°C for 30 min prior to the deposition of the copolymer PFBT5. This process ensures resistance to dissolution in solvents used in subsequent layer depositions (Cheng et al., 2008). Most of the highest efficiency devices include a PEDOT:PSS HIL, a hole conducting layer, and an interlayer (the latter two layers often being combined into a single layer) as for the device in Fig. 6.41. For example, **9B** with saturated blue color coordinates of (0.16, 0.09),

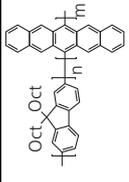

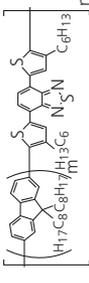

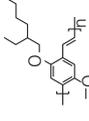

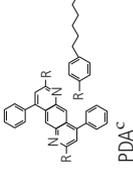

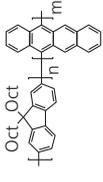

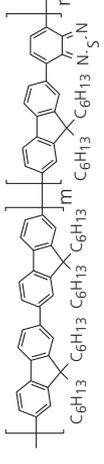

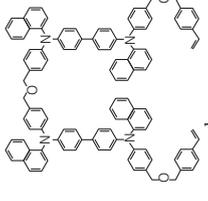

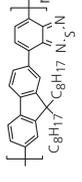

**Figure 6.47** Electroluminescence spectra of OLEDs comprising three fluorine-based copolymers in Table 6.6 based on polyacenes of increasing conjugation length from anthracene (PDOFA, compound **7B**), to tetracene (PDOFN, **4G**), to pentacene (PDOFP, **1R**). This copolymer design strategy shifts the emission peak from the deep blue into the deep red (Tokito et al., 2001).

comprises both a HQTZ HTL and a PVK interlayer, followed by an emissive poly(silafuorene) (PSF) blue EML. All layers were directly spin-coated onto each other, so it is reasonable to assume that a degree of material diffusion and intermixing occurs at the interfaces. Nevertheless, the efficiency of nearly 5% is high for a fluorescent OLED (Xia et al., 2015).

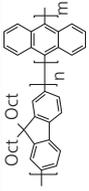

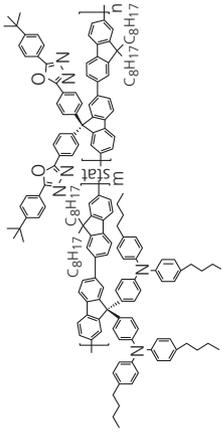

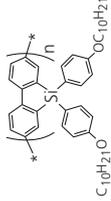

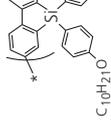

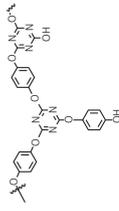

A further notable blue structure is **8B**, comprising the spirofluorene polymer, PF-TPA-OXD, with bipolar transporting groups copolymerized with the PF emitting backbone. The oxadiazole (OXD) group is preferentially electron transporting, whereas the TPA is hole transporting. This is exemplary of the “all-in-one” design strategy illustrated in Fig. 6.46. While this design unquestionably leads to processing simplicity, it is also apparent that performance is sacrificed when employed in an OLED, where only  $\eta_{\text{ext}} = 1.2\%$  is achieved (Shu et al., 2003).

Finally, we point out that the MEH-PPV orange-emitting device, **3O**, differs from the other structures in that it employs an ETL near the cathode. This OLED has the structure of ITO anode/PEDOT:PSS HIL/MEH-PPV EML/PDA ETL/Al. The problem of layer dissolution is resolved by employing an aqueous HIL, followed by deposition of MEH-PPV using an organic solvent. This is followed by VTE of the small molecule ETL, PDA. As a result, the layers have sharp interfaces, leading to a reasonably high  $\eta_{\text{ext}} = 3.1\%$ .

There are numerous other approaches to achieving high efficiency polymer OLEDs. Perhaps the most common is to simply blend in a high efficiency small molecules or dendrimers into the polymer conductive host. This method relies on efficient energy transfer from the polymer to the guest. But an unavoidable conclusion in comparing polymer to small molecule devices is that the potential advantages gained in the simplified layer structures of polymer OLEDs is outweighed by difficulties in device processing, and the consequent loss in device performance arising from interlayer mixing and material incompatibilities. For this reason, small molecule OLEDs have been overwhelmingly adopted for practical applications compared with their polymer analogues.

### 6.3.3 Phosphorescent OLEDs (PHOLEDs)

A significant disadvantage of the fluorescent OLED is that 75% of the electrons and holes injected from the contacts generate non-radiative triplet states, and hence are wasted. This results in devices with low external efficiencies, typically between only 1% and 5%. The situation changed dramatically with the introduction of electrophosphorescence, that is, the use of molecules containing a heavy metal atom that mixes the singlet and triplet states via spin-orbit coupling (Baldo et al., 1998). Electrophosphorescence is characterized by a spin utilization factor of  $\chi_{ST} = 1$ , and hence a possible  $\eta_{\text{int}} = 100\%$  (Adachi et al., 2001a). PHOLEDs also feature longer radiative emission lifetimes ( $\sim 500$  ns to several microseconds) compared with fluorescent devices (1–10 ns). With the prospect of achieving high efficiency PHOLEDs across the visible spectrum, the display industry underwent a tectonic shift that has resulted in OLED domination of the mobile display market where high efficiency leads to longer battery life. More recently, PHOLEDs are making significant inroads into the television and monitor markets

for the same performance-related reasons. Indeed, PHOLEDs are now contenders for use in interior illumination due to their ultrahigh efficiencies, flexible and conformable form factors, and attractive, tunable color coordinates.

Before we consider the technological details, we must first define what is meant by the term, phosphorescence. In Chapter 3 it was found that phosphorescence is conventionally defined as a radiative process that occurs a “noticeable” time after the excitation source has been removed. In the context of organic light emission, it is more accurate to state that *phosphorescence refers to all processes limited by triplet state dynamics*. Direct triplet emission from molecules, whether it originates from slow, spin-forbidden or relatively fast spin-allowed (due to strong spin-orbit coupling) transitions is unambiguously classified as phosphorescence. Triplet-dominated emission also refers to both delayed fluorescence due to TTA, as well as TADF, where the molecules spend typically 99% of the time in a triplet state.

#### 6.3.3.1 Small molecule PHOLED architectures

Electroluminescence from 100% of the molecular excited states using heavy-metal-induced spin-orbit coupling was first demonstrated in a red PHOLED comprising the metalloporphyrin, PtOEP doped into Alq<sub>3</sub> (Baldo et al., 1998). Triplet emission was identified from its high external quantum efficiency (approximately 4% compared to 1% for red fluorescent dopants such as DCM2), but more importantly, due to the slow luminescence decay of 20–30  $\mu\text{s}$ , which is nearly three orders of magnitude longer than for fluorescent emission. A further finding suggesting its triplet origin was the relatively high concentration of the dopant (6%) required to achieve maximum efficiency. As we have seen in Section 6.3.2, fluorescent dopants exchange energy with the host via FRET, which is effective over distances of a few nanometers. However, triplets are most efficiently transferred via Dexter exchange interactions. This process requires the donor and acceptor to be nearly in contact. The doping concentration to achieve high efficiency is, therefore, significantly higher than Förster-mediated transfer. Indeed, it was found that the PtOEP/Alq<sub>3</sub> device had  $\eta_{\text{ext}} = 2\%$  even at concentrations as high as 20%, where Dexter transfer alone is dominant.

A further development in improving the efficiency of triplet-harvesting devices was the introduction of a wide energy gap exciton/hole blocking layer (EBL, or alternatively, HBL) between the EML and the

ETL. The very long lifetime of triplet excitons is accompanied by a long diffusion length, particularly in a host that does not contain a heavy metal atom to promote radiative recombination of the triplet population. As a result, triplets can migrate out of the EML where they are subsequently quenched at the cathode contact. Insertion of a wide energy gap blocking layer prevents quenching by corralling all triplets within the EML, ultimately allowing them to transfer to the heavy metal phosphor. This architecture, applied to a PtOEP based PHOLED, is shown in Fig. 6.48. The host is CBP, bounded by a  $\alpha$ -NPD HTL and a BCP exciton blocking layer, placed between the Alq<sub>3</sub> ETL and the Mg-Ag cathode contact. The blocking layer must have an energy gap higher than that of either of the materials comprising the EML to prevent energy transfer, and if it is on the electron-injecting side of the device, its LUMO should be approximately aligned to that of the ETL to avoid impeding the electron current.

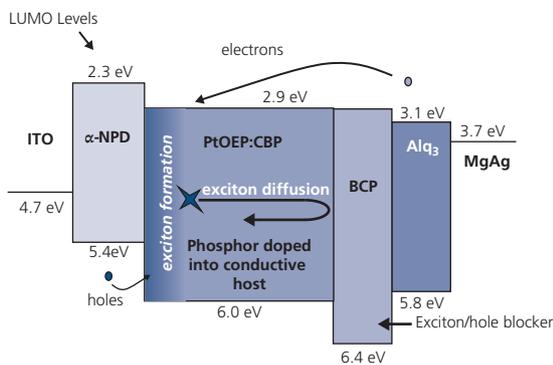

This device achieves a maximum  $\eta_{ext} = 5.6\%$ , compared to 4% for devices lacking a blocking layer (O'Brien et al., 1999). The blocking efficiency of the structure is apparent from the spectra obtained at several different current densities for devices with and without the EBL as shown in Fig. 6.49. The device lacking a blocking layer shows emission from the Alq<sub>3</sub> ETL, whereas that emission is absent in the blocked device. Thus, the EBL completely eliminates both hole and exciton transfer from the EML into the ETL. Due to their effectiveness in increasing efficiency, blocking layers are now a standard feature of PHOLEDs.

The final major step in bringing PHOLEDs into the mainstream was the introduction of Ir-based heavy metal phosphors whose ligand structure can be modified to emit with  $\sim 100\%$  internal quantum efficiency

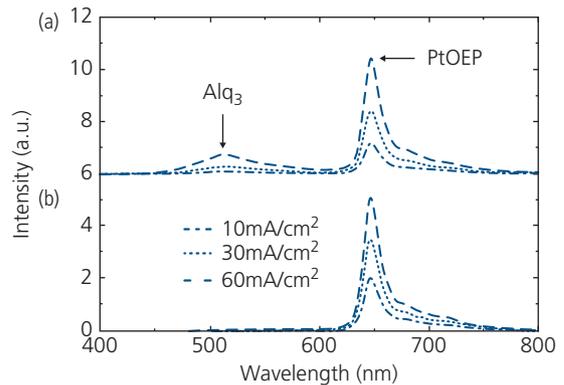

from the deep blue into the deep red. The first such device contained a CBP/Ir(ppy)<sub>3</sub> EML that employed a layer structure analogous to that in Fig. 6.48 (Baldo et al., 1999a). There, it was found that the green emission, centered at 520 nm wavelength had a surprisingly short decay time of 500 ns when used in a device, compared with 2  $\mu$ s in solution. We have seen in Section 3.6 that this short decay time is a feature of the strong spin-orbit coupling of the triplet metal-ligand charge transfer (<sup>3</sup>MLCT) state of the Ir(ppy)<sub>3</sub>, and most other pseudo-octahedral Ir-complexes. This is in contrast to the lower interstate mixing (and hence reduced intersystem crossing rate) of ligand centered (<sup>3</sup>LC) states of square planar Pt complexes, typified by PtOEP. As a consequence, the Ir(ppy)<sub>3</sub>-based PHOLED external efficiency had a maximum at low current of 8% with a roll-off in efficiency as the current was increased above 100 mA/cm<sup>2</sup>.

Shortly after the demonstration of the Ir(ppy)<sub>3</sub> OLED, a similar structure using the bidentate, Ir(ppy)<sub>2</sub>acac doped at 12 vol.% into the electron transporting TAZ achieved  $\eta_{ext} = 19\%$ , corresponding to  $\eta_{int} = 87\%$ . This constituted the first demonstration of an OLED with ostensibly 100% electron-to-photon conversion efficiency (Adachi et al., 2001a). It was proposed that the energy transfer mechanism was by direct hole injection from the HMTPD HTL onto the hole-conducting Ir phosphor, with electrons injected from the ETL onto this same molecule. There was no energy transfer from host to dopant in the optimized Ir(ppy)<sub>2</sub>acac/TAZ EML.

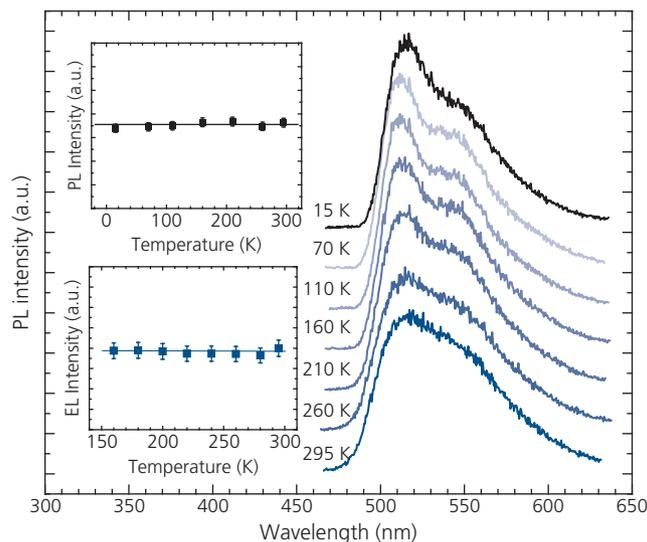

A convincing indication that this device had unity internal efficiency was obtained by measuring the EL and PL efficiencies as functions of temperature, from

**Figure 6.48** Energy level diagram of a PHOLED comprising an exciton/hole blocking layer.

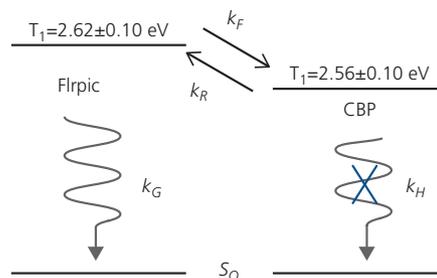

**Figure 6.49** PHOLED emission spectra at three different drive currents for devices (a) without and (b) with a BCP blocking layer (O'Brien et al., 1999).

**Figure 6.50** Temperature dependent PL spectrum of a 12% Ir(ppy)<sub>2</sub>acac/TAZ film, with the PL and EL intensity of an OLED using this same emitting region shown in the insets (Adachi et al., 2001a).

300 K to 15 K (Fig. 6.50). The lack of change in efficiency over this wide temperature range indicates that there are no temperature-dependent losses due to non-radiative recombination. As shown in Chapters 3 and 4, recombination via defect states or coupling to disorder is expected to be thermally activated, depending on the position of the defect within the energy gap of the host. The temperature independence of the data in Fig. 6.50 attests to the lack of loss channels. Hence, in the space of little more than two years from the first introduction of electrophosphorescence in PtOEP,  $\eta_{int} = 100\%$  was shown to be possible using heavy metal organic complexes with strong spin-orbit coupling.

As we move toward deeper blue emission needed in displays with large color gamuts, the choice of materials becomes limited. The first blue PHOLEDs were based on *endothermic energy transfer* from host to guest. That is, the CBP host triplet energy was higher than that of the cyan-emitting phosphor, Flrpic. The energy level diagram of this system is shown in Fig. 6.51 (Adachi et al., 2001b). Although the CBP triplet energy is lower than that of the dopant by 60 meV, the reverse, or endothermic transfer of triplets to CBP is much faster than the competing process of the disallowed host emission at rate,  $k_H$ . As long as the guest emission rate is  $k_G \gg k_R + k_H$ , the triplet emission can be efficient. Note that endothermic transfer is similar to

**Figure 6.51** Energy level scheme for a Flrpic/CBP guest/host system. The various transfer rates are indicated.

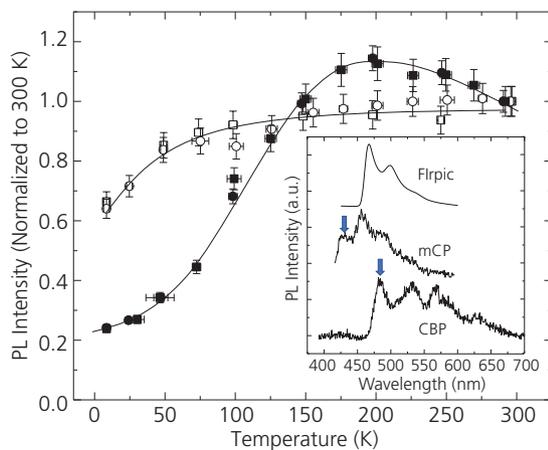

that used in thermally activated delayed fluorescent OLEDs discussed in Section 6.3.4.

Of course, it is preferable to use hosts that allow for exothermic energy transfer to eliminate competition with processes such as  $k_H$  that reduce PHOLED efficiency. This was achieved by replacing CBP with mCP with its higher triplet energy of  $T_1 = 2.90$  eV. The PL spectra from which the various triplet energies are obtained are shown in Fig. 6.52, inset. The triplet energy of mCP is higher than that of Flrpic, whereas CBP is considerably lower, leading to less efficient energy transfer (Holmes et al., 2003b). The Flrpic:CBP PHOLED had a peak efficiency of 6.1% in contrast to the Flrpic:mCP device that reaches  $\eta_{ext} = 7.5\%$ .

A signature of endothermic transfer is the pronounced temperature dependence of its emission. In

Fig. 6.52 we show a comparison of the PL intensity between the endo- and exothermic Flrpic-doped thin films. The CBP-based PL shows a peak PL intensity near 200 K, and then a rapid decrease at lower temperatures. These data suggest that at the highest temperatures, the thermally activated non-radiative recombination rate via defect states is higher than  $k_R$ , leading to a reduction in emission efficiency. Similarly, as temperature is lowered, defect-related recombination is frozen out and the efficiency increases until at  $T < 200$  K,  $k_R$  must compete, and the efficiency drops once more with direct host emission,  $k_H$ . In contrast, the exothermic mCP system shows relatively temperature independent phosphorescent emission intensity until  $T < 50$  K. At the lowest temperatures, host exciton diffusion slows to the extent that the excitons recombine before reaching a phosphor dopant. The PL transient response of the mCP-based film reinforces this picture. That is, as the temperature is lowered to 10K, the Flrpic radiative lifetime is 23  $\mu$ s, compared to only 1  $\mu$ s at room temperature since thermally activated exciton diffusion on mCP substantially increases the probability of non-radiative recombination prior to transfer to a Flrpic molecule at low  $T$ .

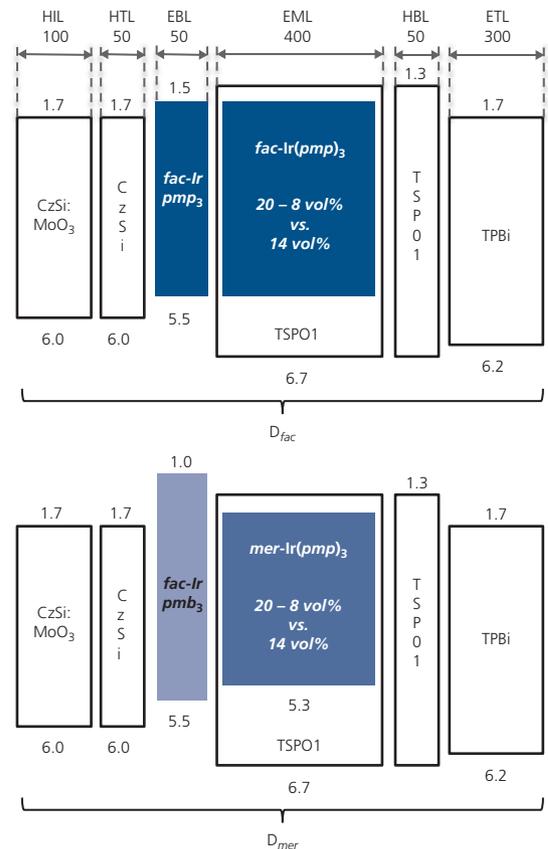

Blue PHOLEDs require both wide energy gap dopants and hosts. The LUMO energies of these materials necessarily lie close to the vacuum level that can lead to potentially damaging molecular oxidation. This limits the choice of effective and stable blocking materials. For example, in Fig. 6.53 we show the energy

**Figure 6.52** PL intensity vs. temperature of Flrpic in mCP (open symbols) and CBP (closed symbols). *Inset:* Triplet emission spectra of Flrpic, mCP, and CBP. Since the latter two molecules are fluorophores, the weak triplet emission spectra are obtained at 10K to freeze out non-radiative recombination channels. Arrows indicate the 0–0,  $T_1 \rightarrow S_0$  transitions. (Holmes et al., 2003b).

level diagrams for two blue OLEDs based on the *cyclo-metallated carbene* ( $\text{Ir}(\text{C}^\wedge\text{C})_3$ ) compound,  $(\text{Ir}(\text{pmp})_3)$ . Recall from Section 3.7.3 that the  $^3\text{LC}$ -dominated *fac*-isomer emission is blue-shifted from that of the  $^3\text{MLCT}$ -dominated *mer*-isomer due to the stronger spin–orbit coupling of the latter compound. For both isomers, a high energy gap electron-conducting host, TSP01 is used for the ETL, CzSi for the HTL, and TPBi and a blend of CzSi at 15% vol. concentration in  $\text{MoO}_3$  are used as the EIL and HIL, respectively. The LUMO energies of these compounds are considerably less than 2 eV, and in some cases as small as 1 eV from the vacuum level, suggesting that all of these materials are easily oxidized, perhaps negatively impacting their reliability.

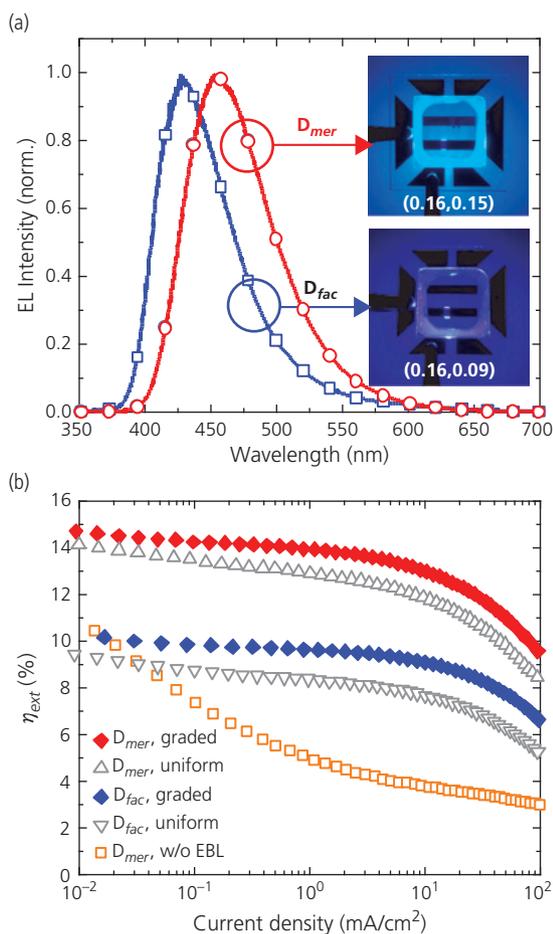

Here, TSP01 is used as an exciton/hole blocking layer since its HOMO energy extends well below that of 5.0–5.3 eV of the hole conducting  $\text{Ir}(\text{pmp})_3$  isomers. However, in a device where both the host and dopant have small differences in energy between the LUMO

**Figure 6.53** Energy level diagrams of a deep blue (a) *fac*- and (b) *mer*- $\text{Ir}(\text{pmp})_3$  PHOLEDs. These devices are labeled  $D_{\text{fac}}$  and  $D_{\text{mer}}$  respectively. Energies relative to vacuum are shown adjacent to the appropriate level for all materials (Lee et al., 2016).

and the vacuum level, EBLs are also required. The dopant itself,  $fac\text{-Ir}(\text{pmp})_3$  is, therefore, used as the electron blocker in the  $fac$ -isomer emitting device (called  $D_{fac}$ ), whereas an even smaller LUMO energy blocker,  $fac\text{-Ir}(\text{pmb})_3$  is used as an EBL for the meridional device (called  $D_{mer}$ ).

The EL spectra and quantum efficiencies of the two devices are shown in Figs. 6.54a and b, respectively. As expected for systems with strong spin-orbit coupling, the  $^3\text{MLCT}$ -rich  $mer\text{-Ir}(\text{pmp})_3$  spectral peak is significantly red-shifted compared with the  $fac$ -isomer. Also, the quantum efficiency is  $\sim 50\%$  higher for  $mer$ - than for  $fac\text{-Ir}(\text{pmp})_3$  due to

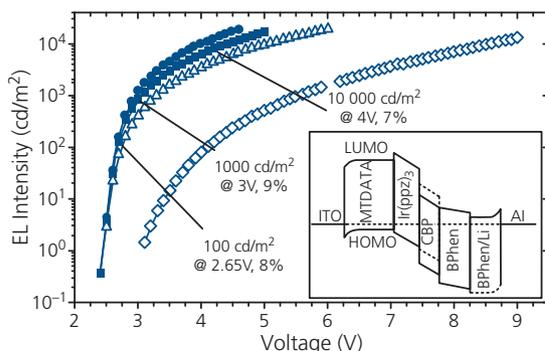

**Figure 6.54** (a) Normalized EL spectra of  $mer$ - and  $fac\text{-Ir}(\text{pmp})_3$  PHOLEDs (labeled  $D_{mer}$   $D_{fac}$  respectively). Inset: Photographic images of the deep blue emission from these PHOLEDs along with their CIE coordinates (in parentheses). (b) External quantum efficiency vs. current density for  $D_{fac}$  and  $D_{mer}$  with the dopant graded or uniformly doped throughout the EML. Squares are data for  $D_{mer}$  without an EBL (Lee et al., 2016).

its higher radiative rate. Note that there are two  $D_{mer}$  and  $D_{fac}$  devices shown: one each with uniformly doped EMLs, and the other with the doping graded from 8 vol.% to 20% to more evenly distribute the exciton formation zone across the EML, thus reducing the rate of TTA (Section 6.3.5). As discussed above, the dopant is a conductor whose hole mobility is larger than the electron mobility in the host (TSPO1). Decreasing the  $\text{Ir}(\text{pmp})_3$  concentration by grading moves the recombination zone away from the HTL/EML interface toward the ETL, thus reducing the opportunity for annihilation, and hence increasing efficiency.

Finally, we point out that  $D_{mer}$  in the absence of an EBL has a comparatively low quantum efficiency that continuously decreases from its value at  $j \rightarrow 0$ . Clearly, while charge blocking is challenging in deep blue emitting devices, it is nevertheless essential for achieving high efficiency at high brightness.

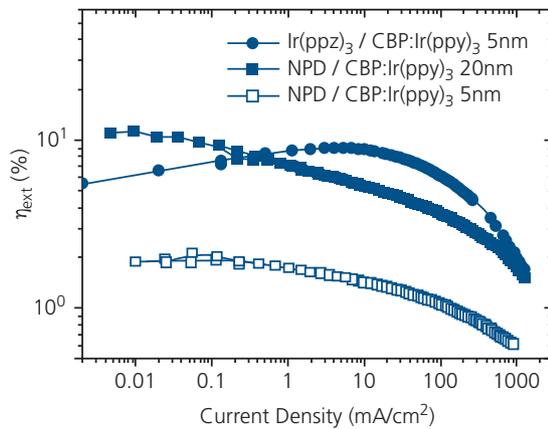

An example green emitting PHOLED employing a doped p-i-n structure is shown in Fig. 6.55. The energy level diagram is shown in the inset. The device consists of an ITO anode, and a 50 nm thick layer of m-MTDATA doped p-type with 2 mol. %  $\text{F}_4\text{-TCNQ}$  that serves as both HIL and HTL. This is followed by a 10 nm thick, wide energy gap  $\text{Ir}(\text{ppz})_3$  EBL that also confines excitons within the 5 nm thick, 7 wt%  $\text{Ir}(\text{ppy})_3$  in CBP EML. Here,  $\text{Ir}(\text{ppz})_3$  has a very shallow LUMO energy that provides a barrier to electron conduction, yet its HOMO is aligned with that of m-MTDATA to allow efficient hole injection into the EML. Furthermore, its wide energy gap prevents excitons from quenching in the doped HTL. The ETL/exciton blocking layer is comprised of a 55 nm thick Bphen layer that was either undoped, or doped with LiF or Li to

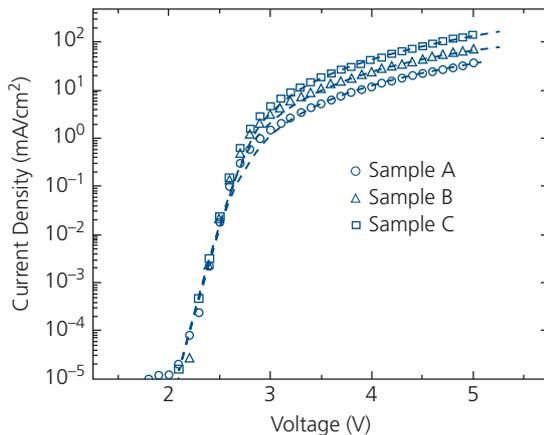

**Figure 6.55** Electroluminescence intensity vs. voltage characteristics of  $\text{Ir}(\text{ppy})_3$  PHOLEDs with an undoped Bphen HBL (diamonds), LiF-doped Bphen (triangles), 15 nm-thick Li-doped Bphen (squares), and 30 nm thick Bphen (circles). Inset: Energy level diagram and layer scheme of the conductivity-doped OLEDs. Dashed lines in the EML indicate the frontier energy levels of  $\text{Ir}(\text{ppy})_3$  (Pfeiffer et al., 2002).

increase conductivity. This is capped by a Li-doped Bphen EIL with an electron concentration of  $\sim 10^{18} \text{ cm}^{-3}$ , and finally an Al cathode. The total thickness of the ETL and EIL combination is 55 nm.

To understand the effectiveness of *n*-type doping of the ETL on the operating voltage, three devices were compared with their EL intensity vs. voltage behavior shown. The undoped ETL showed considerably higher operating voltage (i.e. the voltage to achieve a given luminance) than devices where the ETL was doped with either LiF or Li. For example, the undoped device achieves a luminance of 10,000  $\text{cd/m}^2$  at 8.5 V, compared to only 4 V for devices with Li-doped Bphen layers (Pfeiffer et al., 2002).

**Figure 6.56** External quantum efficiency for PHOLEDs with an  $\text{Ir}(\text{ppz})_3$  blocking layer vs. devices employing the hole transporting NPD in its place. The EML compositions and thicknesses are noted (Pfeiffer et al., 2002).

**Figure 6.57** Current density–voltage characteristics of the doped p-i-n OLEDs in Figs. 6.55 and 6.56. Dashed lines are fits to the data using Eq. 6.39 (Pfeiffer et al., 2002).

The  $\text{Ir}(\text{ppz})_3$  HBL increases the quantum efficiency, particularly for very thin EMLs where exciton leakage into the doped HTLs results in quenching, or alternatively, very low emission intensity in the HTL due to electron leakage. Figure 6.56 shows the external quantum efficiency for a 5 nm thick EML device with the  $\text{Ir}(\text{ppz})_3$  blocking layer, compared to a device lacking this layer and another with a thicker (20 nm) EML. In the devices without  $\text{Ir}(\text{ppz})_3$ , the EBL was replaced with an undoped hole transporting but non-blocking NPD layer to maintain a constant device thickness. If there is unity quantum efficiency, the light output should be directly proportional to the current, that is, every electron injected results in the emission of a photon. In Fig. 6.56, this is clearly not the case: often there is a decrease in efficiency at low current due to traps that lead to non-radiative exciton recombination. Once the traps are filled at higher current (i.e. the recombination rate is less than the charge injection rate), the efficiency increases. At the highest currents, exciton annihilation with charges and/or other excitons leads to a further decrease in efficiency. These processes will be discussed in subsequent sections: here we point out that the devices in Fig. 6.56 suffer from both trap recombination and annihilation.

The increase in efficiency for the 5 nm thick EML with the blocking layer compared to one without is dramatic. The thicker EML results in the same high efficiency as the thin, blocked device but only at very low currents. There, the hole concentration is sufficiently low for complete recombination of all injected holes within the thick emission zone. However, charge balance is reduced at higher currents due to leakage into the HTL.

Interestingly, the p-i-n current density–voltage (*j*–*V*) characteristics differ from trap-limited space charge conduction commonly observed for simple bilayer OLEDs considered in Chapter 4. In Figure 6.57 we show fits of the *j*–*V* characteristics to a Shockley-type diode equation:

$$j = j_0 \left( \exp \left( q \left\{ V - [j/j_T]^{1/m} \right\} / nk_B T \right) - 1 \right), \quad (6.39)$$

where, following our notation in Chapter 4,  $j_0$  is the saturation current, and  $n$  is the ideality factor. The term in square brackets is the voltage drop outside of the junction due to space charge limited current, where  $j_T = (9/8)(\epsilon_r \epsilon_0 \mu / d^3)$ . Here,  $\mu$  is the mobility,  $d$  is the thickness of the undoped EML, and  $m$  is the characteristic trap exponent. Then  $m = 2$  for trap free transport, and  $n = 2$  for generation and recombination via mid-energy-gap states.

The fits to Eq. 6.39 shown by dashed lines in Fig. 6.57 extend over seven decades using  $m = 1.7$

and  $n = 2.1$ . This implies that at high voltages, the current is dominated by trap-free space charge limited injection, while at low currents (in the exponential region of the  $j$ - $V$  characteristics), the dominant conduction mechanism is diffusion across the anisotype HJ limited by generation-recombination within the energy gap. That is, the doped device behaves analogously to an inorganic p-n junction diode, rather than as a dielectric OLED simply limited by trap-dominated space charge limited currents, as in the device in Fig. 6.22. The fits for the different samples are due to differences in the doping of the ETL. This reflects that the doped Bphen HTL (Sample C) has a thinner space charge region (i.e. smaller  $d$ ) than that doped only half way across (Sample B), or one in which LiF leads to only a very thin doped region near the cathode (Sample A).

### 6.3.3.2 Polymer PHOLEDs

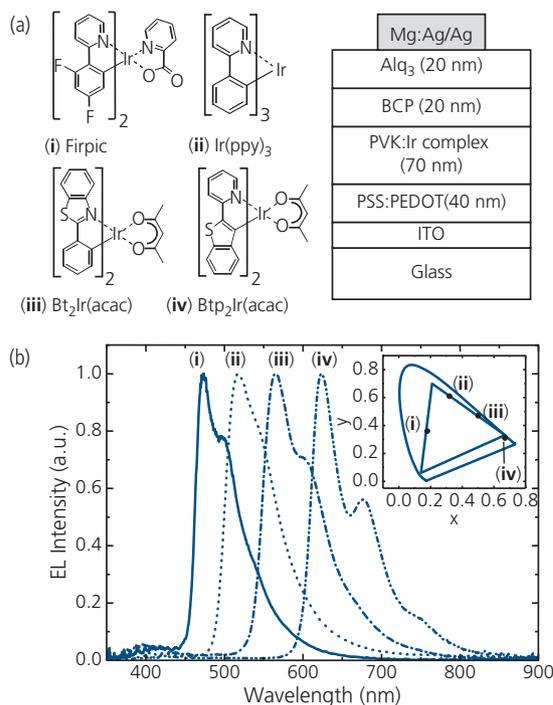

There are three strategies for realizing high efficiency polymer PHOLEDs. The most actively pursued is blending small molecule phosphorescent complexes into a polymer host. The polymer host transports the electrons and holes to the doped region, followed by energy transfer from the polymer to the phosphor molecule. In a second copolymerization strategy, the phosphor moiety is part of the polymer backbone. The third approach incorporates the triplet-emitting transition metal complex as a pendant group attached to the polymer chain. The highest efficiency is achieved in multilayer combinations comprising an HIL and active region adjacent to the anode contact, followed by vacuum deposited small molecule EBL and ETL layers capped by a metal cathode (Han et al., 2015).

The most commonly used polymer host is the non-conjugated PVK due to its high singlet and triplet energies that enable efficient energy transfer for chromophores spanning the visible spectrum. The effectiveness of multilayer structures, particularly the use of an exciton blocking layer in PVK:Ir(ppy)<sub>3</sub> PHOLEDs is illustrated by comparing devices with and without an EBL/ETL bilayer deposited on the polymer blend EML. For example, a 70 nm thick layer of PVK:Ir(ppy)<sub>3</sub> (3.5%) blend sandwiched between an ITO anode and a Mg:Ag cathode was directly compared to a device comprising a 70 nm PVK<sub>0.9</sub>PBD<sub>0.1</sub>:Ir(ppy)<sub>3</sub> (3.5%)/5 nm TPBI/30 nm Alq<sub>3</sub> PHOLED with contacts similar to that used in the single layer device (Vaeth and Tang, 2002). Here, PBD is blended with PVK due to its superior electron conducting properties. Furthermore, TPBI is a vacuum-deposited, wide energy gap blocking layer. Finally, Alq<sub>3</sub> is the ETL, also deposited in

vacuum. The single layer device had an external quantum efficiency of approximately 2.5% at an operating voltage of 15.1 V, whereas the device with the EBL had  $\eta_{\text{ext}} = 6.7\%$  at 15.9 V, increasing to 8.5% at somewhat lower voltages. Thus, blocking layers can improve exciton confinement in both polymer and small molecule PHOLEDs.

The ability of PVK to excite triplet emission across the visible spectrum is demonstrated by blending with the Ir(III) dopants in Fig. 6.58a. The spectra of the devices shown in Fig. 6.58b span the visible spectrum from the sky blue when doped with 10 wt% Flrpic, 5 wt% Irppy<sub>3</sub> in the green, 5 wt% Bt<sub>2</sub>Ir(acac) in the yellow, and 5–10 wt% Btp<sub>2</sub>Ir(acac) in the deep red. Longer wavelength emission is accessed by increasing the conjugation length of the ligand. Blue emission from Flrpic is achieved by attaching electron-withdrawing fluorine atoms to the phenyl group. The peak external efficiencies of the devices were 1.2%, 5.2%, 2.0%, and 2.1%, respectively, which are substantially below vacuum deposited devices using these same phosphors (Kawamura et al., 2002).

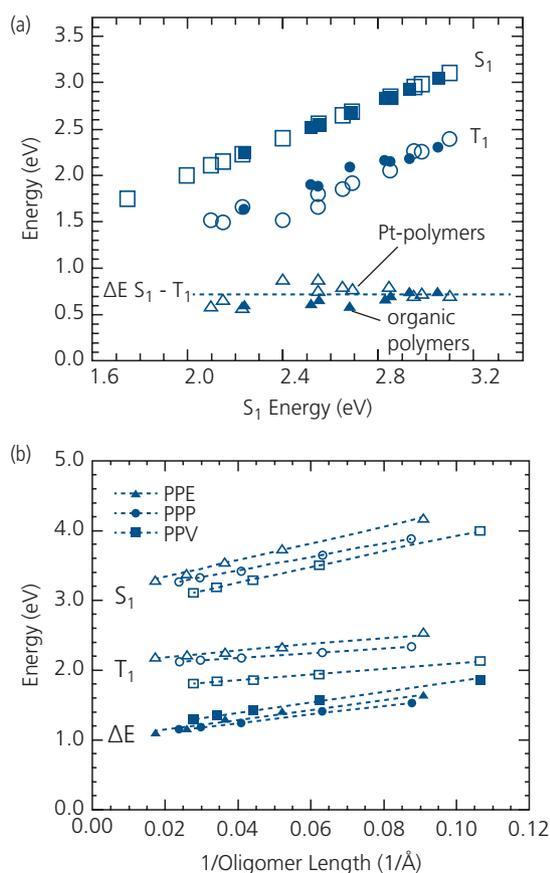

One of the difficulties in employing conjugated polymer hosts is that they tend to have a large exchange energy ( $\sim 0.5$ – $0.7$  eV) that appears to be

**Figure 6.58** (a) Molecular structures of four Ir(III) complexes numbered i–iv used in the device structure on the right. (b) Spectra from the PVK-based PHOLEDs in (a) along with their CIE chromaticity coordinates (inset) (Kawamura et al., 2002).

independent of polymer composition or chain length. The resulting low triplet energy makes it difficult or even impossible to transfer triplets from the host to a comparatively high energy green or blue emitting phosphor. However, when conjugated polyfluorenes are used as hosts for deep red emitting phosphors, the PHOLED performance is comparable with non-conjugated PVK (Jiang et al., 2004).

A striking example of the material-independent exchange energy is shown in Fig. 6.59a for a series of conjugated polymers including PPP, ladder type LPPP, phenyl-substituted PPV, polyfluorenes, as well as polymers with Pt in the main chain (Köhler and Beljonne, 2004). It is remarkable that the exchange energy,  $\Delta E_{ST} \approx 0.7$  eV, which is the difference between the  $S_1 \rightarrow S_0$  and  $T_1 \rightarrow S_0$  transitions, is independent of the polymer composition. To

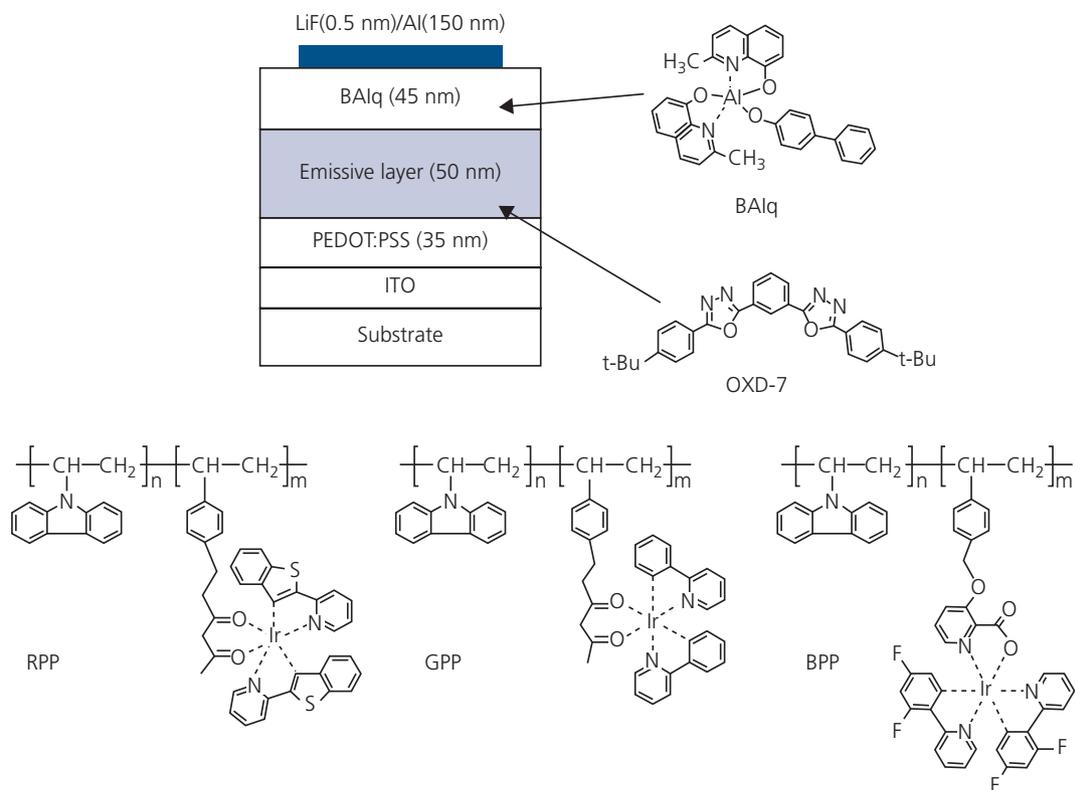

**Figure 6.59** (a) The lowest singlet ( $S_1$ ) and triplet ( $T_1$ ) energies vs.  $S_1$  energy for a variety of conjugated Pt-containing and organic conjugated polymers. Also shown is their energy difference of  $\Delta E_{ST} \approx 0.7$  eV for all materials investigated. (b) Calculated transition energies for three conjugated molecules as a function of (oligomer length) $^{-1}$  (Köhler and Beljonne, 2004).

understand this phenomenon, Hartree–Fock semi-empirical intermediate neglect of differential overlap calculations (Section 3.4.2) were used to estimate the excited state energies of oligomers of varying length of three molecules, namely PPP, PPV, and PPE. The theoretical results in Fig. 6.59b are consistent with experiment. That is, while the energies of  $S_1$  and  $T_1$  decrease only weakly with increasing oligomer length due to the increase in conjugation length, and is independent of polymer composition. The residual dependence of  $\Delta E_{ST}$  on oligomer length is due to the limited extent of the singlet and triplet states. Torsional twists in the chain along the polymer backbone increase the dependence of  $S_1$  energy on length, while the far more compact triplet state does not have a length dependence (Köhler and Beljonne, 2004). This limitation in tuning  $\Delta E_{ST}$  is lifted to a significant degree in small molecules, where the exciton radius,  $r_{exc}$  can be engineered by structurally separating the electron and hole on electron withdrawing and donating groups within a single molecule. Indeed,  $\Delta E_{ST}$  can be reduced to nearly zero in small molecules optimized for delayed fluorescence (see Sections 3.7.5 and 6.3.4).

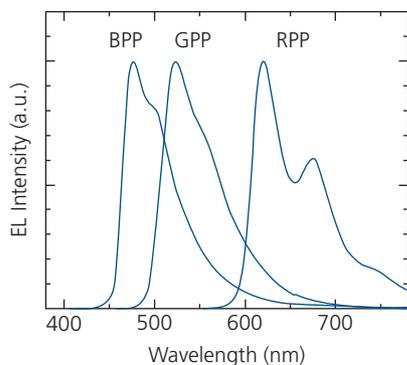

High efficiency polymer PHOLED emission across the visible spectrum has been achieved using the hybrid solution process-vacuum deposited device in Fig. 6.60. The emissive material consists of a vinyl backbone onto which are appended both a hole transporting carbazole unit, as well as 0.1–2.0 mol. % of either a red, green or blue phosphorescent (RPP, GPP, BPP, respectively) functional group. The Ir(III) complexes are red emitting Btp<sub>2</sub>Ir(acac), green Irppy<sub>2</sub>(acac) or blue FIrpic. Electron conduction is enhanced by also blending in 30 wt% OXD-7 into the 50 nm thick emissive layer. Importantly, the efficiency is increased by 20% in the red to nearly 100% in the blue by including the vacuum deposited BAq hole blocking layer (Tokito et al., 2003a, 2003b).

The emission spectra of the three different devices are shown in Fig. 6.61, with the devices exhibiting  $\eta_{ext} = 6.6\%$  (R), 11% (G), and 6.9% (B). Appending the emissive group onto a polymer backbone, along with functionalization of the polymer and blend to balance carrier injection can be used to precisely control the emissive dopant concentration while preventing aggregation. However, the molecular synthesis routes leading to these structures are more complex than in simple blends, and hence may increase the cost of the materials.

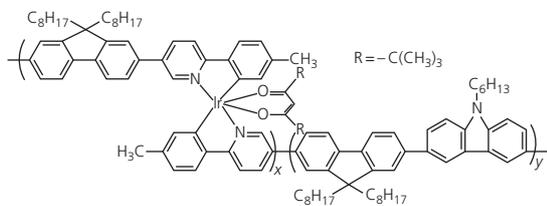

Finally, we discuss copolymers that combine a transporting moiety and the triplet-emitting center

**Figure 6.60** Red, green, and blue device structures and chemical structural formulae of materials used in the blocking layer (BAQ) and in the emissive layer (OXD-7), and the red (RPP), green (GPP), or blue (BPP) phosphorescent polymer materials (Tokito et al., 2003a).

**Scheme 1.**

within the chain itself. Such a bis-chelating Ir(III) copolymer is shown in **Scheme 1** (Zhen et al., 2005). These polymers consist of a polyfluorene-chelating unit combined with a fluorine-*alt*-carbazole (PFCz) unit. Energy transfer from the fluorine to the emissive complex is nearly complete, even at complex concentrations of only 4%. Indeed, it was observed that intrachain energy transfer is more efficient than transfer to small molecules in blended PHOLEDs with comparable concentrations of the same Ir complex. Interestingly, the peak wavelength of the copolymer is shifted to 575 nm from 550 nm for the analogous blended device. This results from the extended conjugation of the pyridine group due to its linkage with the neighboring fluorenes.

A PHOLED with the structure ITO/PEDOT:PSS/PVK/copolymer/Ba/Al, where  $(x, y) = (0.04, 0.96)$  in Scheme 1, had a peak quantum efficiency of 4.1% along with a somewhat elevated voltage of 13 V at  $32 \text{ mA/cm}^2$ .

In summary, numerous strategies have been devised to achieve efficient polymer PHOLEDs based on both Pt(II) and Ir(III) complexes. Generally, the highest quantum efficiencies and lowest voltages are

obtained by blending a small molecule triplet-emitting molecule along with a charge conducting polymer host that transfers energy to the emitter. High efficiency can also be obtained by combining polymeric emitting regions with a vacuum deposited EBL and ETL. In spite of the considerable effort that has been devoted to developing solution processed PHOLEDs, the highest performances across the visible spectrum have been achieved using small molecule devices that benefit from the freedom to deposit high purity layers of precisely controlled thicknesses, and that are optimized to perform their separate functions within the device.

### 6.3.3.3 Triplet emitting complexes

Substantial efforts have focussed on developing high efficiency triplet emitting, transition metal complexes across the visible spectrum. The most successful materials are based on Ir(III) complexes, although efficient emission has also been achieved using Pt(II)-, Os(III)-, Au(III)-, and Cu(II)-centered molecules. In Fig. 6.62 and Table 6.7 we provide a sampling of Ir, Pt, Cu, and Os complexes, including their efficiencies and color coordinates. Further examples of heavy metal phosphor complexes not found in Table 6.7 will be provided in the following sections as their uses in specific device examples are introduced. For a more complete discussion of such complexes, the reader is referred to several reviews (Lamansky et al., 2001, Thompson et al., 2007, Yam and Wong, 2011, Choy et al., 2014, Jou et al., 2015, Li et al., 2016b).

With few exceptions (mostly the Cu complexes with comparatively low spin orbit coupling due to the low atomic number,  $Z = 29$ ), the efficiencies are  $\geq 20\%$ . As apparent from in Eq. 6.1, their 100% emission efficiency results in a potential efficiency of 20% when OLEDs are grown on glass. Reports of higher efficiencies are almost certainly the result of light outcoupling enhancements, either due to a modified device structure or due to alignment of TDMS parallel to the substrate (see Section 6.6).

As noted above, the emission is red-shifted by increasing the conjugation length of the ligands. Hence, red emitting phosphors often feature an extra phenyl group fused to either the phenyl or pyrazole of the phenylpyridine ligand, whereas blue emitting phosphors contain electron-withdrawing halides or cyano groups. The molecules in Table 6.7 span the visible from the deep blue to the deep red. Even 8.5% efficient infrared PHOLEDs with a narrow peak at  $\lambda = 772$  nm have been demonstrated based on Pt(II)-tetraphenyltetraabenzoporphyrin doped at 4 wt% in Alq<sub>3</sub> (Sun et al., 2007).

In Fig. 6.63 we show EL images from a few, high efficiency ( $\eta_{int} \sim 100\%$ ) Ir-complex based PHOLEDs that span the visible spectrum. Also shown are the coordinates of these emitters on the accompanying CIE chromaticity chart. Apparently, even this limited selection of electrophosphorescent OLEDs covers the sRGB and NTSC standard color gamuts indicated by the two triangles in the chart.

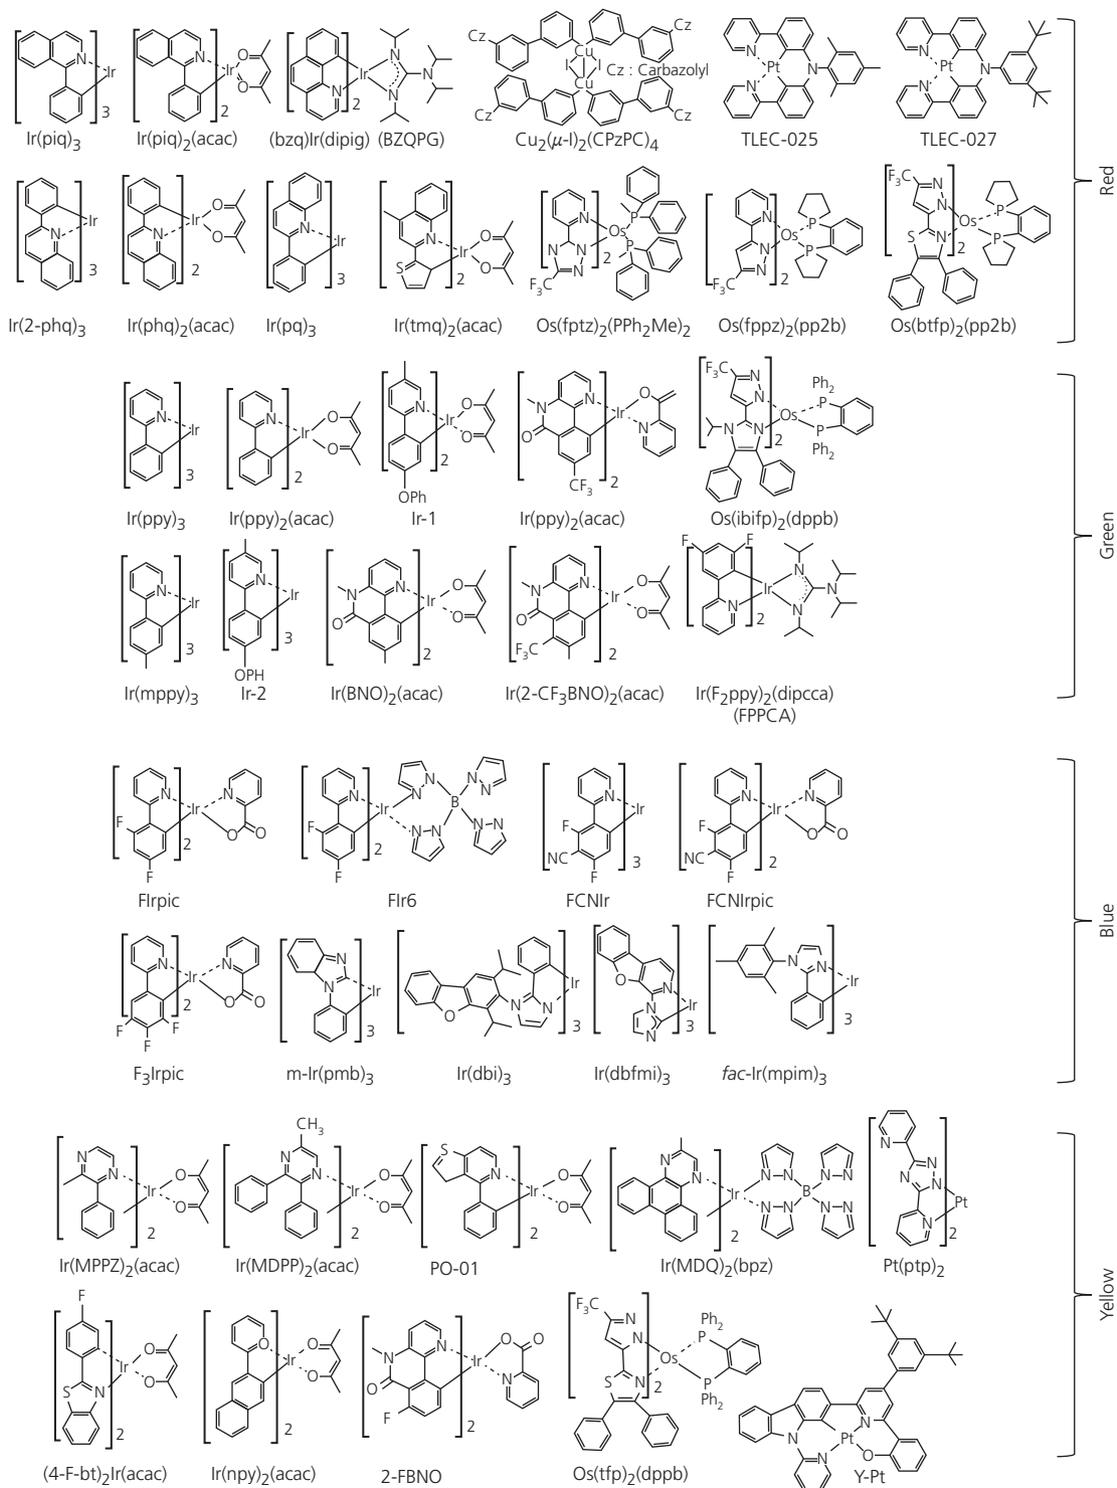

### 6.3.4 Thermally assisted delayed fluorescence

An alternative way to exploit high efficiency triplet emission is known as thermally assisted delayed fluorescence (TADF). This process, described in Section 3.7.5, entails the use of molecules whose singlet-triplet exchange energy splitting,  $\Delta E_{ST}$ , is comparable to or less than the thermal energy,  $k_B T$ . From perturbation theory, the intersystem crossing rate for  $S_1 \leftarrow T_1$  is inversely proportional to  $\Delta E_{ST}$ , with rate  $k_{ISC,T} \sim \left| \frac{\langle S_1 | H_{SO} | T_1 \rangle}{\Delta E_{ST}} \right|^2$  (cf. Eq. 3.189).

Hence, the endothermic intersystem energy transfer  $S_1 \leftarrow T_1$  can be nearly 100% efficient provided that competing non-radiative rates are less than  $k_{ISC,T}$ . This transition, therefore, leads to delayed fluorescence. The  $S_1 \leftarrow T_1$  process is sometimes referred to as reverse intersystem crossing (RISC), but in fact it is simply just an endothermic variation of the exothermic ISC process.

The energetic processes leading to efficient TADF are shown in Fig. 6.67. Efficient radiative transitions from the singlet state require that the natural rate of fluorescence,  $k_F$ , exceed all other rates. In particular,  $k_F \gg k_{ISC,S}, k_{ISC,T}, k_{ph}$ , where  $k_{ISC,S}$  corresponds to the rate of the exothermic ISC process. Since TADF employs molecules with a small  $\Delta E_{ST}$  that lack a heavy metal atom, the phosphorescent emission rate,  $k_{ph}$ , is expected to be smaller than the other competing rates except for non-radiative transitions from  $T_1$  at rate  $k_{nrT}$ . Also, for high efficiency, it follows that the non-radiative transition rate of  $S_1 \rightarrow S_0$  must be  $k_{nrS} \ll k_F$ .

Minimization of  $\Delta E_{ST}$  requires that the HOMO/LUMO overlap within the emissive molecule also be small. This can be achieved with dipolar molecules comprising spatially separated donor and acceptor groups whose interactions are reduced by a twist along the molecular backbone. That is, the small exchange energies of TADF molecules results from reduced *intramolecular charge transfer* between the donor and acceptor groups. The same feature leads to a broadened, featureless emission spectrum characteristic of charge transfer states. This strategy has led to the development of a series of dopants with

$\Delta E_{ST} \leq 0.1$  meV, leading to internal TADF quantum efficiencies of nearly 100% across the visible spectrum at room temperature.

An efficient molecular motif is based on a carbazoyl dicyanobenzene structure, where the carbazole is an electron donating group and the dicyanobenzene is an electron withdrawing acceptor (Uoyama et al., 2012). Several examples of these compounds and their PL spectra are shown in Fig. 6.65. The molecular structural formulae show a pronounced twist between the carbazole and the dicyanobenzene groups that minimize orbital overlaps, and hence results in a small exchange energy. In Fig. 3.87 we showed that

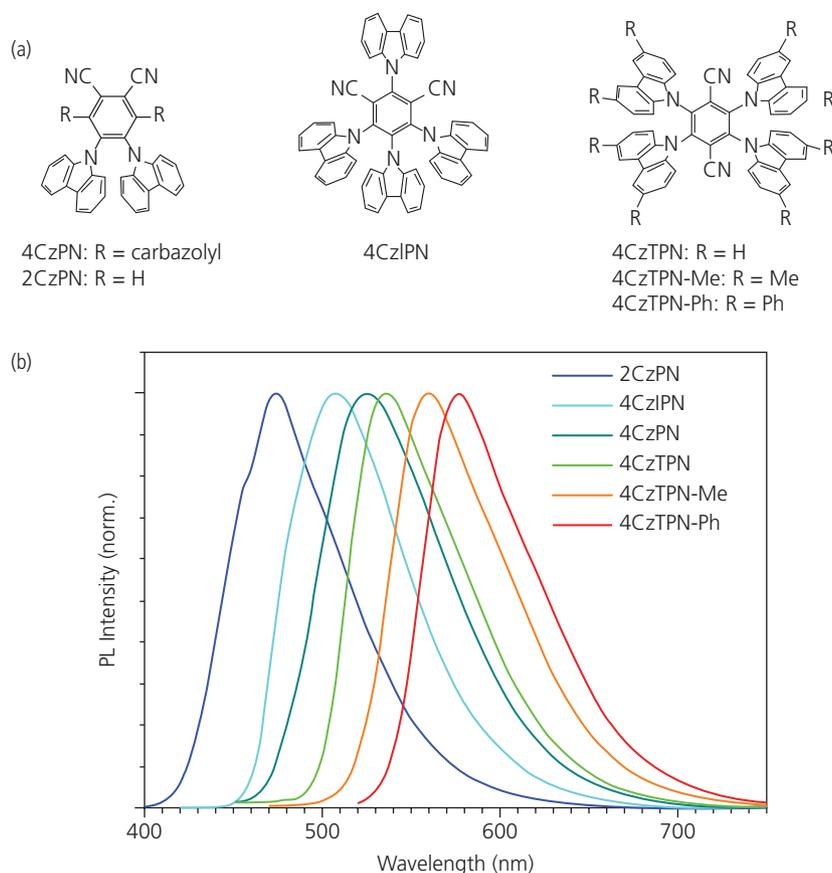

the lowest unoccupied natural transition orbital is centered on the cyanobenzene, whereas the highest occupied transition orbital centers on the carbazole groups in 4CzIPN, with similar orbital configurations expected for analogous molecules in this series. A consequence of the minimal overlap of the transition orbitals is a featureless, broad excimer-like luminescence spectrum. Hence, TADF molecules tend to have non-saturated emission spectra compared with conventional fluorescent or phosphorescent lumophores.

Figure 6.66 shows emission transients of a TADF-based OLED consisting of 5 wt% 4CzIPN in CBP, forming the emissive layer. Prompt fluorescence with a natural lifetime of  $\tau_p = 18$  ns, followed by TADF with  $\tau_{TADF} = 5.1$   $\mu$ s at 300 K is shown in Fig. 6.66a. The transient lifetime increases as temperature is decreased due to thermally activated energy transfer, as implied in Fig. 6.64. The spectra for both the prompt and delayed fluorescence signals in Fig. 6.66b have peaks at a wavelength of 507 nm, which supports the conclusion that the delayed signal is due to the same  $S_1 \rightarrow S_0$  transition as the prompt fluorescence emission.

The TADF efficiency is the integral of both the prompt and delayed emission spectra. That is, from Eq. 6.1,

$$\eta_{ext} = \eta_{int}\eta_{out} = (\eta_F + \eta_{DF})\eta_{out}, \quad (6.40)$$

where for consistency, we use the formal definition of rapid emission as fluorescence (with efficiency  $\eta_F$ ),

**Figure 6.65** (a) Carbazoyl dicyanobenzene molecules and (b) their characteristically featureless photoluminescence spectra. Functionalizing the molecular species leads to tuning of the spectral peak from the blue into the red (Uoyama et al., 2012).

and delayed fluorescence (with efficiency  $\eta_{DF}$ ). Then it follows:

$$\eta_{\text{int}} = \gamma \left[ \chi_S \phi_F + (\chi_S \phi_{ISC,S} + \chi_T) \phi_{ISC,T} \right]. \quad (6.41)$$

Here,  $\gamma$  is the charge balance factor,  $\phi_F$  is the fluorescence quantum yield, and  $\phi_{ISC,S}$  and  $\phi_{ISC,T}$  are the quantum yields for producing triplets and singlets, respectively (cf. Fig. 6.64). Hence, the first term is simply  $\eta_F$  and the second is the efficiency for emission via TADF, namely  $\eta_{DF}$ .

Figure 6.66c shows the PL quantum efficiency for both the fluorescent and TADF emission, along with the combined spectra that corresponds to the integrated area under the transient PL data. There is almost no temperature dependence of the prompt spectral intensity, as expected for direct fluorescence with rate  $k_F$ . However, the TADF signal appears to decrease by approximately 30% from room temperature to  $T < 10$  K, indicating a weak temperature dependence for this

endothermic process. The temperature dependent emission rate is understood if we assume that  $T_1$  and  $S_1$  are in thermal equilibrium (Kirchhoff et al., 1983). The ratio of concentrations of excitations in state  $S_1$  to  $T_1$  (corresponding to  $[S_1]$  and  $[T_1]$ , respectively), is given by their respective ISC rates, that is,

$$K = [S_1]/[T_1] = k_{ISC,T}/k_{ISC,S}. \quad (6.42)$$

This relationship is valid if the rates are greater than the competing rates in Fig. 6.64 to allow for equilibrium between the two states to be established. That is, we assume that  $k_{ISC,S} \gg k_{ph} + k_{nrT}$  and  $k_{ISC,S} \gg k_F + k_{nrS}$ . Then it follows that the quantum yields from  $T_1$  and  $S_1$  are

$$\phi_{ph} = \frac{k_{ph}}{(k_F + k_{nrS})K + k_{ph} + k_{nrT}} \quad (6.43a)$$

and

$$\phi_F = \frac{k_F K}{(k_F + k_{nrS})K + k_{ph} + k_{nrT}}. \quad (6.43b)$$

Note that  $\phi_{ph}$  and  $\phi_F$  are the radiative quantum yields, whereas  $\phi_{ISC,T}$  and  $\phi_{ISC,S}$  in Eq. 6.41 are the yields (i.e. the probabilities) of intersystem crossing for  $S_1 \leftarrow T_1$  and  $S_1 \rightarrow T_1$ , respectively. Then, the rate for delayed fluorescence is given by

$$k_{TADF} = \frac{(k_F + k_{nrS})K + k_{ph} + k_{nrT}}{1 + K} \quad (6.44)$$

In Section 3.7.5 we found the RISC rate is proportional to the Boltzmann factor,  $\exp(-\Delta E_{ST}/k_B T)$ , which weights the relative filling of  $T_1$  and  $S_1$  at thermal equilibrium. Since the degeneracy of the triplet is

three times that of the singlet, and assuming that the zero field splitting for the triplet state is negligible, then we can write the relative concentrations of the triplet and singlet states,  $K$ , as

$$K = \frac{k_{ISC,T}}{k_{ISC,S}} = \frac{1}{3} \exp(-\Delta E_{ST}/k_B T), \quad (6.45)$$

which finally yields the expression for the rate of population of triplet states by ISC:

$$k_{ISC,T} = \frac{k_{ISC,S}}{3} \exp(-\Delta E_{ST}/k_B T). \quad (6.46)$$

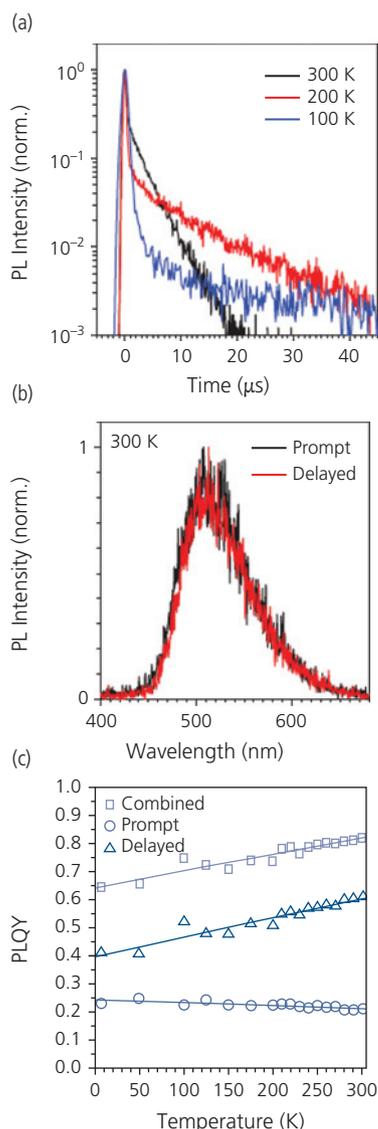

(Compare this with Eq. 3.208, with  $k_{ISC,T}^\infty = k_{ISC,S}/3$ .)

By combining Eqs. 6.42, 6.44, and 6.45, we can obtain  $k_{ISC,T}$  by making the reasonable assumptions that  $k_{ph} + k_{nrT} \ll (k_F + k_{nrS})$  and  $K \lesssim 1$  in efficient TADF systems. Then,

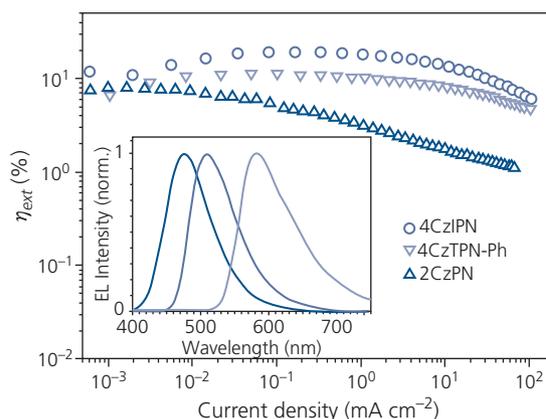

$$k_{ISC,T} \approx \frac{k_{TADF} k_{ISC}}{k_F + k_{nrS} - k_{TADF}} \approx \frac{k_{TADF} k_{ISC}}{k_F}, \quad (6.47)$$

where on the right hand expression we have made the further assumption that  $k_{nrS}$  and  $k_{TADF}$  are small compared to the prompt fluorescence rate,  $k_F$ . Since both  $k_{ISC}$  and  $k_F$  are largely temperature independent, the activation energy taken from the slope of the  $k_{TADF}$  vs.  $1/T$  gives a small exchange energy splitting via Eqs. 6.46 and 6.47. For 4CzIPN, for example, it was found that  $\Delta E_{ST} = 83$  meV (Uoyama et al., 2012). This is more than three times the thermal energy at room temperature. From the intercept of a plot of  $k_{ISC,T}$  vs.  $1/T$ , at  $T \rightarrow \infty$  we obtain  $k_{ISC,T} = k_{ISC,S}/3$ .

Although the singlet-triplet splitting is larger than  $k_B T$ , endothermic transfer  $S_1 \leftarrow T_1$  can, nevertheless, be efficient in the absence of parasitic decay channels. In Fig. 6.67 we show  $\eta_{ext}$  for three OLEDs with EMLs

**Figure 6.66** Dynamics of TADF for a film comprising 5 wt% 4CzIPN doped in CBP. (a) PL transients at three temperatures, (b) prompt and delayed fluorescence at 300 K, (c) PL quantum yield (PLQY) vs.  $T$  for prompt and delayed fluorescence (Uoyama et al., 2012).

**Figure 6.67** Efficiencies and EL spectra (inset) of four TADF OLEDs based on carbazolyl dicyanobenzene molecules doped into CBP at concentrations of 5 wt% (Uoyama et al., 2012).

comprising 15 nm 4CzIPN or 4CzTPN-Ph (5 wt%):CBP for green and yellow emitting devices, respectively. For cyan OLEDs, the EML was 20 nm 2CzPN(5 wt%):PPT:CBP. These structures are similar to those employed in PHOLEDs, consisting of a layering scheme that follows: anode/HTL/EML/HBL/ETL/EIL/cathode. Since triplets have a far longer lifetimes than singlets, it is important to confine them with an HBL/EBL around the EML to ensure that they are harvested by the TADF chromophores. Furthermore, the triplet and singlet energies of the host should exceed that of the guest to ensure efficient energy transfer. As in PHOLEDs, this transfer can occur by exchange (Dexter), dipole coupling (Förster) or even direct charge transfer to the guest from the adjacent ETL and/or HTL layers.

The green emitting 4CzIPN-based device has a peak room temperature efficiency of  $\eta_{ext} = 19.3\%$ , corresponding to  $\eta_{int} \approx 100\%$ , with  $\eta_{ext} = 11 \pm 1\%$  for the yellow, and  $8 \pm 1\%$  for the cyan devices (Uoyama et al., 2012). Since these are inherently phosphorescent devices (i.e. emission rates are controlled by the triplet lifetime,  $1/k_{ph}$ ), they are capable of harvesting both triplets and singlets similar to heavy metal triplet emitters.

The maximum rate for delayed fluorescent emission is given by Eq. 6.44. Hence, for  $k_F \sim 10^8 \text{ s}^{-1}$  and  $\Delta E_{ST} > 0.07 \text{ eV}$ , then  $K \approx 0.025$ , yielding

$$\tau_{TADF} = k_{TADF}^{-1} = \frac{1 + K}{(k_F + k_{nrS})K} \approx 400\text{ns}. \quad (6.48)$$

This is apparently a *lower* limit to the emission time for non-metalorganic TADF molecules, with high performance materials demonstrated that exhibit  $\tau_{TADF} \sim 2\text{--}100 \mu\text{s}$  (Zhang et al., 2012, 2015, Wang et al., 2015, Wang et al., 2016).

Since their introduction in OLEDs, TADF dopant materials based on carbazolyl, Cu and Au complexes have produced devices with  $\eta_{int} \approx 100\%$  and spectra spanning the entire visible spectrum. These molecules consistently follow the motif of electron donating and withdrawing groups at opposite ends of a twisted backbone, thus limiting the orbital overlap between these groups. Examples of a few such organic fluorophores listed in Table 6.8 provide their  $\tau_{TADF}$  in solution or solid matrices, peak emission wavelengths and maximum efficiencies of OLEDs in which they are used. The delay time scales with the exchange energy, as expected. The longest  $\tau_{TADF} = 86 \mu\text{s}$  is found for the deep red fluorophore, TPA-DCPP (compound **1R**) with an  $\Delta E_{ST} = 130 \text{ meV}$ , and the shortest is for DMAC-BP (**7G**) with  $\tau_{TADF} = 2.7 \mu\text{s}$  and a  $\Delta E_{ST} = 70 \text{ meV}$ . It is indeed remarkable that OLEDs

employing molecules with  $\tau_{TADF} > 50 \mu\text{s}$  have  $\eta_{ext} > 10\%$ , indicative the presence of very limited non-radiative recombination pathways.

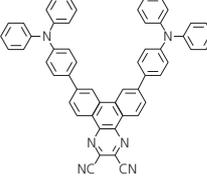

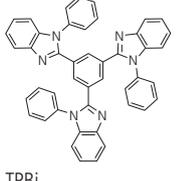

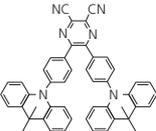

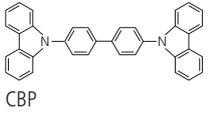

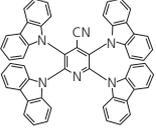

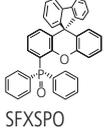

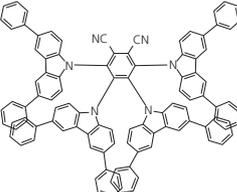

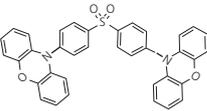

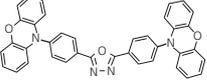

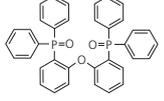

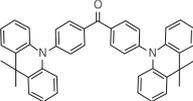

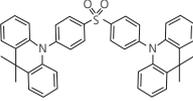

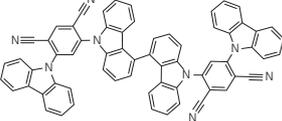

In some cases, both doped and undoped EMLs have been shown to have nearly 100% internal quantum efficiency. The green emitting devices (**4G** and **7G**) have nearly lossless endothermic transfer from the triplet to the singlet state, followed by fluorescence whose rate,  $k_F$ , is significantly larger than competing non-radiative processes, at rate  $k_{nrS}$ .

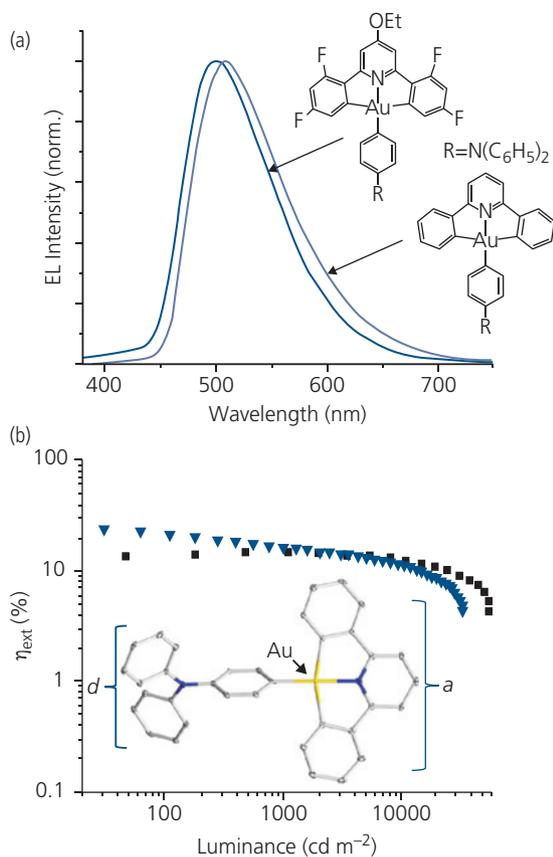

One variation on these molecular motifs is the deep blue “twin emitter” design of 44TCzPN (**9B**) (Kim et al., 2016b). Generally, the carbazole fluorophores are connected via a phenyl group (e.g. **3Y**, **4G**) that is incapable of controlling the degree of conjugation between these units. In the twin emitter design, interconnection is via the pair of carbazoles that controls the angle between the end groups (also carbazoles), thereby decreasing conjugation. This strategy appears to eliminate the red shift, leading to deep blue emission at high OLED quantum efficiency. Indeed, **9B** has a rather short  $\tau_{TADF}$  even with its large exchange energy of 210 meV.

Up to this point, only organic molecules have been discussed. In Sections 3.6.1 and 3.7.5 we introduced metal–organic complexes that use a Cu linker between the donor and acceptor moieties. These moieties show characteristic, structureless emission that is tuned from the blue to the NIR spectral regions, often with nearly 100% internal quantum efficiency (Wallesch et al., 2014, Yersin et al., 2017, Shi et al., 2019). Similarly Ag and Au can link the donor acceptor groups with similar characteristics to those obtained for the organic complexes in Table 6.8. Figure 6.68a shows the emission spectra of OLEDs employing two Au(III) aryl emitting TADF compounds whose molecular structural formulae are also provided. The device structure was: ITO/PEDOT:PSS/PVK:OXD-7:Au(III) complex (80:20)/TPBi/LiF/Al, where the bottom layers are deposited from solutions, whereas the TPBi blocker and cathode contacts are deposited by VTE. As for the carbazolyl and Cu complexes, the emission spectra are broad and featureless extending from the blue into the NIR at 700 nm. The peak emission intensity is at 509 nm and 500 nm, with the shorter wavelength corresponding to the fluorinated compound that has stronger electron-withdrawing character than the compound lacking the four F atoms.

The structure of the non-fluorinated compound is shown in Fig. 6.68b. The twist in the molecular structure across the Au linker provides isolation between the orbitals on the donor and acceptor moieties. This

twist leads to a reduced HOMO-LUMO overlap, and hence a reduced exchange energy, giving Au(III)-aryl compounds their TADF character. The temperature dependence of the emission lifetime of this Au complex following an analysis used for the Cu compounds in Eq. 3.212 gives  $\Delta E_{ST} = 26$  meV, with 39 meV for the fluorinated complex in Fig. 6.68a (To et al., 2017). Notably, metalorganic TADF molecules often have radiative lifetimes  $< 1\mu\text{s}$ , in contrast to the generally far longer lifetimes (typically  $> 5\mu\text{s}$ ) for pure organic compounds.

It is found in Fig. 6.68b that at  $1000\text{ cd/m}^2$ , external efficiencies of 14.7% and 16.5% are obtained for the non-fluorinated and fluorinated complexes, respectively, with corresponding peak efficiencies at low luminance of 14.8% and 23.8%. These high room temperature efficiencies are due to the very small exchange energies, and hence small TADF lifetimes of these molecules.

The broad and unsaturated emission of TADF compounds results from the lack of intramolecular overlap of the donor-acceptor moieties, giving the emission a charge transfer character. More saturated emission can be achieved using a TADF *molecular sensitizer* (or *assistant molecule*) co-doped with a conventional fluorophore with its reduced, excitonic emission linewidths (Nakanotani et al., 2014). If the singlet level of the sensitizing molecule is higher than that of the fluorophore, and if there is spectral overlap between the singlet emission spectrum of the sensitizer and the absorption spectrum of the fluorescent emitter, then efficient Förster energy transfer can occur from the TADF molecule to the fluorescent emitter. Sensitized TADF is analogous to phosphor-sensitized fluorescence discussed in Section 6.3.1 (cf. Figs. 6.30 and 6.31) that was similarly developed to access the exceptionally large palette of highly efficient fluorescent dopants in OLEDs (Baldo et al., 2000b, Kanno et al., 2006c, Chang et al., 2007). The mechanism of charge to exciton to dopant transfer is shown in Fig. 6.69. Note that sensitized TADF has the added benefit of accessing the far larger number of fluorescent dyes that are available as compared with TADF compounds, thus providing greater flexibility in choosing an emission color to satisfy a particular application need.

For sensitized TADF to be efficient, there must be 100% triplet-to-singlet up-conversion on the sensitizer, followed by equally efficient singlet transfer from the sensitizer to the fluorescent emitter. We have seen that the first step in this energy cascade can be achieved using TADF molecules with a small exchange energy splitting. We have also shown in Sections 6.3.2, 6.3.3, and Chapter 3, that FRET can also be highly efficient when the acceptor and donor are in resonance, and within a Förster radius,  $R_0$ .

The down-conversion process in Fig. 6.69 starts by the formation of an injected electron and hole into an exciton. This can occur on the host molecule, or directly on the TADF assistant. The exciton on the assistant is excited to  $S_1$  and then subsequently exothermically transferred by FRET onto the emitting fluorophore. Figure 6.70a shows the PL spectrum of the blue TADF-assisted system consisting of a film using the TADF assistant ACRSA in DPEPO as host, along with the absorption and PL spectra of the TBPe dopant in a solution of  $\text{CH}_2\text{Cl}_2$ . The overlap between the ACRSA emission and TBPe absorption spectra yields a transfer radius is  $R_0 = 2.2$  nm. The energies of the  $S_1$  and  $T_1$  states are 3.50 and 3.00 eV for DPEPO, and 2.55 eV and 2.52 eV for ACRSA, respectively, and  $S_1$  for the emitter is 2.69 eV. Since ACRSA

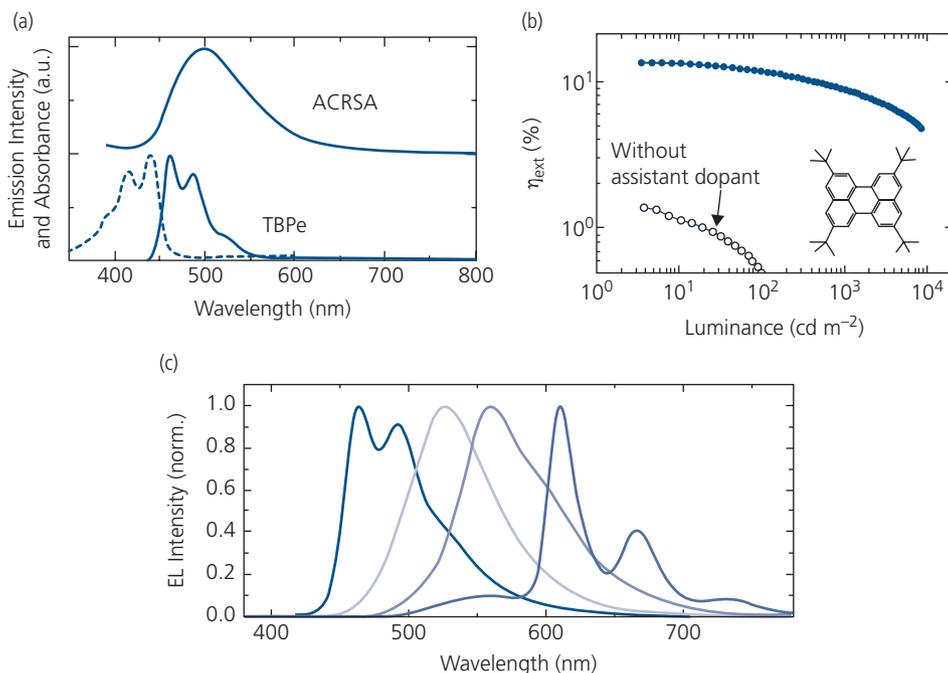

**Figure 6.69** TADF sensitized fluorescence. A host transfers charge to a TADF assistant molecule (dashed box) doped with a fluorophore. Exothermic FRET transfer of the exciton from the assistant to the fluorophore results in emission within the visible or NIR spectrum, depending on the excitonic energy of the fluorophore. Molecular formulae of several assistant TADF dopants are shown at the bottom (Nakanotani et al., 2014).

is doped at 15 wt% into DPEPO, both singlets and triplets are efficiently transferred by exchange and/or FRET to the assistant. In contrast, the emitter molecule, TBPe, is doped at only 1wt% into the host-assistant blend, ensuring that only FRET of the singlets in the assistant is active. This avoids direct transfer of triplets from the assistant to the emitter molecule, which would lead to their loss. The effect of the assistant is apparent in Fig. 6.70b. The external quantum efficiency of the device with the TADF sensitizer has a maximum of 13.4%, falling to 8.7% at 1000 cd/m<sup>2</sup>, with cyan CIE coordinates of (0.17, 0.30). This is compared with a maximum efficiency of only 1.5% for the TPBe device lacking the sensitizer.

The high energy spectra in Fig. 6.70a point to one of the challenges of the sensitization strategy used in both PHOLEDs and TADF OLEDs: deep blue fluorescent OLEDs require a sensitizer molecule of even higher (ultraviolet) energy emission to allow for efficient exothermic transfer to the fluorophore, and perhaps even higher energy for the host excited

states. As will be shown in Section 6.7, high energy emitting materials have considerably shorter operational lifetimes than their lower energy (e.g. green or red) emitting counterparts. Hence, it is problematic to realize long-lived devices with emission in the deep blue.

The spectra of sensitized OLEDs using the various materials combinations in Fig. 6.69 are shown in Fig. 6.70c. Unlike TADF emission, the vibronic structure of the emitting fluorophore is apparent, resulting in spectra that are comparatively narrow. All materials combinations have the appropriate energetic arrangement of  $S_1^H, T_1^H > S_1^A, T_1^A \gtrsim S_1^F$ , where superscripts H, A, and F correspond to the host, assistant and fluorescent emitter molecules, respectively. The peak efficiencies thus obtained using 1 wt% of the fluorophore in 15–50 wt% assistant doped into their respective hosts, are 8.7%, 11.7%, 17.2%, and 10.9% for the blue, green, yellow, and red OLEDs, respectively. The efficiencies are consistently lower than optimized TADF devices due to energy transfer losses incurred at each of the

**Figure 6.70** (a) Emission spectra of the TADF sensitizer, ACRSA doped at 15 wt% into a DPEPO host, and the absorption (dashed line) and emission (lower solid line) spectra of TBPe in a 10  $\mu\text{M/L}$  solution of  $\text{CH}_2\text{Cl}_2$ . (b) External quantum efficiency of a DPEPO:TBPe (1 wt%) EML OLED with and without 15 wt% doping with ACRSA. Inset: Chemical structural formula of TBPe. (c) Spectra of the blue, green, orange, and red fluorescent dopants in Fig. 6.69 (Nakanotani et al., 2014).

steps in the cascade from host to assistant to emitter, as well as to the less than unity PLQY of the various molecules employed. This is particularly clear in the red-emitting device in Fig. 6.70c where incomplete transfer results in a short wavelength tail extending from  $\lambda = 500$  to 590 nm.

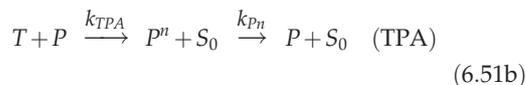

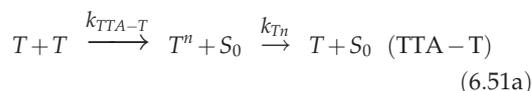

### 6.3.5 Exciton annihilation and management in OLEDs

At high current, the efficiency of all OLEDs decreases (see, for example, Figs. 6.54 and 6.56). There are three primary sources for this phenomenon: saturation of dopant molecular sites with excited states, loss of charge balance in the EML, and exciton annihilation, all of which increase with current (Giebink and Forrest, 2008). Exciton annihilation with other excitons and/or polarons is particularly important, and was introduced in Section 3.10. The annihilation reactions that result in decreased efficiency at high current are the following:

*Fluorescent OLEDs*

*Phosphorescent and TADF OLEDs*

Here, the annihilation processes are defined as in Chapter 3: singlet-triplet (STA), singlet-polaron (SPA), singlet-singlet (SSA), triplet-triplet that produces singlets or triplets (TTA-S or TTA-T, respectively), and triplet-polaron (TPA). Note that Eq. 6.50 gives rise to delayed fluorescence, and thus leads to *increased* efficiency in singlet emitting OLEDs.

These processes require the collision of two particles (either an exciton or a polaron) at a common molecular site. The collision results in the delivery of the energy from the emitting exciton to a second species (exciton or polaron), which is promoted to a higher energy (hot)

state, denoted as  $S^n$ ,  $P^n$ , or  $T^n$ , where  $n > 1$ . Non-radiative relaxation then returns the hot state back to its lowest energy level where either a further annihilation event, or a transition to the ground state occurs. The rates ( $k$ ) of the corresponding processes are also defined in Eqs. 6.49–6.51. Since the same triplet population leads to singlet or triplet annihilation, the rate constants governing the relative contributions of processes in Eqs. 6.50 and 6.51a are related via  $k_{TTA-S} = \alpha k_{TT}$  and  $k_{TTA-T} = (1 - \alpha)k_{TT}$ , respectively, where  $\alpha$  is the fraction of annihilation events that follow TTA-S *vs.*  $k_{TT}$ , which is the total TTA rate constant. Since these processes depend on exciton concentration, then TTA-S occurs at rate  $\alpha k_{TT}T^2$  and TTA-T at rate and  $(1 - \alpha)k_{TT}T^2$ .

With these processes and rates, we can write a generalized rate equation for the dynamics of the exciton population in the presence of both optical and electrical excitation at position  $x$  within the emission zone of the OLED, *viz.*

$$\frac{dN(x, t)}{dt} = G(x, j) - N(x, t)[k_N + K(x, j)], \quad (6.52)$$

where  $G(x, j)$  is the electrical generation rate at current density  $j$ ,  $k_N = k_F$  or  $k_{Ph}$  for a singlet or triplet exciton, respectively, and the exciton concentration,  $N(x, t)$  is either the singlet ( $S(x, t)$ ) or triplet ( $T(x, t)$ ) density. These can be either optically or electrically generated or both, such that  $N(x, t) = N_{EL}(x, t) + N_{PL}(x, t)$ . Finally,  $K(x, j)$  is the aggregate rate due to quenching by all possible mono- and bimolecular processes, and can be written (Giebink and Forrest, 2008)

$$K(x, j) = k_n n(x, j) + k_p p(x, j) + k_{NNE}N_{EL}(x, j) + k_{NNP}N_{PL}(x) + \zeta(F) + \dots \quad (6.53)$$

In this expression, the generalized rates due to electron or hole quenching are  $k_n$  and  $k_p$  with corresponding electron and hole densities,  $n(x)$  and  $p(x)$ . The second two terms are the generalized bimolecular exciton recombination rates due to electrical ( $k_{NNE}$ ) or optical ( $k_{NNP}$ ) excitation. Finally,  $\zeta(F)$  is exciton quenching rate due to the local electric field  $F(j)$ . As we will see below, most practical situations require that we consider only the few processes that are the most significant to the exciton dynamics in a particular OLED.

### 6.3.5.1 Exciton annihilation, triplet fusion, and singlet fission in fluorescent OLEDs

From Eqs. 6.49a and 6.50, we see that triplet annihilation can lead to either a decrease or an increase in the singlet density (Zhang and Forrest, 2012). Process

TTA-S results in delayed fluorescent emission that adds to OLED efficiency by creating additional singlets from non-radiative triplets. Several reports (Kondakov et al., 2009, Yokoyama et al., 2011, Wallikewitz et al., 2012) show  $\alpha > 0$ , resulting in fluorescent OLEDs whose internal efficiency exceeds the 25% spin-statistical limit due to this process.

The rate of STA is  $k_{STA}ST$ . Thus, using Eqs. 6.52 and 6.53 we can describe the singlet and triplet density dynamics by

$$\frac{dS}{dt} = \gamma(j) \frac{j}{4qd} - k_F S - k_{STA}ST + \alpha k_{TT}T^2, \quad (6.54)$$

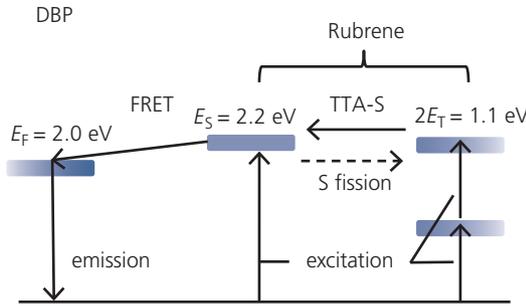

$$\frac{dT}{dt} = \gamma(j) \frac{3j}{4qd} - k_{Ph}T - (1 + \alpha)k_{TT}T^2, \quad (6.55)$$

where  $\gamma(j)$  is the current-dependent charge balance factor, and  $d$  is the EML thickness. The  $\frac{1}{4}$  and  $\frac{3}{4}$  terms in these expressions reflect the statistics of singlet and triplet spin formation. In steady state, the external quantum efficiency is calculated for  $S(t = \infty, J)$  to give (Zhang and Forrest, 2012)

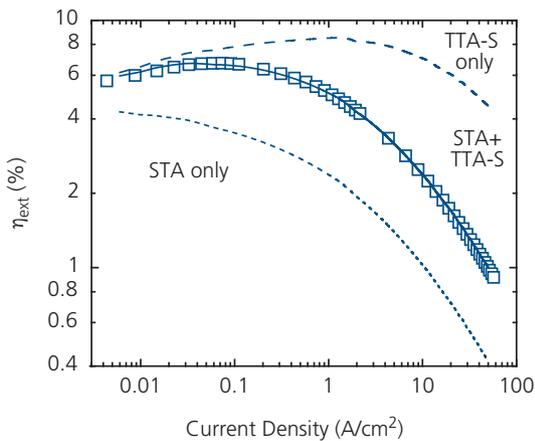

$$\eta_{ext}(j) = \eta_{out}\phi_S \frac{k_F S(t = \infty, j)}{j/qd}. \quad (6.56)$$

Rubrene is a particularly interesting fluorescent molecule since its singlet energy ( $E_S \sim 2.2$  eV) is twice that of the triplet ( $E_T \sim 1.1$  eV), thereby enabling efficient, resonant TTA-S (Kondakov et al., 2009). When rubrene is doped with a fluorophore with emission energy,  $E_F$ , such that  $E_T < E_F < E_S$  (e.g. DBP with  $E_F = 2.0$  eV), two triplets produced on rubrene can undergo TTA-T (a process called *triplet fusion*), to produce one rubrene singlet. Subsequently, the singlets can transfer via FRET to the fluorophore followed by radiative emission. Unlike TADF, this route to singlet generation is lossy, since it takes two excited states (triplets) to generate a radiative singlet, see Fig. 6.71. Given the dual generation processes of direct singlet excitation and singlet production via triplet fusion, the OLED efficiency can exceed that determined by spin statistics, where only one singlet is generated per three triplets. Figure 6.71 also shows the competing process of singlet fission, whereby one singlet can produce two triplets, following:  $S \xrightarrow{k_{S2T}} 2T$  under the condition that  $E_S \geq 2E_T$ . This process competes with radiative emission from DBP. Due to the exothermic transfer from rubrene to DBP, it is likely that  $k_F \gg k_{S2T}$ , and hence the latter process is largely inactive.

These several processes have been identified in a 1 vol.% DBP:rubrene OLED with a peak  $\eta_{ext} = 6.7\%$  at  $j = 75$  mA/cm<sup>2</sup> (Fig. 6.72), clearly exceeding the spin-

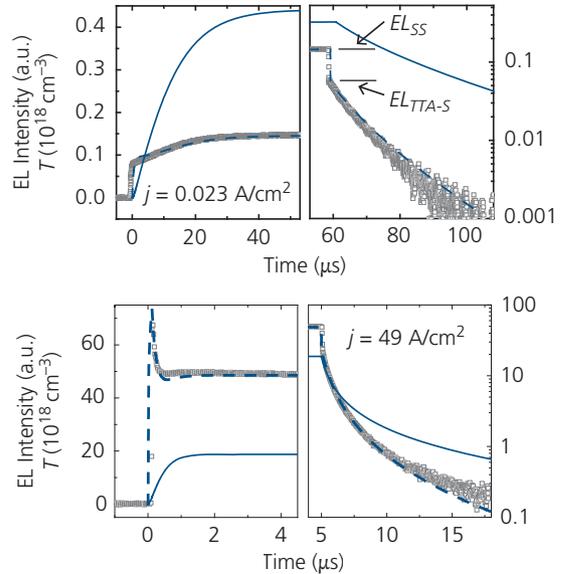

**Figure 6.71** Emission from a DBP:rubrene OLED due to a combination of direct electrical excitation of rubrene singlets and triplets, along with triplet fusion (right) resulting in additional rubrene singlets.

**Figure 6.72** External quantum efficiency vs. current density for a DBP:rubrene OLED (square symbols), along with fits to the data using Eqs. 6.54–6.55 in steady state, assuming the presence of TTA, STA and a combination of the two processes (Zhang and Forrest, 2012).

statistical limit of  $\eta_{ext} \approx 5\%$ . The  $\eta_{ext}$  undergoes a rapid roll-off with increasing  $j$ , decreasing to only 0.9% at 57 A/cm<sup>2</sup>. The EL spectrum shows pure DBP emission with a peak wavelength of  $\lambda = 610$  nm, and with almost no change with  $j$ , indicating that FRET is efficient (Zhang and Forrest, 2012). A solution to the steady state rate equations that considers both triplet fusion and STA (Eqs. 6.54–6.56), yields a fit to the data (solid line) for  $k_{STA} = 7.1 \times 10^{-11} \text{ cm}^{-3} \text{ s}^{-1}$  and  $k_{TTA-S} = 6.0 \times 10^{-14} \text{ cm}^{-3} \text{ s}^{-1}$ . Eliminating one or the other of the processes, however, does not adequately describe the observed dependence of  $\eta_{ext}$  on  $j$ .

The theory also requires charge balance. The fits are reasonable assuming  $\gamma(j) = 1$  for  $j > 1 \text{ A/cm}^2$ , after which  $\gamma(j)$  decreases due to charge leakage through the emissive layer, and field-induced exciton dissociation (Giebink and Forrest, 2008). The leakage is evident in

**Figure 6.73** Transient response of DBP:rubrene OLED EL intensity at pulse turn-on (left panels) and turn-off (right panels) at two different current densities. Calculated triplet densities (solid lines) and singlet densities (dashed lines) are compared with the data. The steady state  $EL_{SS}$  and delayed  $EL_{TTA-S}$  due to triplet fusion are shown (Zhang and Forrest, 2012).

the emission spectra for OLEDs that show a noticeable increase in the contribution from rubrene (at  $\lambda = 550$  nm) at  $j > 60 \text{ A/cm}^2$ . Exciton–polaron annihilation is also possible in fluorescent OLEDs; however, it is not needed to achieve the fit in Fig. 6.72.

The time dependent solutions to Eqs. 6.54 and 6.55 that include both STA and TTA-S with rate constants used in Fig. 6.72 also accurately represent the data obtained for both the turn-on and turn-off transients of the EL intensity, shown in Fig. 6.73. At low  $j$ , the EL intensity gradually increases to steady state over tens of microseconds. This is consistent with TTA-S since the triplet density slowly increases over this timescale. In contrast, at high  $j$ , the EL intensity rapidly peaks, and then gradually decays to a steady-state intensity approximately 70% of its peak value. This is a signature of STA since the singlet density decreases with increasing triplet density due to increased annihilation (Zhang et al., 2010). The EL turn-off transients for all current densities show delayed fluorescence (right hand graphs in Fig. 6.73) due to TTA-S (Kondakov et al., 2009, Zhang et al., 2010). The steady-state EL intensity,  $EL_{SS}$ , and the initial delayed fluorescence intensity,  $EL_{TTA-S}$  are related by the ratio,  $\rho(j) = EL_{TTA-S}/EL_{SS}$  that characterizes the fraction of TTA-generated-emission relative to the total emission intensity.

The question now arises: what is the maximum quantum efficiency that can be achieved by delayed fluorescence generated by TTA-S? Using Eqs. 6.54 and 6.55, we can write  $\rho(j)$  as

$$\rho(j) = \frac{3ak_{TTA-S}T^2}{k_{Ph}T + (1+a)k_{TTA-S}T^2 + 3ak_{TTA-S}T^2}. \quad (6.57)$$

Since the phosphorescent rate is very small compared to the other rates; then  $\lim \rho = 3a/(4a+1)$ . The upper limit of the internal quantum efficiency is  $\eta_{int,max} = 25\%/(1-\rho) = 25\% \times (4a+1)/(a+1)$ . When  $a = 1$ ,  $\eta_{int,max} = 62.5\%$ ; a limit can only be reached for  $k_{TTA-S}T \gg k_{Ph}$  with negligible STA. This limit is considerably lower than 100% that is accessible by triplet emission via phosphorescence or TADF. Indeed, the highest observed internal quantum efficiency via delayed fluorescence is  $\sim 50\text{--}55\%$  (Kondakov et al., 2009, Zhang and Forrest, 2012).

It is apparent from the foregoing that TTA-S can add to the device efficiency at low  $j$ , but at high  $j$  it must compete with losses due to STA, where the build-up of triplets results in quenching of the high density of singlets. To find the  $j$  where the increase in efficiency is overcome by losses, we define the effective triplet current density as

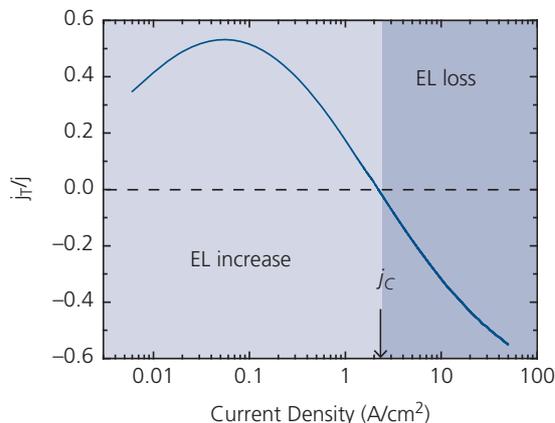

$$j_T = \frac{4qd}{\gamma(j)} (ak_{TT}T^2 - k_{STA}ST), \quad (6.58)$$

which allows us to rewrite Eq. 6.54 as

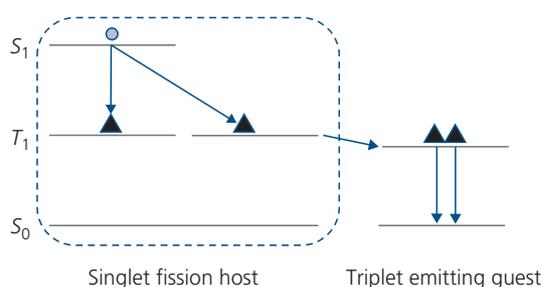

$$\frac{dS}{dt} = \gamma(j) \frac{j}{4qd} \left[ 1 + \frac{j_T}{j} \right] - k_F S. \quad (6.59)$$

Now,  $j_T$  can be either positive or negative, depending on whether TTA-S or STA dominates. The calculated  $j_T/j$  for the DBP:rubrene OLED is shown in Fig. 6.74. With increasing  $j$ ,  $j_T/j$  is initially positive, and increases due to TTA-S to a peak of 0.53 at  $j = 50 \text{ mA/cm}^2$ ; and then decreases due to the increased rate of STA. A critical current density,  $j_C$  can be defined when  $j_T/j = 0$  where the effects of TTA and STA are equal. Above  $j_C = 2.2 \text{ A/cm}^2$  triplets lead to a net decrease in quantum efficiency.

Singlet fission can result up to 125% internal efficiency if the triplets are harvested by a molecule with a large phosphorescent efficiency, such as a heavy metal complex. An energy level diagram showing singlet fission yielding two triplets is shown in Fig. 6.75. We assume that the host molecule can engage in efficient singlet fission, that is,  $E_{HS1} \geq 2E_{HT1}$ , where the substrate H refers to the host. A guest phosphor whose triplet energy is  $E_{GT1} \leq E_{HT1}$  is doped into the host at a concentration that

**Figure 6.74** Effective triplet normalized current density,  $j_T$  vs.  $j$  for a 1% vol. DBP:rubrene OLED. The critical current ( $j_C$ ) where the increase in quantum efficiency due to TTA-S is exceeded by loss due to STA is shown.

**Figure 6.75** Energy level diagram of the emission region of an OLED undergoing the process of singlet fission yielding two emissive triplets (triangles) for every singlet (circle).

permits Dexter transfer of triplets from the host to the guest molecule. The host is electrically excited, creating the usual 1:3 singlet:triplet ratio. The triplets are transferred directly to the guest, accounting for 75% of the excited states. On the other hand, the singlet population undergoes fission to create two triplets for each singlet. These excess triplets then transfer to the phosphor, which add to the emission intensity. In principle, therefore, there are 125 emitting triplets generated for each 100 electron-hole pairs injected into the OLED EML.

There is somewhat weak evidence that this process has been observed in the rubrene:Erq<sub>3</sub> host/guest system (Nagata et al., 2018). The guest is a rare earth phosphor. Unlike heavy metal electrophosphorescent complexes, the triplet transition occurs directly between atomic orbitals on the rare earth, rather than via ligand transitions. For Er, the intra-4f transition  $^4I_{13/2} \rightarrow ^4I_{15/2}$  ( $^4I_{15/2}$  corresponds to the ground state) has a NIR emission energy of 0.80 eV. This is below the rubrene triplet at 1.14 eV, which allows for

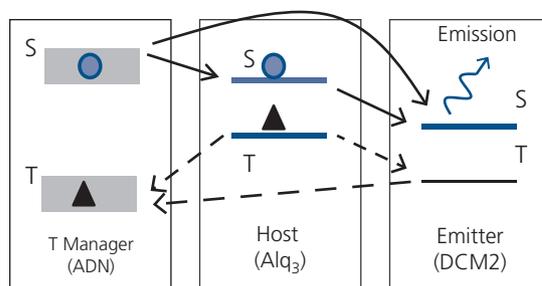

efficient exothermic transfer to the Er ion. The 8-hydroxyquinoline ligand singlet and triplet energies on Erq<sub>3</sub> are 2.85 eV and 2.23 eV, respectively, and hence do not participate in the emission process. While rare earth molecules undergo triplet emission with narrow emission spectra, coupling to the atomic orbitals is weak, and hence such devices have not been found useful for OLED applications.

To determine whether or not singlet fission to the Er complex, the change in PL intensity,  $\Delta I_{PL}$ , vs. magnetic field was measured for a 2 mol. % Erq<sub>3</sub>:rubrene film. As we will discuss in detail in Section 7.6, the magnetic field,  $B$ , decreases the number of correlated triplet pairs with singlet character, denoted by  $^1(TT)$ . Thus, the magnetic field enhances the rate of the reaction:  $S_1 \rightleftharpoons ^1(TT) \rightleftharpoons T_1 + T_1$  (Piland et al., 2013). As the field increases, there should be a decrease in the number of singlet fission products. It is observed that the fraction of light emitted in the NIR by the Er-complex with increasing magnetic field decreases by 9.5% at  $B = 0.4T$  from its value at  $B = 0$  due to a decrease in the production of  $^1(TT)$  precursor states. Also, note that the fraction of PL in the visible from rubrene fluorescence increases (+11.3%) due to a concomitant increase in singlets that are not lost to triplets.

The emission spectrum from an OLED employing an Erq<sub>3</sub>:rubrene EML is identical to the narrow emission spectrum centered at 1.55  $\mu\text{m}$  characteristic of the Er  $^4I_{13/2} \rightarrow ^4I_{15/2}$  transition. Quantitative analysis of the dependence of the intensity dependence on  $B$  yields a singlet fission yield under electrical excitation of 51.6%. However, the efficiency of the OLED is very low (i.e. far from the predicted 125%), which is attributed to the PLQY of only  $\Phi_{PL} \sim 10^{-3}$  for Erq<sub>3</sub>.

### 6.3.5.2 Reducing efficiency roll-off via triplet management

Triplet-induced quenching in OLEDs (Eq. 6.49a) can be reduced or even eliminated by blending a “triplet manager” molecule into the EML to divert triplets from the emitting guest molecule. The process of triplet management is illustrated in Fig. 6.76. If the  $T$  manager has a higher  $S$  and lower  $T$  energy than the guest, it facilitates Förster transfer of singlets to the guest, and Dexter transfer of triplets from the guest to the manager, thereby potentially eliminating STA on the guest. This strategy was demonstrated in OLEDs with EMLs comprising an Alq<sub>3</sub> host doped with 2 vol. % of DCM2 along with various concentrations ( $0 \leq x \leq 70$  vol.%) of ADN for triplet management. The triplet energies of Alq<sub>3</sub> ( $E_{T1} = 2$  eV), DCM2 (1.74 eV), and ADN (1.69 eV) are consistent with the requirements in Fig. 6.76 (Zhang et al., 2011). Since

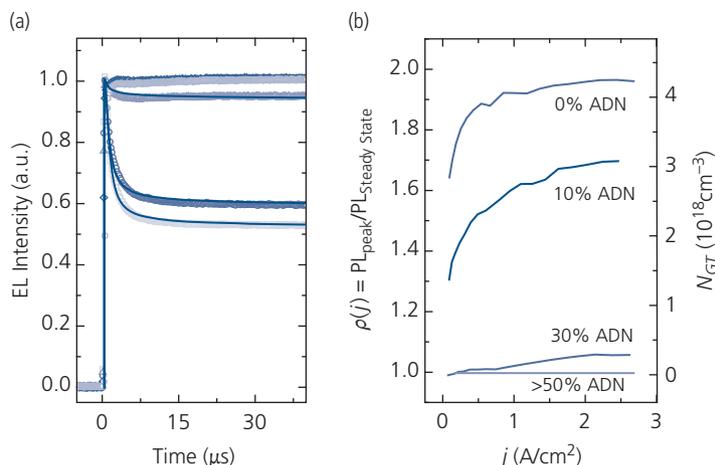

**Figure 6.76** Concept of a triplet managed fluorescent OLED EML. The triplet and singlet levels and the transitions between them are shown. The manager is co-doped with the emitter (guest) and host molecules in the EML. Its triplet energy is lower than that of the host and the fluorophore to capture triplets before they can undergo STA with host and emitter singlets. Förster transfers are shown as solid arrows, and exchange (Dexter) transfers by dashed arrows.

triplet transfer occurs primarily by exchange interactions, the manager concentration must be high ( $> 10\%$ ) for this scheme to be effective. Transfer of singlets is via Förster transfer, requiring dopant concentrations of only a few percent, which is sufficiently low to avoid concentration quenching.

Figure 6.77a shows the transient EL for a series of managed OLEDs with the structure of: ITO/35 nm NPd/25 nm-thick EML/25 nm BCP ETL/0.8 nm LiF/100 nm Al with different ADN fractions,  $x$ , in the EML. For the unmanaged (control) device ( $x = 0$ ), the EL rapidly reaches a peak and then decays to a steady state intensity at  $\sim 50\%$  of its initial value. This decrease in efficiency is due to STA as the triplet population builds up over several milliseconds (see Fig. 6.73, lower left) (Zhang et al., 2010). When the guest triplet population approaches steady state, STA stabilizes at a reduced equilibrium singlet population. In the presence of the  $T$  manager, the magnitude of the EL transient decay reduces with increasing  $x$ , and disappears entirely at  $x \geq 50\%$ , indicating the complete suppression of STA. Figure 6.77b shows the EL intensity peak-to-steady-state ratio,  $\rho(j)$ . We find that  $\rho(j)$  decreases with increased manager concentration, and  $\rho(j) = 1$  for  $x \geq 50\%$ , corresponding to an absence of STA.

Two annihilation processes dominate energy transfer in triplet-managed OLEDs, namely guest STA,  $S + T_G \rightarrow S_0 + T_G$ , and host-to-guest triplet Dexter transfer,  $T_H \rightarrow T_G$ . The EL transient follows the singlet population whose dynamics are described by (Zhang et al., 2011)

$$\frac{dS(t)}{dt} = -(k_F + k_{STA}T_G(t))S(t) + \gamma \frac{1}{4} \frac{j}{qd}, \quad (6.60)$$

**Figure 6.77** (a) Triplet managed transients for an OLED with an Alq<sub>3</sub> host, 2 vol.% DCM2 and an ADN manager at an injection current of  $j = 2 \text{ A/cm}^2$ . The transients, from top to bottom, have an ADN concentration of 70% (yellow), 50% (green), 30%, 10%, 0%. Solid lines are fits the STA theory in Eqs. 6.60–6.62. (b) Peak PL to steady state PL intensities as functions of ADN concentration vs. current density. Also shown is the guest triplet concentration,  $N_{GT}$  (Zhang et al., 2011).

$$\frac{dT_H(t)}{dt} = -k_{HG} \exp\left(-\frac{2}{L} \sqrt[3]{\frac{1}{N_{GT}(j) - T_G(t)}}\right) T_H(t) + \gamma \frac{3j}{4qd}, \quad (6.61)$$

and

$$\frac{dT_G(t)}{dt} = k_{HG} \exp\left(-\frac{2}{L} \sqrt[3]{\frac{1}{N_{GT}(j) - T_G(t)}}\right) T_H(t), \quad (6.62)$$

where we assume  $\gamma$  is independent of current,  $k_{HG}$  and  $L$  are the host-to-guest triplet transfer rate coefficient and molecular van der Waals radius, respectively, and  $N_{GT}(j)$  is the saturation guest  $T$  population. That is, when  $T_G(t) \rightarrow N_{GT}(j)$ , the transfer stops and  $dT_G/dt = 0$ . The exponential factors are due to transfer of excitons between molecules consistent with the Dexter process. Eventually,  $T_H$  saturates due to TTA and natural decay, but these processes are slower ( $\sim 1 \text{ ms}$ ) than the time scale for EL decay, and are thus neglected.

Assuming the boundary condition that  $T_G = 0$  at  $t = 0$ , and  $T_G = N_{GT}$  as  $t \rightarrow \infty$  in Eq. 6.61, we obtain

$$\rho(j) = 1 + \frac{k_{STA} N_{GT}(j)}{k_F}. \quad (6.63)$$

The external quantum efficiency roll-off is then given by  $\frac{\eta_{ext}(j)}{\eta_0} = \frac{\gamma(j)}{\rho(j)}$ , where  $\eta_0$  is the external efficiency for  $\gamma = 1$ , and  $\gamma(j)$  includes the current dependent charge balance along with all other loss factors under electrical excitation, such as SPA.

For a 2 vol.% DCM2 concentration,  $L \approx 3 \text{ nm}$  as determined from the average distance between dopant molecules. With the constraint on  $N_{GT}(j)$  given by Eq. 6.63 and  $\gamma = 1$ , the EL transients are fit by Eqs. 6.60–6.62 as shown by the solid lines in Fig. 6.77a. From the fits, we obtain  $k_{STA} = 1.5 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$  independent of host and manager concentrations, and  $k_{HG} = 2.5 \times 10^7 \text{ s}^{-1}$  for  $x = 0$  and 10%, and  $k_{HG} = 3 \times 10^8 \text{ s}^{-1}$  for  $x = 30\%$  ADN. Also,  $N_{GT}$  is obtained using Eq. 6.63, with results indicated on the right hand side of Fig. 6.77b. The introduction of the triplet manager substantially reduces  $N_{GT}$ . For example, at  $j = 0.5\text{--}2.5 \text{ A/cm}^2$ ,  $N_{GT}$  is reduced from  $4 \times 10^{18} \text{ cm}^{-3}$  ( $x = 0$ ) to  $< 3 \times 10^{17} \text{ cm}^{-3}$  ( $x = 30\%$ ), and to  $0 \text{ cm}^{-3}$  at  $x \geq 50\%$ . The manager effectively eliminates the nearly 50% decline in brightness (and efficiency) observed in its absence. This strategy not only emphasizes the importance of STA in fluorescent OLEDs, but it also shows a path to achieve very high brightness via the intentional reduction in the triplet population. We will show in Sections 6.7 and 6.8 that triplet management can also result in an increased PHOLED lifetime and continuous wave (CW) operation of optically pumped organic lasers.

### 6.3.5.3 Efficiency roll-off in PHOLEDs

A defining characteristic of phosphorescent emission is its long triplet decay time ( $\sim 500 \text{ ns}$  to  $10\text{'s}$  of  $\mu\text{s}$ ) compared with fluorescence (1–10 ns). While this is the origin of the high efficiency in PHOLEDs and TADF OLEDs, it also provides an extended period in which a triplet can interact with another excited state or polaron. Given the lack of a strong absorption into

the triplet manifold and the non-radiative nature of the host triplet, energy transfer occurs via hopping or direct charge trapping in phosphorescent devices. This requires a phosphor doping density that is significantly greater than used in fluorescent devices, where energy transfer is primarily via long-range FRET. This also results in an increased probability for triplet-triplet and triplet-polaron encounters on the dopant molecules, or in dopant molecular clusters at high current densities, leading to additional channels for non-radiative recombination at high current.

In Section 3.9 we showed that  $k_{TTA}$  is related to the triplet diffusion constant,  $D$ , via

$$k_{TTA} = 8\pi DR_c \quad (6.64)$$

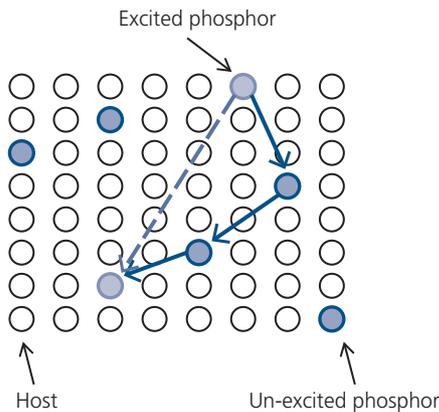

where  $R_c$  is the exciton capture radius. The factor of two difference between this expression and Eq. 3.261 is that here we consider the collision rate between two identical (i.e. triplet-triplet) particles. It has been argued that exciton annihilation can occur in a single step via FRET (Staroske et al., 2007, Zhang et al., 2016a), or via multiple exchange transfers from molecule to molecule (Zhang and Forrest, 2013), as illustrated in Fig. 6.78. Following the treatment in Section 3.9, we obtain the diffusion constants for these two different processes:

$$D_{FRET} = a^2 k_{ph} \left(\frac{R_0}{a}\right)^6 \quad (6.65)$$

and

$$D_{ex} = a^2 K J_\lambda \exp(-2a/L), \quad (6.66)$$

where  $a = 1/\sqrt[3]{CN}$  is nominally the distance between dopant molecules determined by the doping fraction,  $C$ , and the molecular density,  $N$ . Also,  $R_0$  is the Förster

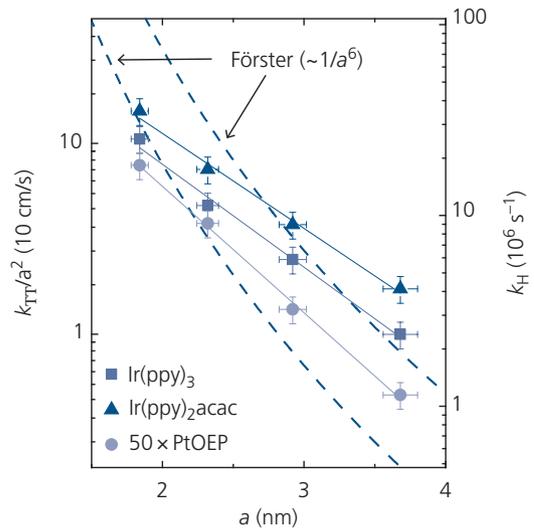

**Figure 6.78** Single step (dashed arrow) FRET vs. multistep (solid arrows) exchange-mediated diffusion resulting in triplet-triplet annihilation.

transfer radius,  $K$  is a constant, and  $J_\lambda$  is the overlap integral between the emission and absorption spectra of the donor and acceptor molecules, respectively (see Section 3.8). By measuring the dependence of  $k_{TTA}$  vs.  $a$  for PtOEP:CBP, Ir(ppy)<sub>3</sub>:CBP, and Ir(ppy)<sub>2</sub>acac:CBP guest-host systems in Fig. 6.79, the analysis using Eqs. 6.64–6.66 accurately fits the Dexter process (straight lines) compared to FRET (dashed lines), suggesting that triplet diffusion in is predominantly due to multi-step transfer. Note that all of these systems are characterized by strongly confined triplets on the guest molecules whose triplet energies are significantly less than that of the host (e.g. the Ir-complexes both have  $E_{T1} = 2.4$  eV). On the right hand axis in Fig. 6.79, we show the intermolecular hopping rate,  $k_H = 6k_{TTA}/(8\pi a^2)$ . The number of steps taken prior to an annihilation reaction is  $N = k_H/k_{ph}$ , which gives  $N \sim 3$ –30 (Zhang and Forrest, 2013).

The efficiency roll-off in PHOLEDs at high current density is thus due to a combination of: (i) TTA yielding singlets and triplets, (ii) TPA (Baldo et al., 2000a), and (iii) loss of charge balance (Reineke et al., 2007, Giebink and Forrest, 2008). It has also been suggested (Kalinowski et al., 2002) that loss of triplets in PHOLEDs can arise from field-induced quenching due to field ionization (Onsager, 1938). Given the compact nature of triplets, this mechanism is unlikely to be important.

Focusing our attention on the primary mechanism of TTA, we write the respective dynamical equation:

**Figure 6.79** Triplet-triplet annihilation rate,  $k_{TTA}/a^2$ , vs. the distance between dopant molecules,  $a$ , for three phosphors doped into CBP. Also shown (right hand axis) is the intermolecular hopping rate,  $k_H$  (Zhang and Forrest, 2013).

$$\frac{dT}{dt} = \frac{\gamma(j)j}{qd} - k_{ph}T - \frac{1}{2}k_{TTA}T^2. \quad (6.67)$$

The factor of  $\frac{1}{2}$  accounts for the loss of one of two triplets in TTA (Chandrasekhar, 1943). Following the end of the excitation pulse (i.e.  $j = 0$ ), the solution to Eq. 6.68 is

$$T(t) = \frac{T(0)}{\left(1 + T(0)\frac{k_{TTA}}{2k_{ph}}\right)\exp(k_{ph}t) - T(0)\frac{k_{TTA}}{k_{ph}}}. \quad (6.68)$$

Assuming that the luminescence intensity ( $L$ ) is linearly proportional to the concentration of excited states, that is,  $L(t) \propto k_{ph}T$ , then the time evolution of phosphorescent emission referenced to its value at  $t = 0$  is obtained from Eq. 6.67:

$$L(t) = \frac{L(0)}{\left(1 + T(0)\frac{k_{TTA}}{2k_{ph}}\right)\exp(k_{ph}t) - T(0)\frac{k_{TTA}}{2k_{ph}}}. \quad (6.69)$$

The external quantum efficiency can also be calculated from the steady state solution of Eq. 6.67:

$$\frac{\eta_{ext}}{\eta_0} = \frac{j_0}{4j} \left( \sqrt{1 + 8\frac{j}{j_0}} - 1 \right), \quad (6.70)$$

where  $\eta_0$  is the quantum efficiency in the absence of TTA (measured at  $j \rightarrow 0$ ), and the roll-off current,  $j_0$ , is defined at  $\eta_{ext} = \frac{1}{2}\eta_0$ . Then it follows that:

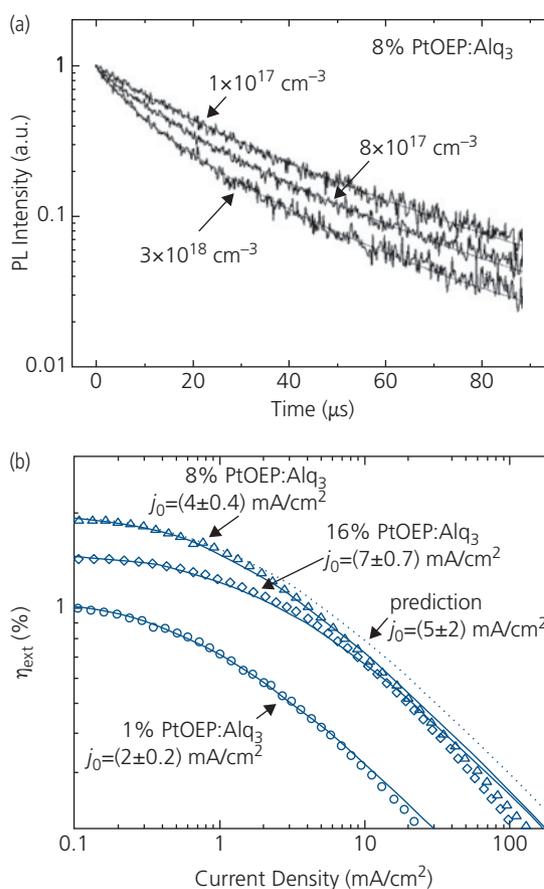

$$j_0 = \frac{2k_{ph}^2qd}{k_{TTA}}. \quad (6.71)$$

The importance of TTA in determining the roll-off in efficiency of PHOLEDs has been widely observed. For example, in Fig. 6.80a we show the transient PL transient data of an 8 vol.% PtOEP:Alq<sub>3</sub> film. The triplet density,  $T(0)$ , obtained from the absorption coefficient of Alq<sub>3</sub> (Garbuzov et al., 1996) and the optical intensity, are provided. The increased curvature with triplet density shows the quadratic dependence of TTA. Solutions to Eq. 6.69 provide fits to the data, yielding  $k_{ph} = 3.1 \times 10^4 \text{ s}^{-1}$  and  $k_{TTA} = 1.2 \times 10^{-13} \text{ cm}^3 \text{ s}^{-1}$ , shown by the solid lines in the figure (Baldo et al., 2000a).

This same materials system was used in a PHOLED with a 10 nm PtOEP:Alq<sub>3</sub> EML, where the PtOEP doping concentration was 1, 8, and 16 vol.%. The solid lines in Fig. 6.80b are steady state solutions to Eq. 6.67, yielding the roll-off current densities,  $j_0$ , shown for each PtOEP concentration. Apparently,  $j_0$  increases with concentration due to triplet diffusion. As the dopant concentration increases, triplets diffusing on the host can more easily find a dopant molecule and subsequently radiatively recombine,

leading to reduced collisions with other triplets at high current. The value of  $j_0$  that is inferred from  $k_{TTA}$  obtained from transient analysis (Eq. 6.71, dashed line in Fig. 6.80b) is in reasonable agreement with that obtained in steady state for the sample with 8 vol.% PtOEP, providing further support for the dominance of TTA at high  $j$ .

The theory in Eq. 6.67 neglects host triplets. However, at the highest current densities and lowest dopant concentrations, the exceptionally long-lived triplets on the fluorescent host molecules will themselves annihilate. To take this into account, terms corresponding to guest–host and host–host triplet annihilation of the form  $\frac{1}{2}k_{GH}T_G T_H$  and  $\frac{1}{2}k_{HH}T_H^2$ , respectively, must be included. Here,  $k_{GH}$  and  $k_{HH}$  are the

**Figure 6.80** (a) Transient PL of a 8 vol.% PtOEP:Alq<sub>3</sub> film excited by 500 ps pulses at  $\lambda = 337 \text{ nm}$ . The triplet densities at  $t = 0$  are indicated for each transient (see text). (b) Steady state external quantum efficiencies (data points) of PHOLEDs employing PtOEP:Alq<sub>3</sub> EMLs with various PtOEP concentrations. Also shown are fits to steady state theory (solid lines) with the corresponding roll-off current densities,  $j_0$ , indicated. Also shown is a fit (dashed line) to the 8 vol.% PtOEP:Alq<sub>3</sub> EML PHOLED using  $k_{TTA}$  obtained from the transient data in (a) (Baldo et al., 2000a).

respective guest–host and host–host triplet annihilation rates (Baldo et al., 2000a).

One further high triplet process that must be considered in PHOLEDs is TPA. In this case, the generalized dynamical Eqs. 6.52 and 6.53 reduce to

$$\frac{dT}{dt} = -k_{ph} - (k_{TPAn}n + k_{TPAp}p)T + \frac{\gamma(j)j}{qd}, \quad (6.72)$$

where  $k_{TPAn,p}$  is the TPA rate for electrons, holes with densities  $n$ ,  $p$ , respectively. Now, the current in OLEDs typically follows  $j \propto V^{m+1}$ . Hence, solutions to Eq. 6.72 are

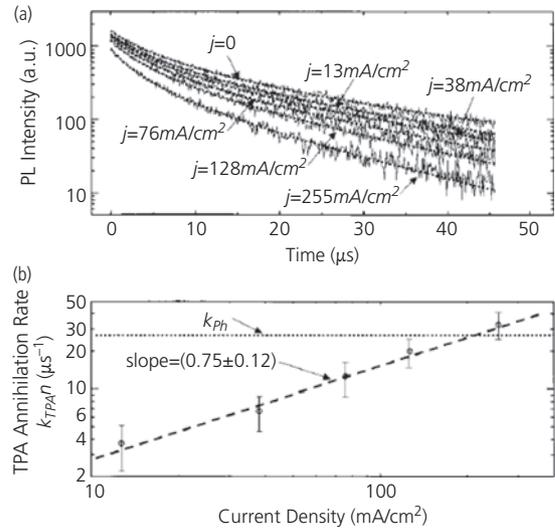

$$\frac{\eta_{ext}(j)}{\eta_0} = \frac{1}{1 + \alpha j^{1/(m+1)}}, \quad (6.73)$$

where we have assumed that  $\gamma$  and  $\alpha$  are constants independent of  $j$  (Baldo et al., 2000a, Reineke et al., 2007).

The importance of TPA has been investigated by observing the PL intensity due to optical pumping of the EML as a function of current in single carrier (i.e. electron or hole) devices. Then, from changes in the transient decay rate, the magnitude of  $k_{TPA}$  can be determined (Baldo et al., 2000a, Reineke et al., 2007, Giebink and Forrest, 2008). This method has been applied to study TPA in electron-only devices with the structure: ITO/45 nm Alq<sub>3</sub>/10 nm 6 vol.% PtOEP:Alq<sub>3</sub>/45 nm Alq<sub>3</sub>/Mg:Ag cathode. The PL transients were obtained by exciting the devices with a pulsed N<sub>2</sub> laser at  $\lambda = 337$  nm, with results shown in Fig. 6.81a. The transient solutions to Eq. 6.72 with  $p = 0$  and  $m = 1$  in Eq. 6.74 are shown by the dashed lines that provide a convincing fit to the data. The decay rate increases with  $j$ , characteristic of enhanced TPA at high electron densities. Values of  $k_{TPAn}$  ranging from 4 to 35  $\mu\text{s}^{-1}$  as inferred from these fits are provided in Fig. 6.81b. The lifetime is decreased to half its initial value at  $j_0 = 200$  mA/cm<sup>2</sup>. This is compared with  $j_0 \simeq 4$  mA/cm<sup>2</sup> due to TTA. Hence, while TPA is present in the PtOEP:Alq<sub>3</sub> system, its contribution to the observed efficiency roll-off is insignificant at even the highest currents. This same conclusion has been reached for Ir-based devices (Reineke et al., 2007, Giebink and Forrest, 2008).

## 6.4 OLED displays

Mobile applications such as smart phones and tablets are now dominantly featuring OLED displays due to their high contrast, high efficiency (leading to long battery lifetimes), thinness, and optical design simplicity (which leads to lower costs). As we have discussed in

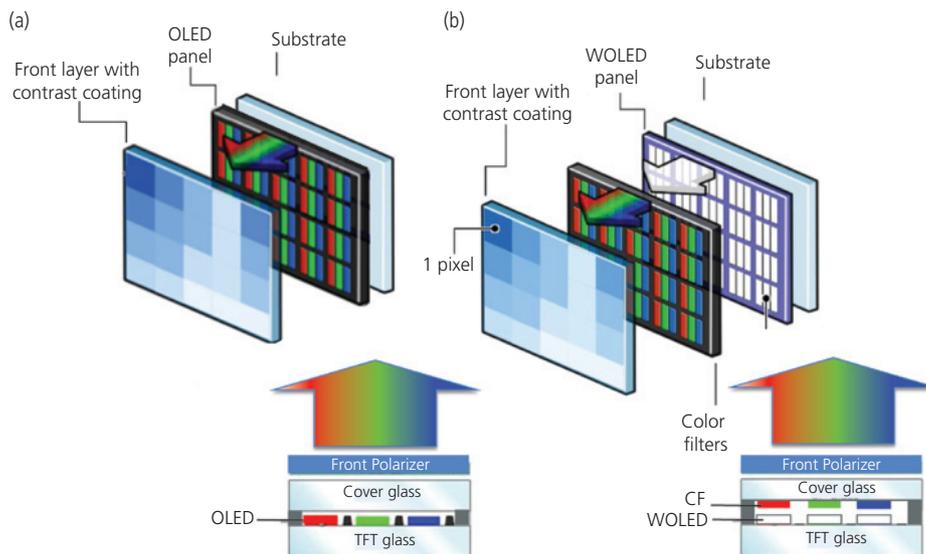

**Figure 6.81** (a) Photoluminescence intensity vs. time and drive current of a 6 vol.% PtOEP:Alq<sub>3</sub> electron-only device. Lines fit to the data follow Eq. 6.73. (b) TPA annihilation rate vs. current density for the device in (a). The EL lifetime,  $k_{ph}$ , is reduced to 50% of its zero current at  $j = j_0 = 200$  mA/cm<sup>2</sup> (Baldo et al., 2000a).

Section 6.1, OLEDs are also moving rapidly into the TV market for many of these same reasons. In this section, we discuss the elements of an OLED display, and the demands their designs place on the pixel architecture itself.

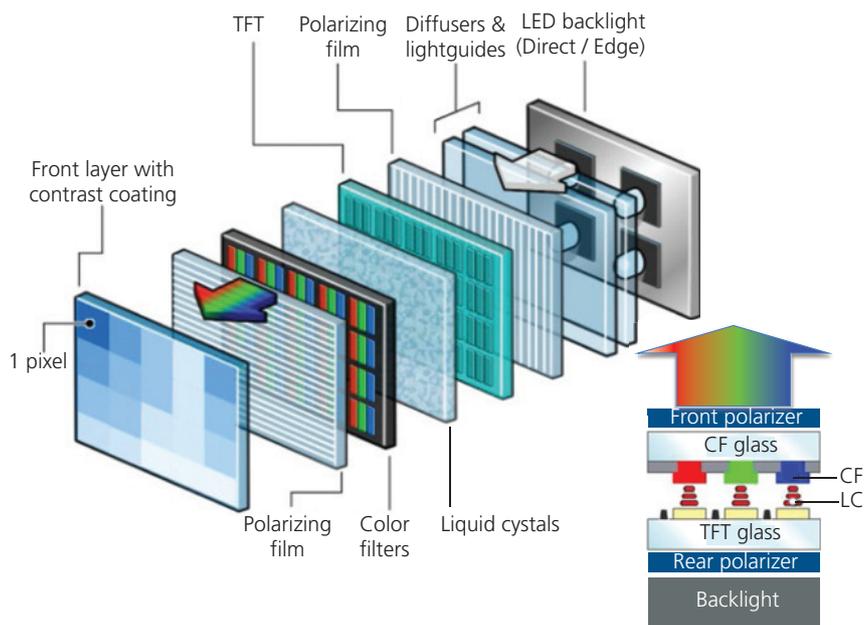

A schematic design of OLED displays is illustrated in Fig. 6.82. There are two OLED display architectures. For mobile applications, red, green and blue OLED sub-pixels are positioned side-by-side above the substrate plane to give the appearance of full color rendition to the viewer who, in the far field, cannot resolve the individual pixels (typically  $\sim 10$ – $30$   $\mu\text{m}$  in diameter). Each sub-pixel is a top emitting device using a transparent cathode that rests on its own driver transistor circuit to provide rapid, individual addressing of the OLEDs. A circular polarizer with a low reflection coating is located on the display surface to eliminate back reflections. The second architecture employed in many television sets comprises three white OLED (WOLED) sub-pixels positioned beneath a set of color filters (CF). The color filters produce the R, G, and B output needed to generate the full-color image. Often, a fourth white emitting OLED is used along with the R, G, and B pixels to enhance luminosity of a white display field, enabling intense high definition images. Since these displays are viewed from a distance, the pixel pitch and dimensions ( $>50$   $\mu\text{m}$ ) are more relaxed than for mobile displays. The color-filtered designs in Fig. 6.82b are inherently less

efficient than the RGB architecture in Fig. 6.82a since the unwanted portions of the spectrum are removed from the white emission spectrum, whereas the RGB display pixel delivers only the color needed to achieve the desired color coordinates of the pixel triad.

The relative simplicity of the OLED display is in striking contrast to a LCD shown in Fig. 6.83. The LCD is based on a white backlight that distributes light across the entire image field. Interposed between the backlight and the observer are several layers needed to create the image: a polarizer is followed by the

**Figure 6.82** Schematic illustration of two types of OLED displays. (a) Full color RGB OLED pixel display used predominantly in mobile applications, and (b) white OLED (WOLED) pixels + color filters used in televisions. The front contrast layer includes a circular polarizer and an additional coating to minimize reflections. Insets: Cross-sections showing the essential details of the full color pixels used in these displays. TFT = thin film transistor drive electronics, CF = color filter. (www.flatpanelshd.com)

**Figure 6.83** Schematic illustration of a liquid crystal (LC) display using an LED backlight. Inset: Cross-section showing the essential details of the full color pixels used in the display. TFT = thin film transistor drive electronics. (www.flatpanelshd.com)

LC light valve array that switches the light on and off by application of an electric field. The field rotates the LC molecules, which in turn rotate the polarization vector of the incident light. Similar to an OLED display, the LC array is addressed by a TFT backplane positioned behind each light valve. Next is the color filter array that admits only R, G, or B light from each of the LC devices. This is followed by a second polarizer oriented perpendicular to the first, and finally the front glass with an antireflection coating to provide a high contrast image. Great care is needed to generate a uniform backlight that prevents visible differences in intensity, contrast, shadowing, etc. (known as display *mura*). This is done by using either a compact fluorescent tube, or an array of LEDs located around the display periphery. Its light output is then evenly distributed across the entire panel via diffusers and light guides. Alternatively, an array of LEDs is placed on the backplane itself to locally illuminate a few thousand pixels at an intensity that ensures image consistency under a variety of room lighting situations. There are several optical elements used in light distribution not shown in Fig. 6.83 including a diffuser, reflector, light guides, etc.

The LCD is inherently different than an OLED display in that an LCD is a color-subtractive device, whereas an OLED is a color-additive device. Color subtraction results in the waste of energy since light is required to illuminate a pixel even when it is turned off. Also, since the LC light valve itself is not 100% opaque when off, the color gamut as well as the contrast of the LCD is considerably less than an OLED display. One means to improve LCD efficiency and color gamut is to use a sheet of quantum dots (QDs) in front of a blue LED backlight. The QD

diameters are varied to down-convert the blue light to a narrow green and red emission spectrum. The larger QDs emit in the red, whereas the smaller in the green. Hence, the spectrally broad emission of a white LED or fluorescent backlight is replaced by more saturated and efficient R, G, and B sources whose colors are once again selected by the LC arrays. This improved display is called QD-LED LCD. We note that the speed of response and viewing angle dependence of LCDs remain unchanged by the presence of QD *color-changing media*.

A qualitative comparison of the performance LCDs, QD-LED and OLED displays is provided in Table 6.9. Display pixels are required to deliver a maximum brightness of 100 nits. Given the several optical elements with only limited transparency, approximately 5% of the light from the LCD backlight reaches the viewer. In contrast, 30–40% of the light emitted by the OLED is viewed, resulting in a considerable savings in power consumption. The reduced complexity and thinness of the OLED display allows for flexible or foldable form factors that are unachievable via LCD technology. Indeed, the fewer layers and optical elements of the OLED display should also lead to lower cost, although to date LCD displays are less expensive due to the much longer experience gained in their manufacture. As we have discussed, OLEDs can be switched on or off in a few microseconds, whereas switching the LC molecules requires their physical rotation, which takes place over several milliseconds. Hence, fast moving images are blurred or *tunnel* (i.e. rapidly moving objects briefly vanish), which is completely avoided in OLED displays. The polarized light in an LCD also results in variations in contrast and brightness with viewing angle.

**Table 6.9** Qualitative comparison of features of LCD and OLED displays

Feature	LCD	QD-LED LCD	OLED
Thickness	>2.5 cm	>2.5 cm	≤ 3 mm
Power <sup>a</sup>	1	0.7	0.3
Life span	50,000 h	50,000 h	40,000 h
Viewing angle <sup>b</sup>	100–150°	100–150°	170°
Contrast ratio <sup>c</sup>	5000:1	5000:1	10 <sup>6</sup> :1
Response speed	1–5 ms	1–5 ms	1–10 μs
Form factor	flat	flat	flat, curved, flexible

<sup>a</sup> Power consumption is approximate and normalized to that of an LCD assuming all displays have the same area. The OLED display assumes that R and G colors are produced by phosphorescence, and B by fluorescence.

<sup>b</sup> Viewing angle in LCD and QD-LED LCD displays is superior along the horizontal compared with the vertical directions. OLEDs are nearly ideal Lambertian sources, and hence have no angular viewing dependence.

<sup>c</sup> Contrasts ratios of OLEDs are limited by front surface reflections.

Importantly, the exceptionally high on/off ratio of an OLED display compared with an LCD gives the images a crisp, high contrast, and even 3D appearance.

Finally, we note that both standard and high definition (4K and 8K) LCD and OLED displays are commercialized, with the latter displays now available up to 77" along the diagonal. Given the ability to achieve extremely small OLED pixels coupled to their fast response time, OLEDs are now entering the virtual and augmented reality equipment markets. The performance objectives for OLEDs used in displays are:

- (i) *High external quantum efficiency* for all R, G, and B sub-pixel OLEDs used to achieve the desired color gamut at maximum display intensity (typically  $\sim 100$  nits) is required to reduce the total display current, and hence increase the battery life in mobile applications. While 100 nits is the intensity needed for a white display field, we will show in the following section that the actual device intensity needs to be significantly higher than this when its limited *aperture ratio* (i.e. the area of a pixel that emits light vs. the total pixel footprint) and the front surface polarizer losses are considered.
- (ii) *Minimal angle dependence of intensity and wavelength*, that is, they should be close to ideal Lambertian sources to avoid color shifts and display dimming with angle that are common in LCDs.
- (iii) *Low voltage operation at display intensities* to be compatible with low power drive electronics. Combined with a high quantum efficiency, this implies a high display power efficiency.
- (iv) *Saturated color emission in blue, green, and red* permitting the largest possible color gamut. This implies narrow natural emission linewidths for the R, G and B sub-pixels.
- (v) *Very long operational lifetimes* with stable color and intensities extending to  $>10,000$  h at display brightness.
- (vi) *Top emission* is important for high-resolution displays used in small appliances for mobile applications. This allows for a high pixel pitch when combined with an opaque transistor driver backplane.
- (vii) *Rapid temporal response* to create realistic, fast moving images. Pixel switching times of  $\sim 1$  ms are generally adequate.
- (viii) *Low cost materials and fabrication processes*. To date, most displays are fabricated on glass and plastic substrates that can be costly. Also, the organic materials should be easily accessible via simple and efficient synthetic processes of only a

few steps. Synthetic accessibility has a far greater impact on cost than does that of the materials themselves. For example, Ir or Pt in phosphors have only a minimal impact on the total display cost if the emitting metal complexes are readily synthesized. Also, fabrication costs can be excessive when using shadow masks and similar "indirect" patterning processes. Direct printing via OVJP or ink jet printing, for example, hold promise for lowering costs in future generation OLED displays. Patterning must also have a sufficient resolution for the particular display application:  $\sim 10\text{--}30\ \mu\text{m}$  for mobile appliances, and  $50\text{--}100\ \mu\text{m}$  for high definition TVs.

In the following section, we will discuss a few of the most important considerations that displays require in the design of the OLED itself.

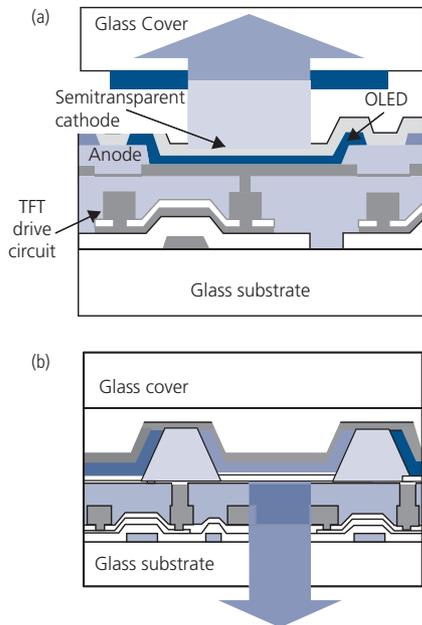

#### 6.4.1 Top emitting OLEDs for displays

Example sub-pixel structures used in displays are illustrated in Fig. 6.84. The OLED is often constructed directly onto the source or drain contact of the driver TFT that is fabricated on the substrate surface. The array of TFT drivers is called the *backplane*. The backplane is typically based on *low temperature poly-Si* (LTPS) technology. Recently, considerable progress has been made in metal oxide transistor technology, which is attractive for OLED displays due to its low temperature processing. Metal oxide electronics may eventually overtake LTPS backplanes, particularly in flexible displays where the substrate is a temperature-sensitive plastic foil. The backplane circuit comprises a multi-transistor current driver (e.g. a four transistor current mirror or a voltage stabilization circuit, Sasaoka et al., 2001) used to provide a high on/off contrast ratio (i.e. high *image dynamic range*), fast pixel switching, and temperature and compensation to prevent color shifts with prolonged operation of the display (Tsujimura, 2012).

To save space and achieve a high pixel pitch, top emitting devices are placed directly onto the TFT surface (Fig. 6.84a). This architecture is particularly relevant for small mobile displays, or displays employed in virtual reality appliances that require very high resolution. The architecture features a transparent or semitransparent cathode on top of a conventional OLED stack consisting of an anode on the bottom and cathode on top, or inverted OLED whose anode and cathode are reversed. There are two choices to achieve an efficient transparent cathode: use a very thin, semitransparent low work

function metal, or employ a transparent metal oxide such as ITO. Whereas the former approach may have high resistance or a discontinuous contact, the high work functions of metal oxides can create an energy barrier to electron injection that can reduce efficiency. In Fig. 6.84b, we see that a bottom emitting pixel requires that the OLED be fabricated over a window in the backplane. High resolution may not always be required, making this architecture desirable for many applications.

Table 6.10 shows the approximate R, G, and B pixel brightness needed for a tablet display (Samsung S8/4 at 100% duty cycle) used at a maximum viewing brightness of 400 nits, assuming a front polarizer loss of 50%. Interestingly, the low aperture ratio and

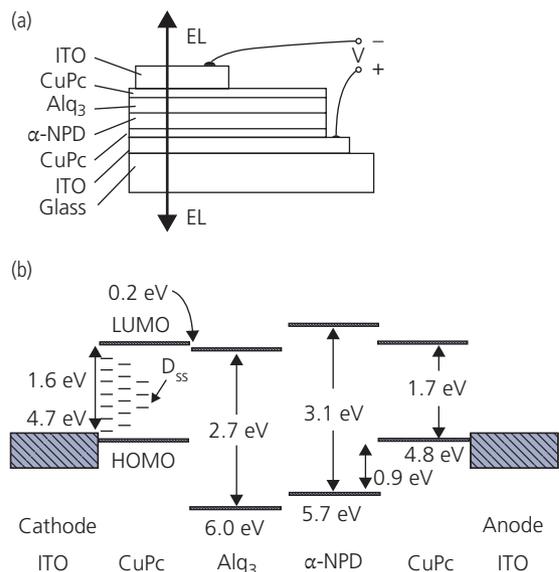

**Figure 6.84** (a) Example top emitting pixel used in a display. The OLED is constructed onto the surface of a TFT circuit, and uses either a fully transparent metal oxide or semitransparent thin metal cathode at the emitting surface. A color filter may or may not be used for modifying the pixel spectrum. (b) A bottom emitting display pixel.

**Table 6.10** Approximate pixel aperture ratios and brightnesses used in a mobile tablet display (C. W. Tang, private communication, 2017)

Color	Aperture ratio (%)	Screen lum. (nits)	Pixel lum. (nits)
Red	6.7	100	2990
Green	9.7	285	5880
Blue	8.4	25	600
White	24.8	400	3225

polarizer losses require that the actual pixel brightness is >10 times the intensity that is viewed. Also note that the green pixel is operated at  $\sim 10$  times the luminance of the blue pixel, and nearly three times that of the red. This allows for uniform aging of all pixels to avoid color shifts with display use, since the green PHOLED lives far longer than the blue fluorescent OLED (see Section 6.7). It is worth noting, too, that the intensities required in mobile appliances such as tablets are considerably higher than for TVs and monitors, since the former are designed for use in bright outdoor environments, whereas larger, stationary displays are ordinarily viewed indoors.

In Chapter 4 we showed that efficient electron injection requires that the cathode work function align with the LUMO of the organic layer that it contacts. Alternatively, defects at the surface of the semiconductor can act as an energy “ladder” to assist electrons in surmounting the cathode-organic barrier. This is illustrated for an  $\text{Alq}_3$ -based device with an ITO cathode sputtered onto a CuPc buffer in Fig. 6.85 (Parthasarathy et al., 1998). To avoid damage to the underlying organic induced during ITO sputter deposition, a very low power (5–10 W for the initial layer) is used. This results in a growth rate of  $<0.1$  Å/s for the initial few monolayers. The growth rate is then increased to achieve the final thickness. Some degree of damage to the interface is necessary since the ionization potential of ITO is too large for electron

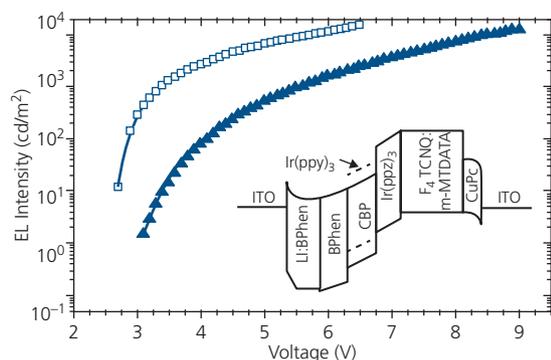

**Figure 6.85** (a) Transparent OLED with ITO serving as both cathode and anode. CuPc is a buffer layer that prevents sputtering damage to the emitting  $\text{Alq}_3$  layer. (b) Energy level diagram showing the defect levels of density  $D_{ss}$  in the CuPc buffer (Parthasarathy et al., 1998).

injection. Hence a thin (3–6 nm) and relatively robust CuPc interface buffer layer is grown on the Alq<sub>3</sub> EML surface. The buffer incurs limited damage that provides defect levels, or energy steps that lower the injection barrier (Parthasarathy et al., 1998).

A feature of a top emitting OLED is that the anode contact on the substrate can also be made transparent using a second metal oxide contact such as ITO or indium zinc oxide (IZO). This type of device is very nearly totally transparent, thereby enabling transparent OLED (TOLED) displays and windows, shown in Figs. 6.1 and 6.2 (Bulovic et al., 1996).

Doping the electron and hole transport layers in an inverted n-i-p PHOLED with transparent cathode and anode contacts results in considerably lower voltage operation compared with transparent fluorescent OLEDs. The device in Fig. 6.86 features a 15 nm thick Li-doped Bphen EIL deposited onto an ITO bottom cathode, followed by a 20 nm thick Bphen ETL/EBL, a 10 nm thick EML consisting of CBP doped with Ir(ppy)<sub>3</sub>, a 15 nm thick HBL comprising Ir(ppz)<sub>3</sub>, a 200 nm thick F<sub>4</sub>-TCNQ doped m-MTDATA HTL, and a 20 nm thick CuPc HIL capped with a 60 nm thick ITO anode (Pfeiffer et al., 2003). The Li-doped BPhen increases the cathode electron injection efficiency while also absorbing sputtering damage during ITO deposition. This device is 80% transparent at the peak emission wavelength of Ir(ppy)<sub>3</sub> of  $\lambda = 510$  nm, and is >65% transparent across the entire visible spectrum. The voltage required to achieve a given luminance is reduced by  $\sim 1.5$ –2 V compared to a conventional bottom emitting OLED due to the doping of the transport layers. The peak quantum efficiency of the n-i-p OLED is 7.5% at a luminance of 1000 cd/m<sup>2</sup>, which is less than that for a conventional device with  $\eta_{\text{ext}} = 9\%$  at this brightness, indicative of a

**Figure 6.86** Electroluminescence–voltage characteristics (squares) of a transparent n-i-p PHOLED with the structure shown in the inset. The triangles correspond to a conventional bottom emitting OLED without a doped HTL or ETL (Pfeiffer et al., 2003).

lower injection efficiency of the low work function metal oxide cathode.

Higher efficiencies have been achieved by replacing the ITO cathode with a thin, semitransparent metal contact. Combining a semitransparent metal contact with doped charge transport layers whose thickness can be varied without significantly changing the operating voltage, can be used to adjust the optical field within the device to optimize the light outcoupling efficiency (Lin et al., 2006, Leem et al., 2009, Hofmann et al., 2010). For example,  $\eta_{\text{ext}} = 29\%$  is achieved by combining these features in a top emitting device with a thick metal anode on the substrate surface and a thin, semitransparent Ag cathode capped with an  $\alpha$ -NPD antireflection layer (Hofmann et al., 2010). The red-emitting device shown in the inset of Fig. 6.87 comprises an Ir(MDQ)<sub>2</sub>(acac) phosphor doped at 10 vol.% in  $\alpha$ -NPD. The doped transport layers provide flexible choices for the dielectric stack thicknesses without affecting the drive voltage (and hence luminance power efficiency).

The spectra of this device show a strong dependence on viewing angle. This is a result of the optical microcavity formed between the two reflective metal electrodes; a problem that is significantly reduced when both contacts use more transparent metal oxides such as in Fig. 6.86. The spectra are modeled assuming a weak Fabry–Pérot microcavity, which yields the following angle-dependent intensity spectrum (Deppe et al., 1994):

$$I(\lambda, \theta)/I_0(\lambda) = \frac{T_2[1 + R_1 + 2\sqrt{R_1} \cos(-\phi_1 + 4\pi n_{\text{EML}} z_{\text{EML}} \cos \theta_{\text{EML}}/\lambda)]}{(1 - \sqrt{R_1 R_2})^2 + 4\sqrt{R_1 R_2} \sin^2(\Delta\phi/2)}, \quad (6.74)$$

where  $T$  and  $R$  are the transmissivity and reflectivity of the rear anode mirror (subscript 1) and the front semitransparent cathode (subscript 2),  $z_{\text{EML}}$  is the position of the EML relative to the anode, and  $\theta_{\text{EML}}$  is the angle with index of refraction,  $n_{\text{EML}}$ . Also,  $\phi_1$ ,  $\phi_2$ , and  $\Delta\phi$  are the phase shifts at the mirror, the semitransparent cathode, and the total phase shift accumulated by a photon after one transit of the cavity. The total phase shift due to the accumulation of phase shifts within each layer,  $i$ , in the stack is

$$\Delta\phi = -\phi_1 - \phi_2 + \sum_i \frac{4\pi n_i d_i \cos \theta_i}{\lambda}. \quad (6.75)$$

Here,  $n_i$  and  $d_i$  are the refractive index and thickness of the  $i$ th layer, respectively, and  $\theta_i$  is the angle of propagation. The total optical cavity length is then (Lee et al., 2006)

$$L_{opt} = \frac{\lambda}{4\pi} (|\phi_1| + |\phi_2|) + \sum_i n_i d_i \approx \frac{\lambda}{4\pi} (|\phi_1| + |\phi_2|) + nL. \quad (6.76)$$

At normal incidence, the numerator in Eq. 6.74 has a maximum when the emitting molecule lies precisely at the antinode of the optical field in the dielectric stack, in which case  $nz/\lambda = (2m + 1)/2$ , where  $m = 0, 1, 2, \dots$  is the optical order of the cavity, and  $z$  is the distance to the anode. The denominator in Eq. 6.74 is determined by the interference within the layers. Thus, the thickness of the doped HTL is chosen such that the EML is located at the antinode of the optical field.

One other spectral feature that is affected by the microcavity is the emission full width at half maximum (FWHM):

$$\frac{\Delta\lambda}{\lambda} = \frac{\lambda}{2nL_{cav}} \left[ \frac{1 - \sqrt{R_1 R_2}}{\pi(R_1 R_2)^{1/4}} \right]. \quad (6.77)$$

That is, as the reflectivity increases, the spectral line narrows; an effect that can be significant in OLEDs with both top and bottom reflective metal contacts. The allowed cavity modes are enhanced at the expense of modes that are not resonantly coupled to the cavity. Now the integrated emission intensity enhancement depends on the natural linewidth of the emission source ( $\Delta\lambda_n$ ) and the cavity spectral width in Eq. 6.77, viz.

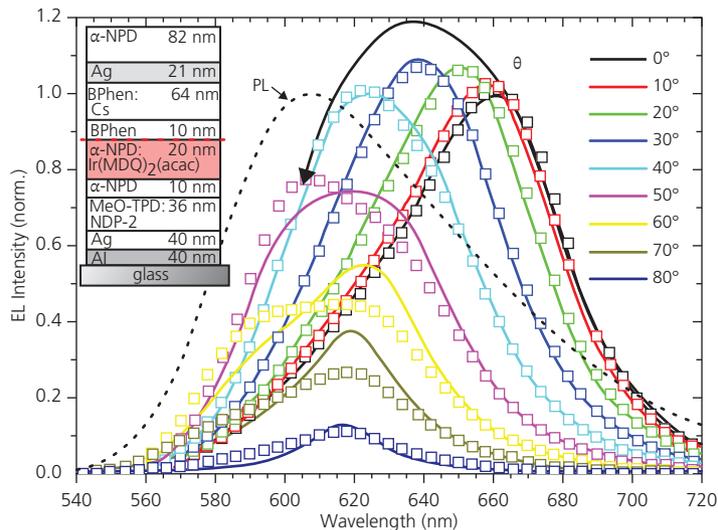

$$I_{int} = I(\lambda_0) \sqrt{\pi \ln 2} (\Delta\lambda / \Delta\lambda_n) \quad (6.78)$$

for a Gaussian lineshape. The resonant enhancement factor is (Deppe et al., 1994)

$$I(\lambda_0) = \frac{\xi (1 + \sqrt{R_1})^2 (1 - R_2)}{2 (1 - \sqrt{R_1 R_2})^2} \left( \frac{\tau_{cav}}{\tau_n} \right), \quad (6.79)$$

where  $\xi = 0, 1$ , or  $2$  if the emitting dipoles are located at a cavity node, if they are distributed over several optical nodes, or if they are located at an antinode, respectively. Also,  $\tau_{cav}$  is the lifetime of the dipole in the cavity that is typically longer than the natural lifetime,  $\tau_n$ , due to the Purcell effect (see below). However, in moderately weak cavities using emitters with broad spectral lifetimes,  $\tau_{cav} \approx \tau_n$ . Indeed, even in relatively strong cavities that comprise cathodes with reflectivities approaching 70% (and hence a greatly attenuated emission intensity according to Eq. 6.79), the spectrum is only slightly narrowed from its natural linewidth, although even a minor narrowing can result in a noticeable angular dependence of the spectrum (Lee et al., 2006).

The spectra in Fig. 6.87 shows pronounced microcavity-induced shifts. The peak wavelength at normal incidence is 665 nm at normal incidence, moving to 610 nm at  $\theta = 50^\circ$ . This is accompanied by intensity attenuation as the viewing angle moves away from the cavity resonance. Furthermore, the spectral narrowing is evident when compared to the PL spectrum of the emitter, Ir(MDQ)<sub>2</sub>(acac) (dashed line). The cavity linewidth at normal incidence is  $\Delta\lambda = 60$  nm compared to a natural linewidth of  $\Delta\lambda_n = 90$  nm. The first order cavity in Fig. 6.87 has a peak quantum efficiency of 29%, falling to 17% and 12% for

**Figure 6.87** Emission intensity vs. wavelength and viewing angle ( $\theta$ ) for the top emitting PHOLED shown in the inset, whose emission region is indicated by the red dashed line. NDP-2 is a proprietary acceptor molecule. The data are shown by the lines, and simulations by the data points. Also shown (dashed line) is the PL spectrum from the phosphor, Ir(MDQ)<sub>2</sub>(acac) (Hofmann et al., 2010).

Reprinted from Hofmann, S., Thomschke, M., Freitag, P., Furno, M., Lüssem, B. & Leo, K. 2010. Top-emitting organic light-emitting diodes: Influence of cavity design. Applied Physics Letters, 97, 253308, with the permission of AIP Publishing.

second and third order cavities obtained by increasing the doped HTL thickness.

The calculated output intensities as a function of the ETL and HTL, and cathode thickness (and hence reflectivity,  $R_1$ ) for these PHOLEDs are shown in Fig. 6.88 (Hofmann et al., 2010). The integrated intensity decreases as the optical cavity thickness is increased to accept higher order optical modes. Similarly, as the optical order is increased, the maximum output is achieved with thinner and less reflective top contacts.

To summarize, we have described two strategies for achieving top emission. The less reflective transparent oxide cathode produces a very weak microcavity, and hence the impact on the OLED optical output intensity and spectral content is minimal, although this is at the expense of a reduced (by  $\sim 20\%$ ) output efficiency. We will show in Section 6.6, however, that optimal designs can eliminate these losses by using improved cathode materials and sputtering conditions. In contrast, semitransparent metal cathodes can produce a higher output intensity compared to conventional devices. This is due to microcavity resonances that dramatically shift the OLED color

coordinates with viewing angle. Careful cavity design and control of layer thicknesses is imperative to assure the device-to-device variations are minimized.

Whether transparent oxide or semitransparent thin metal cathodes are used, both structures present challenges to processing and contact resistance. That is, the metal oxide resistivity is considerably larger than for metals, yet very thin metal films are also resistive and can be discontinuous. Many top emitting OLED displays use semitransparent metal contacts largely due to their simplicity and compatibility with other deposition processes used in display manufacture.

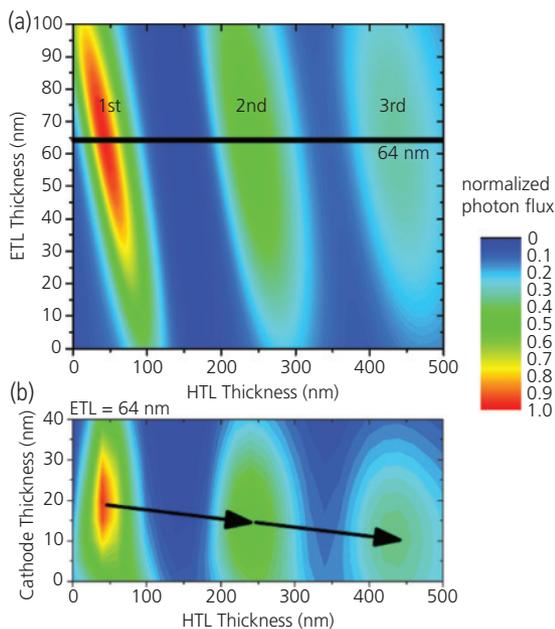

### 6.4.2 Full color displays and pixelation

In the context of Fig. 6.82 we noted that full color images require dividing each pixel into three (R, G, B) sub-pixels that can be independently tuned to achieve the desired luminosity and color coordinates. Each sub-pixel, in turn, requires its own TFT drive circuit. Several different schemes have been devised to pixelate the display, two of which are illustrated in Fig. 6.82: positioning of the triad of sub-pixels side-by-side to achieve a brilliant, large color gamut display, and the use of white emitting OLED (WOLED) pixels positioned beneath R, G and B color filters. Several other methods of pixelation are shown in Fig. 6.89. Bottom emitting pixels are shown, although each configuration can be inverted for top emission.

Beyond the RGB and WOLED + color filter pixelation schemes, two others warrant our attention. In Fig. 6.89c the RGB triad comprises three blue OLEDs, two of them positioned over fluorescent *color changing media* (CCM) (Niko et al., 1997, Sokolik et al., 2001). In contrast to color filters that simply eliminate the unwanted spectral content and thus lead to efficiency losses, CCM are films that luminesce with near unity PL quantum yield when pumped by the blue OLED. Fluorophores such as coumarin for green emission, and laser dyes of lumogen and DCM have been employed to generate the green and red pixels, respectively. Colloids containing QDs of different diameters is another type of CCM. Direct pumping of the red CCM by a blue source is inefficient. Hence, it is usually combined with the green fluorophore, such that there is a cascade from blue to green to red.

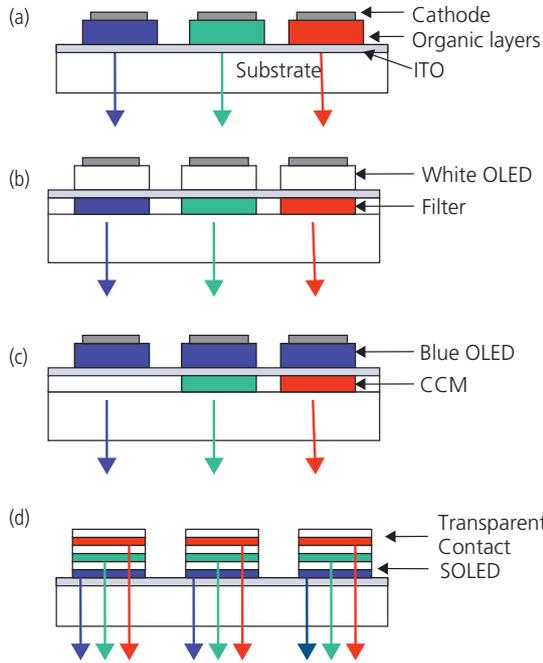

While this scheme is more efficient than simple color filtering of white light, it remains considerably less efficient than direct RGB emission in Fig. 6.89a. The internal efficiency of the CCM (which ignores outcoupling and spin dependent losses) is calculated using

$$\eta_{\text{int,CCM}} = \eta_{\text{ext,OLED}}(1 - R)\phi_{\text{CCM}}\exp(-a_{\text{CCM}}d_{\text{CCM}}), \quad (6.80)$$

**Figure 6.88** Calculation of the output intensity ETL versus (a) HTL and (b) cathode thickness for first, second, and third order cavities with structures analogous to that in Fig. 6.87. In (a) the line at 64 nm corresponds to fabricated devices. In (b), the peak intensity shifts to thinner cathodes as the optical order increases. The integrated intensity also decreases with order (Hofmann et al., 2010).

Reprinted from Hofmann, S., Thomschke, M., Freitag, P., Furno, M., Lüssem, B. & Leo, K. 2010. Top-emitting organic light-emitting diodes: Influence of cavity design. *Applied Physics Letters*, 97, 253308, with the permission of AIP Publishing.

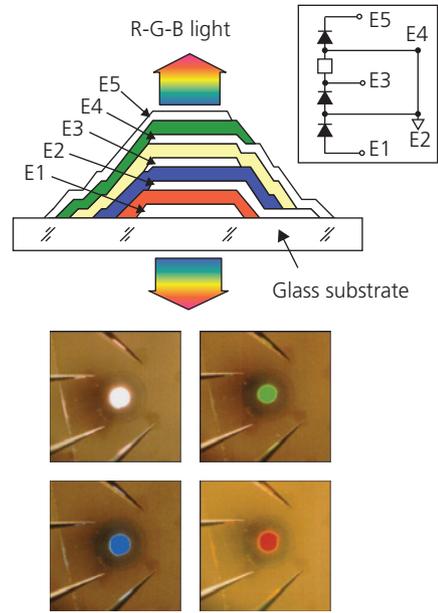

**Figure 6.89** Several methods of pixelation in full color displays. (a) RGB pixels positioned side-by-side, (b) individually addressable WOLEDs positioned above RGB filters, (c) blue OLEDs positioned above R and G emitting color changing media (CCM), and (d) stacked RGB OLEDs (SOLEDs).

where  $\eta_{ext,OLED}$  is the external efficiency of the blue OLED,  $R$  is the reflectivity of the CCM,  $\phi_{CCM}$  its PLQY,  $a_{CCM}$  is its absorption coefficient, and  $d_{CCM}$  its thickness. Similar to filtering schemes, unabsorbed light constitutes both leakage and loss that can result in shifting of color coordinates. Furthermore, we note that there is a power loss associated with down-conversion since a fraction of energy of the blue photon is lost in generating green or red fluorescence. That is, the optical output power of the CCM sub-pixel is reduced by the ratio of the peak OLED and CCM wavelengths. That is,

$$\eta_{P,CCM} = \eta_{P,OLED}(\lambda_{OLED}/\lambda_{CCM}). \quad (6.81)$$

These losses are also present in filtered schemes in Fig. 6.89b. Since the CCM is an active light emitting layer, it is subject to long term degradation experienced by the OLED itself. In spite of its many advantages, CCM pixelation is not widely employed due to the added complexity and requirements for stable and efficient fluorophores that strongly absorb in the blue OLED spectral region. In contrast, QD-based CCMs are currently finding use in large OLED displays.

Direct emission can also be achieved by vertically stacking the sub-pixels, as shown in Fig. 6.89d. The stacked OLED (SOLED) vertically positions the

**Figure 6.90** Cross-section of a SOLED with its biasing scheme shown in inset. Also shown are images of R, G, B, and white emission achieved by separate biasing of the various elements in the stack. White is achieved by simultaneously turning on all three pixels (Parthasarathy et al., 1999).

Copyright © 1999 WILEY-VCH Verlag GmbH, Weinheim, Fed. Rep. of Germany

separately optimized sub-pixels, separated by transparent contacts that allow for individual addressing (Shen et al., 1997). A detail of a SOLED pixel is shown in Fig. 6.90 along with images of the SOLED biased to emit R, G, B, and white (Parthasarathy et al., 1999). This scheme has advantages for high resolution displays since it forms a compact triad in the vertical dimension, thus minimizing the pixel footprint. Each sub-pixel can, in principle, achieve 100% internal efficiency using phosphors or TADF lumophores provided that the intervening electrodes are optically lossless. Metal oxide and thin metal intermediate electrodes are employed for this purpose. In Section 6.5 we show that SOLEDs are attractive for high intensity lighting applications, albeit in those devices there is no need to contact the intermediate electrodes to separately tune elements in the stack.

Although there are several advantages to this architecture, bringing the contacts out from the individual layers onto the substrate without shorting can be challenging, and can occupy a large peripheral area around the base of the stack that increases the effective pixel size. The addressing scheme for stacked contacts in Fig. 6.90 differs from that used in laterally separated, individually addressed pixels. To simplify biasing, an insulating layer (shown by a small box in the inset) is inserted between contacts E3 and E4. This

avoids the need to reverse the polarity of the contacts or inverting one of the devices in the stack, and hence eliminates the need for two different pixel addressing circuits when the current blocking layer is absent.

A design constraint that determines the stacking order and the thickness of each of the sub-pixels is the existence of color-shifting microcavity effects discussed in the previous section (Bulovic et al., 1998a). While the metal-free, ITO interconnection electrodes in Fig. 6.90 show only weak cavity effects, placing them in the deep, multilayer stack of the SOLED can result in significant color shifts that reduce the accessible color gamut of the pixel. In the device in Fig. 6.90, the optimal stacking order that minimizes cavity effects is, from the substrate surface, R–B–G. Also, improved color coordinates are achieved by adjusting the cavity length through the appropriate choice of transport layer thicknesses that is made possible by conductivity doping of the layers. The SOLED can use either top or bottom transparent contacts, or both, for use in transparent or top emitting displays.

## 6.5 OLED lighting and lighting devices

Approximately 25% of the total industrial electricity use in the US is devoted to powering illumination sources, and yet a vast majority of those sources are highly inefficient (~5%) and short-lifetime (800–1000 h) incandescent light bulbs; a technology that is approaching its 150th anniversary. Hence, considerable effort has been devoted over the last few decades to develop alternative sources that can provide pleasant illumination for building interiors as well as for signage and street lighting. Currently,

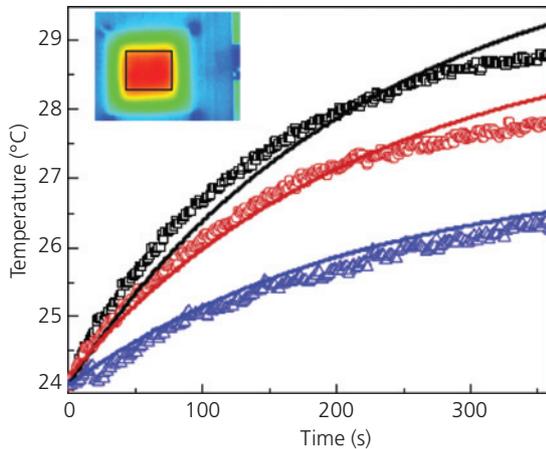

inorganic LEDs provide desirable features of efficiency, brightness and satisfying colors, and as a result are rapidly moving into the marketplace. The ultrahigh efficiency and tunable color emission of OLEDs has also drawn attention for these same applications (Kassakian, 2013). The interest in OLEDs for solid state lighting is motivated by their low form factor including bendability and conformability, and the ability to precisely tune their emission to achieve desired CRI and CCT values. The development of WOLEDs used in displays has also driven rapid progress in lighting applications. Unlike displays, however, WOLED lighting fixtures do not require high resolution patterning of R, G and B emitting pixels, thus leading to a significant cost savings and simplification of their manufacturing process. Interior lighting applications generally require a highly uniform, glare-free emission that casts soft shadows to provide some depth to viewed objects. OLED illumination is ideally suited for this purpose. However, they are less attractive for outdoor lighting due to their relatively low intensities.

Table 6.11 provides a comparison between OLED and other lighting sources. Currently, OLED efficiencies are as high as 150 lm/W, which is second only to inorganic LEDs. By combining multiple emitting phosphors, a high CRI at the desired CCT.

Importantly, the surface temperature of OLED fixtures is only a few degrees above ambient (Qi and Forrest, 2011, Bergemann et al., 2012, Levermore et al., 2012). This feature is critically important when considering installation in buildings since this eliminates the necessity to dissipate heat generated in its fixture, or *luminaire*. A thermal image of a high intensity green

**Table 6.11** Comparison of the performance of lighting sources

Feature	Incandescent	Fluorescent	LED	OLED
Efficacy	17 lm/W	40–90 lm/W	80–90 lm/W, white 65 lm/W, warm white 240 lm/W, lab demo	150 lm/W, lab demos
CRI	100	80–85	80, white 90, warm white	Up to 95
Form factor	Heat generating	Long or compact gas filled glass tube	Point source high intensity lamp	Large area thin diffuse source, flexible, transparent
Bulb temp.	3000°C	50°C	150°C	30°C
Toxicity	None	Mercury	Low	Low
Lifetime	0.8 kh	20 kh	50 kh	40 kh
Dimmable	Yes, but much lower efficacy	Yes, efficiency decreases	Yes, efficiency increases	Yes, efficiency increases
Cost (\$/klm)	0.7	3.00 (CFL)	3.00	~100

**Figure 6.91** Temperature increase of a 25 cm<sup>2</sup> green emitting PHOLED in a sealed glass package following the onset of current steps with steady state values of (from bottom to top) 2, 3, and 4 mA/cm<sup>2</sup>. The lines are fits using a multilayer transfer-matrix approach. The largest impact on the peak temperature is the air gap between the OLED and the top glass package lid. Inset: Infrared thermal image of the device in equilibrium at 3 mA/cm<sup>2</sup>. The ambient (blue color) is at 24°C and the peak temperature (red) is 28.2°C (Bergemann et al., 2012).

PHOLED is shown in Fig. 6.91 along with the thermal transients at different drive currents. The theoretical fits to the data (lines) are based on a transfer matrix approach using Laplace transforms (Qi and Forrest, 2011, Bergemann et al., 2012) to account for the multiple layers comprising the packaged device, and their thermal losses (including convection, conduction and radiation). Even at very high currents, the maximum temperature change is only  $\Delta T \sim 5^\circ\text{C}$ , which is in striking contrast to the temperature at the surface of an inorganic LED ( $\sim 125^\circ\text{C}$ ). Interestingly, the temperature of the OLED is primarily determined by the package configuration. A small air gap between the OLED and the lid in Fig. 6.91 results in reduced heat conduction away from the source, accounting for a significant fraction of the  $\Delta T$  observed.

The low temperature of the OLED is due to a combination of its high luminous efficiency and large area. As a distributed lighting source, its thermal and optical power densities are several orders of magnitude lower than in inorganic devices. For example, a 1 mm<sup>2</sup> LED area can provide >1 klm light output, whereas an OLED requires  $\sim 1 \text{ m}^2$  to deliver the same luminance.

The large area format of OLED lighting has several advantages as well as some notable disadvantages. We have seen in Chapter 5 that OLEDs can be deposited on lightweight flexible plastic or metal foils, allowing them to be adapted to many different building configurations. This feature alone provides architectural advantages when designing lighting fixtures

that are installed in modern structures. Furthermore, unlike other lighting technologies, *the OLED itself is the luminaire*: it does not need to be mounted into reflecting cones or other fixtures that reduce glare and distribute the light. To provide similar areal lighting, LED point sources must be mounted on a light distribution system. For example, diffusers can add weight, complexity, and cost to an otherwise simple LED source. On the other hand, large OLED fixtures can provide uniform lighting where shadows cast are too soft, leading to reduced depth perception of the lighted space. And the large substrate areas lead to high cost and potentially low manufacturing yield. Hence, the current price of OLED lighting is  $\sim$  US \$100/klm, which is at least 20 times higher than LED lighting and 200 times that of incandescence. These costs are expected to be reduced as the demand for OLED lighting increases, but at present they are too high for widespread deployment.

The lifetime of WOLEDs is somewhat less than that of LEDs (40 kh vs.  $> 50$  kh, respectively), which is limited by the lifetime of the blue emitting component (Section 6.7). Nevertheless, WOLED lifetime is sufficient for many indoor illumination applications. And finally, the materials and processes used in fabricating OLED fixtures have relatively low environmental impact. Unlike Hg-containing fluorescent lighting, there are no significant amounts of toxic materials used in OLED fixtures, permitting disposal without special handling.

Hence, OLEDs present an attractive source of efficient solid state-lighting (Kassakian, 2013). As we will see in the following sections, numerous device structures have been developed to improve OLEDs for illumination applications. When considering possible device architectures, the following criteria should be met:

- i. *High efficiency*: Ultimately, the value of a light source is determined by its luminous power efficiency, or efficacy (Section 6.2.3). For this reason, PHOLEDs are suitable for all lighting applications with their potential for  $\eta_{int} = 100\%$ . Doped charge conductive layers are also useful for reducing voltage, and hence power loss. We will show that, in principle, hybrid blue fluorescent/green + red phosphorescent WOLEDs can also obtain unity internal efficiency.
- ii. *High brightness*: The surface brightness of an OLED lighting fixture should be  $\sim 3000\text{--}5000 \text{ cd/m}^2$ . Higher brightness leads to glare, and lower brightness requires excessively large areas to produce the desired level of illumination. Both brightness and

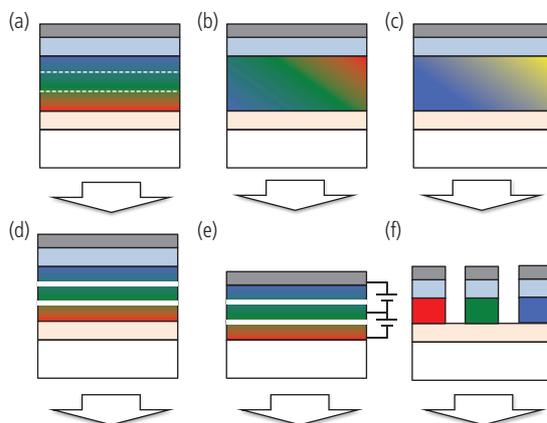

efficiency also demand that effective light outcoupling methods be used to minimize optical losses. This topic is the subject of Section 6.6.

- iii. *High CRI at the desired CCT*: A CRI > 80, and preferably >90, is needed for aesthetically pleasing lighting appliances. CCTs of ~3000–4000 K are also desirable. Due to the relatively narrow emission spectra of OLEDs, this generally requires that the EML comprise three or more lumophores that span the visible spectrum to result in acceptable color renditions while also achieving high efficiency.
- iv. *Color and intensity stability*: The lighting source should be free of color drift over its operational lifetime. Current standards also demand that the source should not lose more than 30% of its initial intensity (known as T70, i.e. the time to reach 70% of its initial luminance) in times less than 10 kh.
- v. *Low cost*: Minimizing OLED complexity and fabrication processes should lead to an increased manufacturing yield and reduced materials cost.

There are a great many approaches to achieving these objectives. Figure 6.92 shows six different example WOLED designs. There are many variations for each of these species, some of which are detailed in the ensuing discussions. The wide choice of structure speaks to the inherent flexibility available in the design of organic electronic devices. Organic thin film devices allow for layering schemes that combine numerous functional materials into a single structure without the need for lattice matching to a particular substrate. While considerable early work focused on fluorescence (Kido et al., 1995), the need for high efficiency compels us to focus our discussion on structures that are capable of achieving unity internal efficiency. All such devices comprise at least one phosphor or TADF material. Similarly, we will not discuss color down conversion via CCM used in displays (Lee et al., 2011a). Our treatment of the topic of WOLED lighting sources is meant to provide insights into how devices are designed and optimized for illumination applications. The reader interested in more in-depth discussions of this topic is referred to *Further reading* and the extensive scientific literature.

### 6.5.1 Multicolor blended EMLs

Figure 6.92a shows a WOLED with a single EML comprising three or four lumophores separated into different sectors in a common EML. These can be phosphors emitting in the red, green and blue to provide

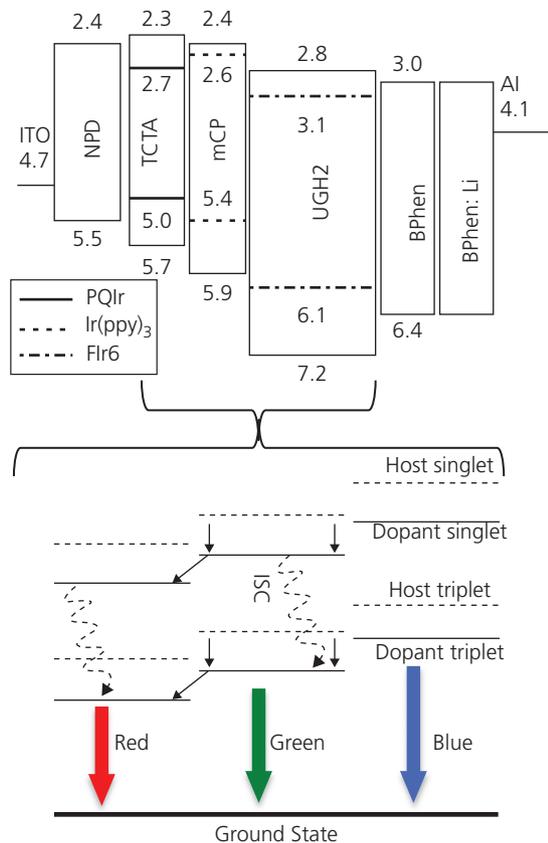

**Figure 6.92** Several different WOLED architectures. The EMLs are in color, the transport layers (e.g. the HTL, ETL, etc.) are shown in orange and light blue, and the cathode is gray. Most layers and details are omitted for clarity. (a) RGB lumophores spatially separated in a single EML (emission zones delineated by dashed lines), (b) blended EML consisting of 3 or more lumophores, (c) two color blended EML consisting of two lumophores or a phosphor that emits from the blue monomer + red/yellow excimer state, (d) stacked WOLED consisting of any combination of R, G, B, or white emitting zones separated by transparent charge generation layers (white stripes), (e) vertically stacked WOLED with each luminous region separately addressable to tune color, and (f) horizontally striped WOLED with each sub-pixel separately addressed to tune color.

a high CRI along with a high efficacy. Even higher CRIs are achieved by including a yellow emitting phosphor into the EML. Alternatively, a fluorescent blue emitter can be combined with red and green phosphors to achieve a *hybrid fluorescent/phosphorescent* WOLED.

The earliest example of an all-phosphor WOLED was based on this structure comprised the cyan-emitting FIrpic ( $\lambda_{peak} = 472$  nm), yellow-emitting Bt<sub>2</sub>Ir(acac) ( $\lambda_{peak} = 563$  nm), and red-emitting Btp<sub>2</sub>Ir(acac) ( $\lambda_{peak} = 620$  nm), doped into a primarily electron conducting CBP host (D'Andrade et al., 2002b). Blending different phosphors into a common transport layer presents several challenges. Since triplets are readily transferred from the blue to the yellow to the red phosphors, their relative positions, doping concentrations, and the thicknesses of zones within the EML determine the spectral balance. Since the exciton formation in this structure is primarily at the HTL/EML interface, and FIrpic is the least efficient of the three phosphors, the highest efficiency is obtained using an EML comprising CBP doped with a 20 nm thick 6 wt% FIrpic region at the HTL/EML interface, followed by a 2 nm thick 8 wt% Btp<sub>2</sub>Ir(acac) region, and topped with a 2 nm thick 8 wt% Bt<sub>2</sub>Ir(acac) region. The exciton blocking ETL comprises BCP, followed by the metal cathode. The triplet exciton transfer length is 8.3 nm in CBP. This distance allows triplet excitons

to drift across the entire 24 nm thick EML while being sequentially transferred to each of the dopants in the desired proportions to result in efficient light emission of the appropriate white color balance. This phosphorescent WOLED had a maximum  $\eta_{ext} = 5.2\%$ , a power efficiency of 6.4 lm/W and a CRI = 83. The CIE coordinates at (0.37, 0.40) place it near to the Planckian locus (Fig. 6.13) with CCT  $\approx$  4000 K. A problem encountered by combining three lumophores in a single layer is that the color balance shifts with intensity, that is, as the current increases, the peak emission can move from one part of the EML toward another, thus resulting in a variation in the balance between blue *vs.* yellow *vs.* red emission.

To more completely separate the dopants and to control color drifts with current, a different host for each emission color can be used. An example is shown in Fig. 6.93, where 20 wt% of the blue dopant, Flr6, is doped into UGH2, followed by 2 wt% Ir(ppy)<sub>3</sub> (green) in mCP and 4 wt% PQIr (red) in TCTA. The

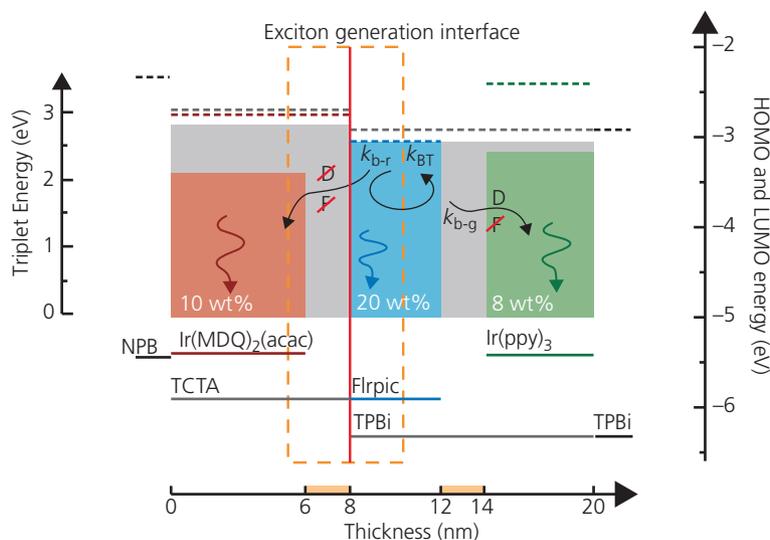

**Figure 6.93** Energy level diagram of a triple dopant/triple host phosphorescent WOLED. The top panel shows the energy level scheme of the diode, with the transitions in the EML in the bottom panel. HOMO and LUMO energies (in eV) for all materials are shown in the top diagram. From Sun and Forrest (2008b).

exciton formation zone is distributed between the blue and green emitting regions of the EML. The small energy steps between each of the layers impede electron and hole transfer, retaining the desired amount of charge within each layer. Combining this balance with the amount and position of phosphor dopants results in the desired spectrum. In this architecture, the red phosphor, PQIr is excited via Dexter transfer from excitons originating on Ir(ppy)<sub>3</sub>, whereas those generated on Flr6 are trapped.

This device exhibits near unity internal quantum efficiency, largely attributed to the generation of all excitons on the dopants themselves, and the high radiative efficiency and energy transfer to the several phosphors. This device has an external efficiency of 23%, along with a power efficiency of 37 lm/W at 500 cd/m<sup>2</sup>, falling only slightly from its low brightness peak efficiency of  $\eta_{ext} = 28\%$ . At 10 mA/cm<sup>2</sup> ( $\sim$ 20 lm/W), the drive voltage is 5.0 V, indicating that the small energy barriers between dopants do not appreciably decrease  $\eta_p$ . This device has CRI = 81 at coordinates (0.37,0.41), corresponding to a CCT  $\approx$  4000 K at 1 mA/cm<sup>2</sup>. Indeed, the CRI and CIE coordinates shift only by  $\sim$ 2–3% even as  $j$  increases by a factor of 100. Hence, this scheme is effective in maintaining color stability at all brightness levels (Sun and Forrest, 2007, 2008b).

High efficiencies have also been achieved with a simplification to the structure in Fig. 6.93 by doping two phosphors (20 wt% Flrpic and 8 wt% Ir(ppy)<sub>3</sub>) into a single, 12 nm thick TPBi host, and the third phosphor (10 wt% Ir(MDQ)<sub>2</sub>(acac)) doped into an even wider gap 8 nm thick TCTA host. Unlike the device in Fig. 6.93 whose spectrum is controlled by energy barriers between layers, the two-host structure is controlled by diffusion across undoped regions of the hosts to limit the rate of energy transfer. Thus, excitons are generated in the interface region (dashed box, Fig. 6.94) primarily on Flrpic and TCTA. The resonant HOMO levels of both materials encourage hole transfer across the HJ, whereas electrons are blocked from entering the red-doped zone. The red dopant is spaced away from the blue doped section at the junction to prevent energy transfer that would substantially decrease the blue spectral content with increasing current. Hence, the primary mechanism for populating the red emission zone is via diffusion from Flrpic at rate  $k_{b-r}$ . Further, a portion of excitons diffuse from this zone to the green-doped region, which again is offset by a 2 nm thick TPBi diffusion zone. This allows host-dopant Dexter transfer at rate  $k_{b-g}$ .

Since the emission is controlled by diffusion rather than energy barriers, there is little or no spectral shift from  $L = 100$  to 5000 cd/m<sup>2</sup>. These devices exhibited

**Figure 6.94** Energy level scheme of a high efficiency triple doped EML comprising two hosts. The TCTA and TPBi hosts and phosphors used are indicated, along with their relative positions within the 20 nm thick EML. Active energy transfer processes are denoted **D** for Dexter and **F** for FRET. These processes are crossed out if inactive. Also, the several transfer rates,  $k$ , are shown (Reineke et al., 2009).

an efficiency (using a hemispherical lens to extract the glass substrate modes) of  $\eta_{ext} = 24\%$  and  $\eta_P = 55 \text{ lm/W}$  at  $1000 \text{ cd/m}^2$ . At this luminance,  $CRI = 80$  and the chromaticity coordinates are (0.45, 0.47) which gives it a yellow-green cast. The spectral shift away from the Planckian locus at  $CCT \approx 3000 \text{ K}$  is one reason for its high power efficiency. The efficiency was increased further via the use of conductivity dopants in both the NPB HTL and the BPhen ETL. Even higher efficiencies are achieved with enhanced light outcoupling schemes, to be discussed in Section 6.6 (Reineke et al., 2009).

The devices thus far have been characterized by thick EMLs (20–25 nm) and color rendering indices that appear to have a maximum value of 80, with most structures achieving a maximum external efficiency (without using additional outcoupling optics) of  $\sim 20\text{--}25\%$ . To achieve the combination of both very high CRI and quantum efficiency comparable to the best available lighting sources, four dopants may be required. That is, including a yellow phosphor can pull the coordinates toward the Planckian locus when added to the red, green, and blue emitting sections. The device in Fig. 6.95a shows an EML comprising a blue emitting FIrpic layer on the EML side of the ETL/EML interface where exciton formation occurs (Chang et al., 2013b). Excitons generated on the TPBi ETL transfer to the common CBP host and are subsequently transferred to FIrpic. Both hosts are chosen for their high triplet energies, leading to efficient energy transfer to FIrpic in the exciton formation region. Those excitons not harvested in FIrpic

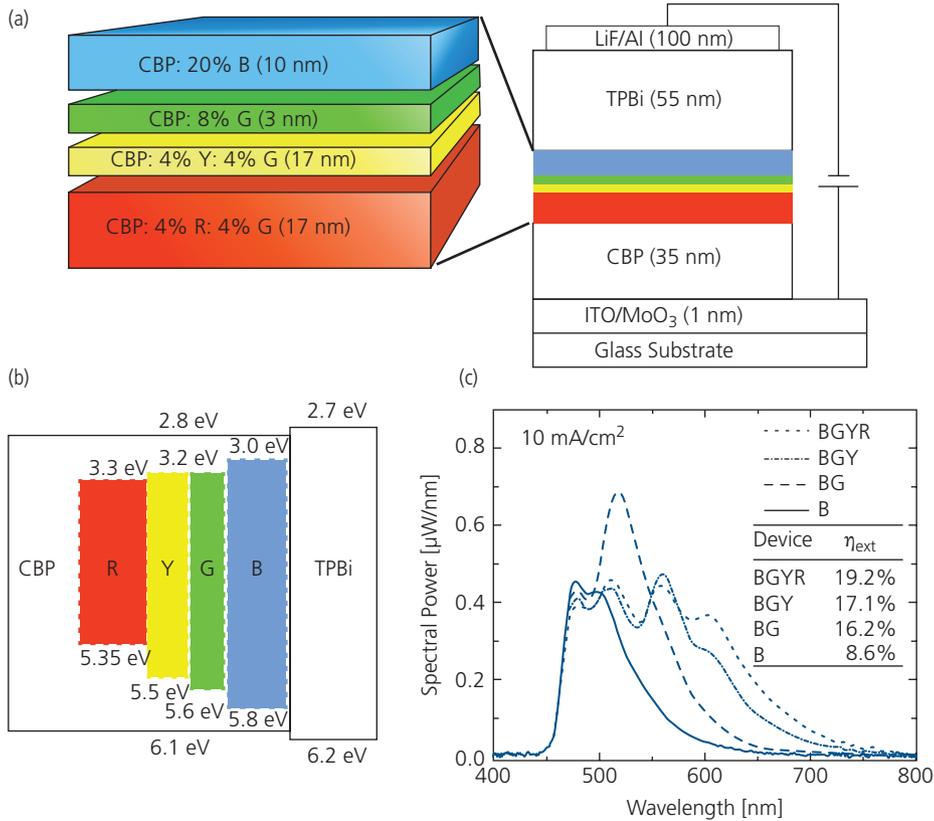

continue to diffuse through the 33.5 nm thick EML, entering layers with dopants with a lower triplet energy than in the previous layer. As in the devices already discussed, the thickness of each layer and the phosphor doping concentration determines the emission intensity as the excitons move along the energy cascade from high to low energy via:  $\text{CBP} \rightarrow \text{FIrpic} \rightarrow \text{Ir(ppy)}_3 \rightarrow \text{Bt}_2\text{Ir(acac)} \rightarrow \text{Ir(MDQ)}_2(\text{acac})$ , shown in the energy level diagram in Fig. 6.95b No intermediate exciton transport layers such as those in Fig. 6.94 are used. This allows for lossless energy harvesting by the lower energy emitting species.

To facilitate energy transfer to the lowest energy phosphors of  $\text{Bt}_2\text{Ir(acac)}$  and  $\text{Ir(MDQ)}_2(\text{acac})$ , the yellow and red emitting zones are co-doped with  $\text{Ir(ppy)}_3$ . This allows for very efficient transfer from CBP to  $\text{Ir(ppy)}_3$  due to the energetic resonance between these two species, and then sequentially from  $\text{Ir(ppy)}_3$  to the redder dopants. Complete transfer is inferred from the lack of  $\text{Ir(ppy)}_3$  emission in PHOLEDs where only  $\text{Ir(ppy)}_3$  and the long wavelength emitters are co-doped into the same EML.

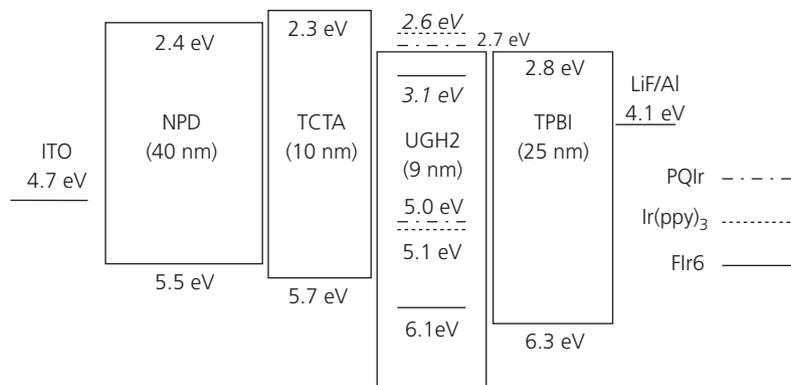

The spectral intensity of the device with only the blue dopant, the B+G dopants, the B+G+Y dopants and then finally all four dopants in Fig. 6.99c show that by increasing the number of dopants, the spectrum naturally broadens, and importantly,  $\eta_{ext}$  at  $L = 1000 \text{ cd/m}^2$  increases from 8.6% to 19.2%. Hence, all four dopants in a single CBP host are needed to harvest  $\sim 100\%$  of the generated excited states. The very high internal efficiency of the device, along with the use of four phosphor dopants

leads to  $\eta_p = 61.7$  lm/W, and  $\eta_{ext} = 41.5\%$  using a hemispherical lens to extract glass substrate modes. The  $CRI = 83$  with chromaticity coordinates of (0.44, 0.45) at  $L = 1000$  cd/m<sup>2</sup>, correspond to a warm white  $CCT = 3332$  K. High performance is obtained at the expense of device complexity, which may lead to high cost.

The three dopants can also be blended within the same zone of a single host EML (Fig. 6.92b). As in other designs, the various doping concentrations must be carefully balanced to obtain the desired emission spectrum and efficiency. The energy level diagram in Fig. 6.96 shows an example of this structure comprising the blue, green and red phosphors, Flr6,

**Figure 6.95** Four-dopant, single-host high CRI WOLED. (a) Schematic of the structure with dopant concentrations in CBP shown. (b) Energy level diagram of the WOLED showing the B→G→Y→R energy cascade. (c) Spectral output powers of OLEDs with different numbers of dopants in the EML. Inset: External quantum efficiency at  $L=1000$  cd/m<sup>2</sup> of the devices in (a) and (b). (Chang et al., 2013b).

**Figure 6.96** Energy level diagram of a three phosphor WOLED blended into a single thin (9 nm) ultrawide energy gap host (UGH2) (D'Andrade et al., 2004).

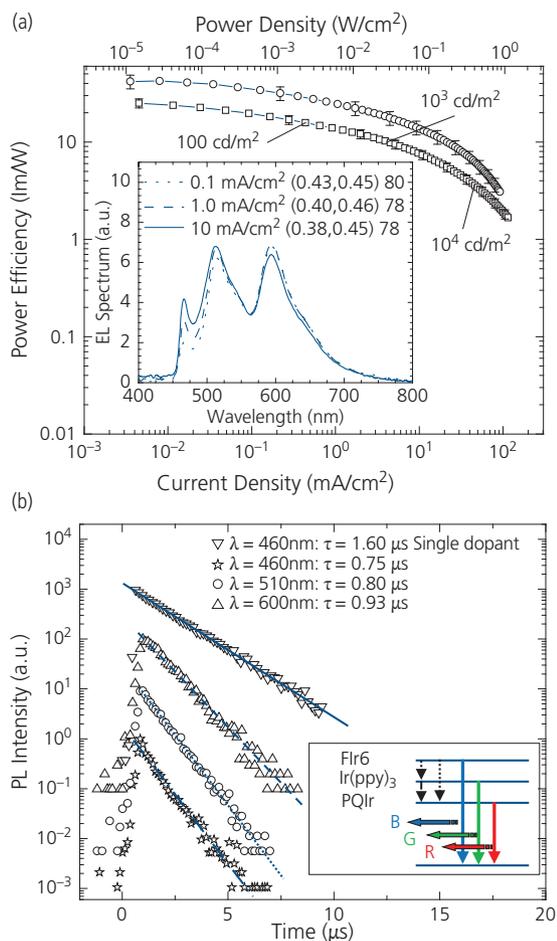

Ir(ppy)<sub>3</sub> and PQIr *simultaneously* co-doped at 20 wt%, 0.5 wt%, and 2 wt%, respectively, into the same UGH2 host. Given its wide energy gap, UGH2 does not carry charge; FIr6 thus serves as both an electron and hole conductor. Its energy levels are aligned to the LUMO of the TPBi ETL/EBL and the HOMO of the TCTA HTL, allowing for direct electron and hole injection onto FIr6. This avoids the need for energy transfer from host to guest, and the accompanying exchange energy losses incurred forming singlets on the host that subsequently transfer to the triplet of the blue dopant.

Direct exciton formation on FIr6 is followed by transfer of some of the triplets onto Ir(ppy)<sub>3</sub> and

PQIr in proportions determined by their relative concentrations. Given the high sensitivity of the eye to green, the Ir(ppy)<sub>3</sub> concentration is kept relatively low to limit its emission intensity. The performance of this device is summarized in Fig. 6.97a. The power efficiencies in both the forward viewing direction, and the total efficiency are indicated. Also shown in the forward direction are the currents at which the WOLED reaches 100, 1000, and 10<sup>4</sup> cd/m<sup>2</sup> luminance. The maximum total external efficiency is 42 lm/W at low luminance intensity, decreasing to 10 lm/W at 20 mA/cm<sup>2</sup>, which is approximately 10 times the current needed to achieve a luminance of  $L_0 = 1000\text{--}3000\text{ cd/m}^2$ . Measurable emission is observed at 3.3 V, which is near the estimated 3.0 V necessary to directly generate a blue emitting triplet exciton on a FIr6 dopant molecule, assuming resonant injection of holes in TCTA into the HOMO, and electrons in TPBi into the LUMO of FIr6. The voltage required to excite green and red emission from Ir(ppy)<sub>3</sub> and PQIr, respectively, is <3.0 V. Thus, the emission color shifts with increasing voltage, as observed in the inset of Fig. 6.97a. The CIE coordinates of (0.43, 0.45) at 0.1 mA/cm<sup>2</sup> blue-shift to (0.38, 0.45) at 10 mA/cm<sup>2</sup>, with CRI = 80 (CCT ≈ 4100 K). The exceptionally low operating voltage is due to the use of thin, multiply doped layers along with near resonant charge injection followed by direct triplet formation on FIr6.

To understand energy transfer between the dopants, the PL transient decay was studied in optically pumped thin-films of UGH2 doped at 20 wt% with FIr6, and of the triple-doped EML. Given its high doping concentration, only FIr6 is excited by the  $\lambda = 337\text{ nm}$  pump. The energy transfer channels originating from the excitation of FIr6 to the various dopants are depicted in Fig. 6.97b, inset. Energy transfer from FIr6 to both Ir(ppy)<sub>3</sub> and PQIr is shown by dotted lines. Although energy transfer from Ir(ppy)<sub>3</sub> to PQIr is possible, the low concentration of both species makes this unlikely. Solid lines show radiative relaxation to the ground state. The lifetime of FIr6 decreases from  $\tau = 1.60\text{ }\mu\text{s}$  in a UGH2:FIr6 film, to 0.75  $\mu\text{s}$  in the triple doped system.

The lifetimes of Ir(ppy)<sub>3</sub> (Baldo and Forrest, 2000) and PQIr (Lamansky et al., 2001) are  $\tau = 0.8\text{ }\mu\text{s}$  and 2.0  $\mu\text{s}$  (D'Andrade et al., 2004). It was found that  $\tau = 0.80\text{ }\mu\text{s}$ , and 0.93  $\mu\text{s}$  for the peak emission features at  $\lambda = 510\text{ nm}$  and 600 nm. Hence, the lifetime decrease in the triple doped film suggests that FIr6 emission is quenched by energy transfer to the green and red dopants. Thus, the luminescence process starts with

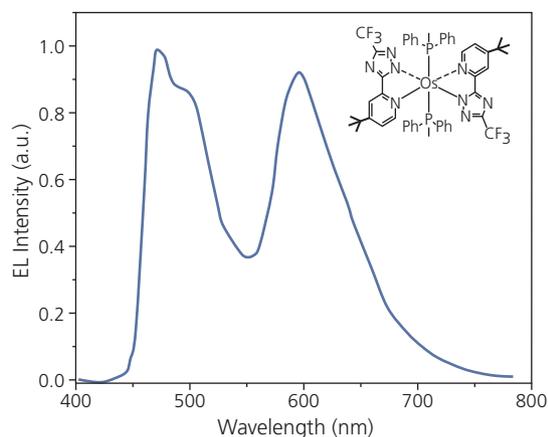

**Figure 6.97** (a) Power efficiency vs. current density of the triple-doped WOLED in Fig. 6.96 in the forward viewing direction (squares), and the total emitted power (circles). Inset: EL spectra at three different current densities, along with the CIE coordinates and CRI values. (b) PL transient response of a FIr6 doped film (inverse triangles), and a triple-doped film taken at the wavelengths indicated in the legend. exciton formation on FIr6, followed by direct transfer to the lower energy phosphors to obtain balanced white emission. The lifetime of the coupled system is determined by the dopant with the shortest natural phosphorescent decay rate (i.e. Ir(ppy)<sub>3</sub>).

Given the large area required to provide the total luminance necessary for interior lighting, solution processing may be a viable path to low cost. As we have shown, high efficiency along with acceptable color content to achieve a pleasant color balance also requires multiple dopants arranged to avoid spectral shifts with brightness. Previously, we showed that solution processes generally impose a trade-off between complexity and performance in OLEDs for displays. The same appears to be the case for WOLED lighting.

A high performance solution processed WOLED consists of the B, G, R phosphors 15% FIrpic, 1% Ir(ppy)<sub>3</sub>, and 0.6% Ir(MDQ)<sub>2</sub>(acac) used with a mixed host comprising the hole conducting moieties, TCTA and TAPC. The 40 nm thick EML was sandwiched between PEDOT:PSS HIL and a vacuum deposited TmPyPB ETL, capped with a LiF/Al cathode. Here, TmPyBP, TCTA and TAPC are all chosen for their high triplet energies of 2.78, 2.78, and 3.5 eV, respectively, compared to FIrpic (2.65 eV). The TCTA was blended at 25% concentration into TAPC due to its resonant LUMO energy (2.3 eV measured from vacuum) alignment with FIrpic, whereas the HOMO of TAPC (5.3 eV) is aligned with PEDOT:PSS (5.1 eV). Hence, this blend comprises three emitters with efficient energy transfer from the host while also supporting both electron and hole transport. As a

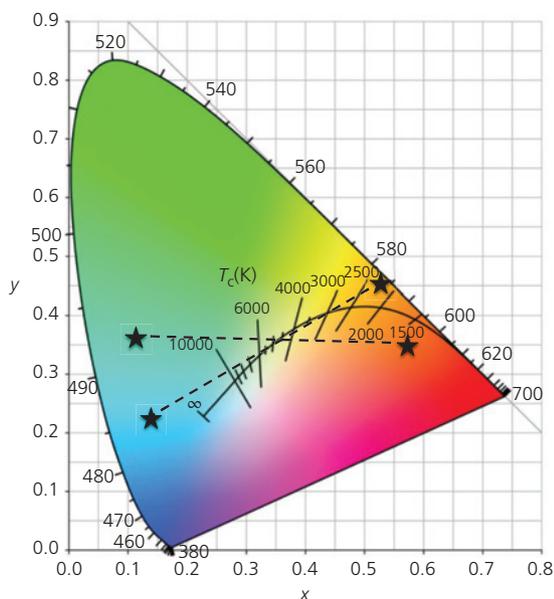

**Figure 6.98** Emission spectra for a solution-processed WOLED. The CIE color coordinates of (0.38, 0.38) are relatively independent of voltage, and hence current. Inset: Chemical structural formula of the orange emitting phosphor, Os-O. After Huang et al. (2009).

result, the solution processed EML WOLED has  $\eta_p = 23.3$  lm/W,  $V = 4.6$  V,  $CRI = 73$ , and  $CIE = (0.35, 0.41)$  corresponding to  $CCT \approx 4700$  K at  $L = 1000$  cd/m<sup>2</sup> (Fu et al., 2012). This performance is competitive with analogous vacuum-deposited blended EML WOLEDs.

An example polymer-based blended two-phosphor EML WOLED is shown in Fig. 6.98 (Huang et al., 2009). This device consists of a 30 nm thick PEDOT:PSS hole injection and transport layer. The electron and hole transporting EML comprise a 70 nm thick blend of the small molecule phosphors, 7 wt% blue emitting FIrpic and 0.25 wt% orange emitting Os-complex, Os-O (see inset, Fig. 6.98), co-doped into PVK mixed with 30 wt% OXD-7. Only a very small amount of Os-O is required since its lower triplet energy makes it an efficient exciton trap. Together, the two dopants emit broadly across the visible to provide white light. The optimized device exhibited  $\eta_p = 18.5$  lm/W and  $\eta_{ext} = 12.6\%$ .

As noted previously, a white light source can be obtained using only two color emitters. This is illustrated for two pairs of illuminants (cyan-red or blue-yellow) in the chromaticity space in Fig. 6.99. As long as the line connecting the CIE coordinates of the illuminant pairs passes through the Planckian locus, white emission will be perceived. However, as apparent from Fig. 6.98, only two emitters result in weak green emission due to the relative narrowness of exciton spectra. Hence, while the source will appear white, its CRI will be lower than required for a high quality illumination source. The device in Fig. 6.98 has CIE coordinates of (0.38, 0.38), but the  $CRI < 70$  results from spectral “holes” in the green (Su et al., 2008, Wang et al., 2009a, Wu et al., 2009). While substituting two phosphors for three lends simplicity to the WOLED design and also to high efficacy, the low color purity would render objects using this source with an odd appearance.

Thus far, we have shown two types of blended EMLs; those with dopants segregated into zones as in Fig. 6.92a, and those that are fully blended (Fig. 6.92b). The zone/fully blended architectures can also be combined. This strategy has been applied to a device in which a separate, 4 nm thick exciton generating zone comprising only 8 wt% FIrpic is placed adjacent to an 11 nm thick zone containing a blend of the green emitting 8 wt% Ir(ppy)<sub>3</sub> and the red phosphor, 1 wt%, Ir(PPQ)<sub>2</sub>(acac) doped into a common, high triplet energy (2.9 eV) mCP host. As in other such designs, the highest triplet energy phosphor, FIrpic, is located at the exciton formation

**Figure 6.99** 1931 chromaticity chart showing two pairs of illuminants indicated by stars. The straight lines connecting these pairs intersect the Planckian locus at a CCT = 4600 K.

zone near the TAZ-based ETL/EML interface. The co-doping of the RG zone results in color that is determined by the energy transfer efficiency from the relatively high concentration of G to R dopants, almost eliminating the color dependence on current. For example, it is found that the color coordinate shift over a luminance variation from 500 to 10,000  $\text{cd}/\text{m}^2$  of the RG-B device is  $\Delta CIE = (0.00, 0.00)$ . This is compared to  $(+0.01, -0.01)$  for a PHOLED comprising the same dopants in an EML of equal thickness (15 nm) but separated into three discrete R-G-B zones. The peak performance of the two-zone, three dopant WOLED is  $\eta_{\text{ext}} = 19.1\%$ ,  $\eta_p = 37.3 \text{ lm}/\text{W}$ ,  $CIE = (0.39, 0.42)$  corresponding to  $CCT \approx 4000 \text{ K}$ , which is competitive with the three zone device using the same materials combinations (Wang et al., 2009b).

### 6.5.2 Hybrid fluorescent/phosphorescent WOLEDs

Among the many properties required for OLED lighting, achieving high power efficiency and long operational lifetime are the most important. Unfortunately, obtaining blue PHOLEDs with long lifetime has been problematic (see Section 6.7), leading to alternative architectures that replace the blue phosphorescent unit with a more stable, but efficient fluorescent substitute. We have shown that OLED displays employ fluorescent blue OLEDs to minimize the loss of reliability encountered in using blue

PHOLEDs, albeit at a significant loss in efficiency for this color pixel. However, this compromise is unacceptable in WOLEDs that must rely on 100% internal efficiency to be competitive with existing lighting sources.

The spectrum of white emission is approximately 25% blue, with the remainder in the green to the red spectral regions. This fortuitous division in spectral content suggests a means for achieving satisfactory white emission with  $\eta_{\text{int}} = 100\%$  by using a blue fluorophore to harvest the 25% electrically generated singlets, and green and red phosphors to harvest the remaining 75% triplets. Harvesting singlets directly on a fluorescent molecule has several advantages: it eliminates the need for a host with a triplet energy that is greater than that of the blue phosphor. Further, it eliminates exchange energy losses in converting singlets to high energy (blue emitting) triplets, thus reducing the PHOLED drive voltage. This results in an increase in power efficiency needed for lighting. And finally, blue singlet emitting materials have considerably longer operational lifetimes than blue phosphors.

The first demonstration of a hybrid fluorescent/phosphorescent WOLED employed a blue fluorophore placed directly into the exciton generation regions of the EML. The red and green phosphors were located within a triplet diffusion length of their origin, but sufficiently far from the blue fluorophore to prevent direct energy transfer. The independent harvesting of singlets and triplets is illustrated by the energy level diagram in Fig. 6.100a (Sun et al., 2006). The process starts with electrical generation of excitons in the host in a ratio of  $\chi_S = 0.25$  and  $\chi_T = 0.75$ . The singlets transfer via FRET to the blue fluorophore, BCzVBi, which is doped at 5 wt% in CBP to minimize direct Dexter transfer of triplets from host to dopant. A thin (6 nm) CBP spacer that is thinner than the triplet diffusion length separates the blue fluorescent/exciton generation region from green (5 wt% Ir(ppy)<sub>3</sub>) and red (4 wt% PQIr) phosphorescent zones that harvest the triplets via Dexter transfer from the CBP host (see inset, Fig. 6.100b for the device structure). In this demonstration, the BCzVBi has a lower triplet energy than either of the phosphors or CBP, and hence transfer to the BCzVBi triplet is a significant loss channel.

By omitting the phosphors and measuring the blue emission for devices with only the blue fluorophore doped near the ETL or HTL interface, it was determined that all excitons were formed within  $\sim 5 \text{ nm}$  of both interfaces. The device spectrum in Fig. 6.100 at  $j = 100 \text{ mA}/\text{cm}^2$  is fit using

$$\eta_{ext} = (1 - \chi_{trap})\eta_B + [(1 - \chi_{trap})\chi_T + \chi_{trap}]\eta_{GR}, \quad (6.82)$$

where  $\chi_{trap}$  is the ratio of excitons formed by charge trapping directly on the phosphors to those diffusing from the generating interfaces,  $\eta_B$  is the efficiency of blue emission (which includes the probability of singlet formation), and  $\eta_{GR}$  is the efficiency of the red and green phosphorescence.

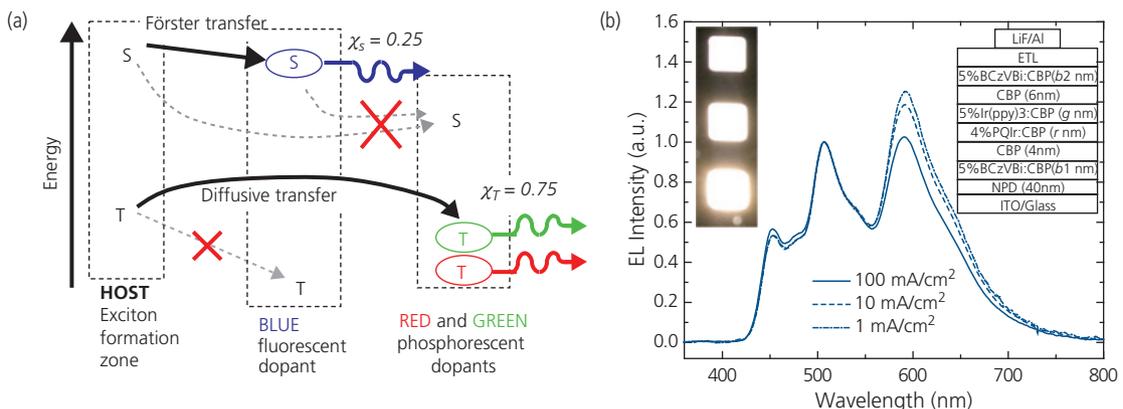

Analysis of the spectra in Fig. 6.100b (with layer thicknesses  $b_1 = 15$  nm,  $b_2 = 10$  nm,  $r = 8$  nm, and  $g = 12$  nm, along with a 20 nm thick BPhen ETL) indicate that  $\chi_{trap} = 20\%$ , with the remaining triplets diffusing through the fluorescent and host layers to reach the phosphors. Note that there is only a small color shift when the current varies by over a factor of 100, indicating a reasonably stable balance of exciton distribution in this diffusion-controlled device. The direct exciton formation via trapping results in a decrease in blue emission, which ultimately limits the device efficiency (Sun et al., 2006). Indeed, the low efficiency of the blue fluorophore coupled to exciton losses ultimately leads to a WOLED efficiency of  $\eta_{ext} = 18.7\%$  and  $\eta_p = 23.8$  lm/W at 500 cd/m<sup>2</sup>, along with  $CRI = 85$  at  $CIE = (0.40, 0.41)$ , corresponding to  $CCT = 3750$  K.

A device similar to that in Fig. 6.100 eliminates the zone containing the red phosphor, which is replaced by the red fluorophore, DCJTb. This is lightly doped ( $\sim 0.08$  wt%) into the 15 nm thick, green emitting zone with 8 wt% Ir(ppy)<sub>3</sub> in CBP (Kanno et al., 2006c). Thus, red emission from the fluorophore is due to phosphor-sensitized fluorescence in the green emitting zone (cf. Fig. 6.30). Triplets generated at the HTL/EML and ETL/EML interfaces drift to the green-red phosphorescent/fluorescent zone across

two, 2 nm thick undoped CBP host spacer layers. Triplets are partially harvested by the phosphor, where a fraction is Förster-transferred to the singlet state of red-emitting DCJTb. The blue spectrum is emitted from singlets transferred directly to BCzVBi from the CBP at the edges of the EML. Since all the singlets are harvested by the blue dopant, and triplets by the green phosphor, this two-dopant structure still has the potential of  $\eta_{int} = 100\%$  even though two fluorescent dopants are used.

Evidence for sensitized fluorescence is shown by the transient EL response in the green and red spectral regions in Fig. 6.101, inset. The rapid ( $\sim 1$  ns) fluorescence of DCJTb takes several hundred nanoseconds since its excitation is via transfer from the Ir(ppy)<sub>3</sub> triplet manifold. Even though the fluorescent/phosphorescent/fluorescent architecture has the potential for unity quantum efficiency, there are several losses using the particular dopants chosen in this particular device. While the spectrum is independent of current in Fig. 6.101 due to diffusion-controlled transfer, the quantum and power efficiencies are approximately 20% lower than the fluorescent/phosphorescent device in Fig. 6.100 due to losses in the sensitized fluorescent transfer. The CRI of the device is 79 with CIE coordinates of approximately (0.38, 0.42).

There are several variations to the hybrid fluorescent/phosphorescent structure that can improve its performance (Rosenow et al., 2010). Nearly unity internal efficiency has been achieved with the structure whose energy level diagram is shown in Fig. 6.102a (Sun et al., 2014a). A common CBP host is used with excitons formed near its interface with the TmPyPb ETL and at the TCTA HTL. The blue fluorescent

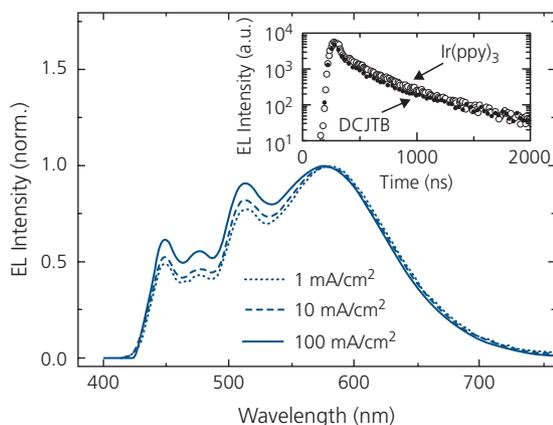

**Figure 6.100** Hybrid fluorescent/phosphorescent WOLED. (a) Energy level scheme showing Dexter (dashed lines) and Förster (solid lines) transfer pathways.  $\chi_S$  and  $\chi_T$  are the singlet and triplet formation ratios, respectively. (b) Spectra of the hybrid WOLED whose structure is shown in the right inset, at several current densities. Left inset: Images of the WOLED emission at these same current densities (Sun et al., 2006).

4P-NPD triplet energy (2.3 eV) is lower than that of the green phosphor, Ir(ppy)<sub>2</sub>(acac) at 2.4 eV. Hence the green phosphor is positioned near to the TCTA with a 2 nm thick spacer between this material and the red emitting Ir(MDQ)<sub>2</sub>(acac), whose triplet energy (2.0 eV) is less than that of 4P-NPD. Since the singlet exciton diffusion length is considerably shorter than the 8 nm thick 4P-NPD, there is efficient triplet transfer between these latter two materials, while the singlets are immediately harvested by the fluorophore. The spacer discourages transfer of Ir(ppy)<sub>2</sub>(acac) triplets to the red phosphor, thus maintaining the desired color balance.

The spectrum in Fig. 6.102b shows significant color shifts with brightness attributed to a shift of the exciton generation zone from the ETL toward the HTL interface with increasing drive current (note that the green intensity stays constant in these normalized spectra). A forward viewing external quantum efficiency of 21.2% indicates nearly unity internal efficiency. Furthermore, the maximum  $\eta_p = 40.7$  lm/W decreases only weakly with intensity. The high power efficiency is achieved by n-type doping the ETL with 4% Cs<sub>2</sub>CO<sub>3</sub> to minimize the drive voltage. The CRI = 85 and CIE = (0.42, 0.44) corresponding to CCT = 3544 K (Sun et al., 2014a).

Following similar design concepts to that in Fig. 6.102, but including a yellow emitting phosphor in a four-color fluorescent/phosphorescent WOLED, a very high CRI = 94 was achieved along with  $\eta_{ext} = 14.3\%$  and  $\eta_p = 26.2$  lm/W (Sun et al., 2014b). Hence,

hybrid devices have been shown to combine high quantum efficiency with good color quality, while potentially eliminating the short operational lifetime of all-phosphorescent WOLEDs.

The hybrid approach has also been demonstrated, albeit with less success, in polymers. Solution processing creates difficulties in the control of emission color via a zone-doped structure such as exploited in vacuum-deposited small molecule WOLEDs. A method that takes advantage of the synthetic diversity of polymers is to copolymerize red, green, and blue emitting moieties along the molecular backbone. In **Scheme 2** we show a polymer with segments that are incorporated into the feed stock at concentrations that lead to the desired color balance (Jiang et al., 2006). In this copolymer, green fluorescent benzothiadiazole units are incorporated into a blue emitting polyfluorene backbone. Then a red emitting, pendant Ir phosphor complex fills out the spectrum. Copolymer WOLEDs based on these three lumophores have not shown particularly high efficiencies, although this approach may

provide a path to achieving high efficiency with improved emitting units and charge conduction characteristics in a simplified WOLED structure.

### 6.5.3 WOLEDs based on excimer emission

In the preceding sections, we have seen that producing high quality white light can entail complex engineering of the EML that typically contains three (or even more) luminescent zones, each with a phosphor or fluorophore emitting in a separate region of the visible spectrum. In this context, in Section 3.6.3 we showed that the emission spectra of excimers and exciplexes are broad and featureless. Hence, it is reasonable to expect that such excited state species might be a route to creating a broad, white spectrum. The blue emitting square planar Pt phosphorescent molecules can efficiently emit from exciplexes due to coupling within the molecular stacks, thus leading to broad white light emission (Adamovich et al., 2002). In particular, the monomeric (blue) emission of a single lumophore can be combined with broad green-red excimer emission from the same molecular species to result in a single-dopant WOLED. By carefully controlling the doping concentration of the phosphors in the host, a fraction of the molecules will form excimer emitting clusters, whereas the remainder will be isolated within the blend to emit from their native blue monomer state.

Monomer/excimer WOLEDs are attractive due to their inherent simplicity. While they have demonstrated high efficiencies, one drawback is that the emission spectrum is difficult to precisely control since it is a sensitive function of both doping concentration as well as the position of the exciton formation and light emitting zones within the device (D'Andrade and Forrest, 2004; Fleetham and Li, 2014). Hence, most such devices have  $CRI \leq 70$ , which is below that required for high quality lighting.

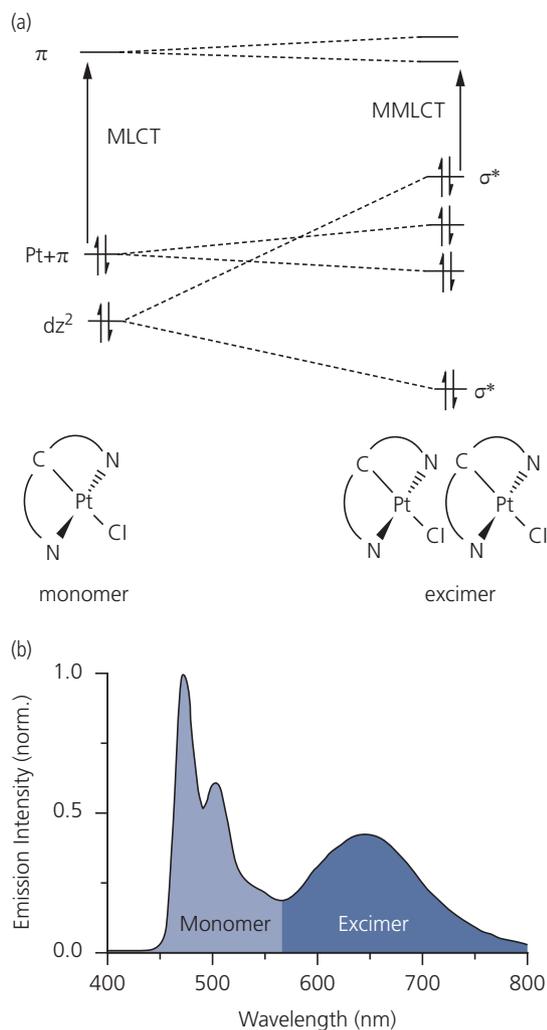

The earliest demonstration of a phosphorescent monomer/excimer WOLED employed a series of blue emitting square planar Pt molecules comprising

fluorine electron withdrawing groups (Adamovich et al., 2002). At high concentrations, the relatively strong Pt  $\cdots$  Pt bonds form oligomers in the ground state. Their close  $\pi$ - $\pi$  stacking gives rise to broad and unstructured excimer emission.

An example of interactions between Pt molecules leading to monomer/excimer WOLED spectra is illustrated in Fig. 6.103. The binuclear Pt interactions result in triplet metal-metal ligand charge transfer states ( $^3\text{MMLCT}$ ) that are destabilized compared to the  $^3\text{MLCT}$  of the monomer. Thus, the  $d_{z^2}$  and Pt- $\pi$  levels are split due to interactions between Pt atoms on neighboring molecules. This leads to additional, lower energy and broadened, non-bonding  $\sigma^*$  transitions. The combination of monomer  $^3\text{MLCT}$  and excimer  $^3\text{MMLCT}$  transitions results in the broad emission spectrum of Fig. 6.103b. In Sections 3.6.3 and 3.7.3 we provide a detailed description of the excimer and spin-orbit interactions in dihedral and octahedral transition metal complexes.

The EL spectra in Fig. 6.104 are from PHOLEDs whose EML comprises a tridentate square planar Pt (II) molecule, Pt-17, mixed at several different concentrations in the host, 26mCPy (Bakken et al., 2012). At only 2 wt% Pt-17, the spectrum is dominated by monomer emission between  $\lambda = 440$  nm and 530 nm, with a weak tail extending to longer wavelengths due to excimer emission from a few molecular aggregates. As the Pt-17 concentration is increased to  $> 18\%$ , the emission is dominated by excimer transitions, resulting in a shift from blue to orange, with broad peak at 600 nm. Due to non-radiative coupling from within the aggregates, however, the peak external efficiency decreases from  $\eta_{ext} = 13\%$  at 2 wt% concentration, to  $\eta_{ext} = 8\%$  when the concentration is increased to 26 wt%. Hence, while excimer transitions can lead to broad spectral emission, at the same time they lead to a decrease in quantum efficiency.

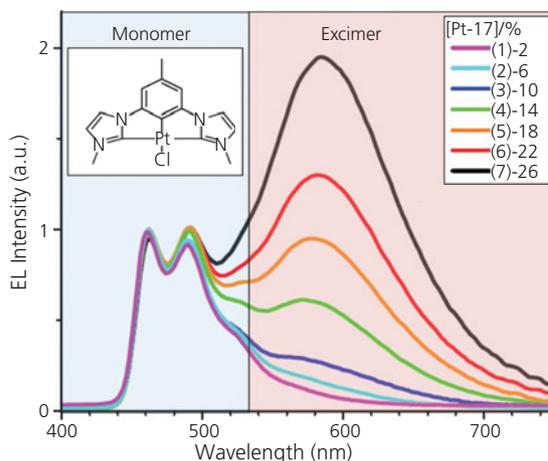

The highest performance WOLEDs reported using the structures in Fig. 6.104 with a 40 nm thick 18 wt% Pt-17:(1:1 TAPC:PO15) EML had a forward viewing

**Figure 6.103** (a) Energy level scheme for the  $^3\text{MLCT}$  state of a dihedral Pt monomer, and the broadened  $^3\text{MMLCT}$  excimer state of a pair of coupled molecules. Molecular structures for the monomer and the Pt  $\cdots$  Pt dimer are illustrated. (b) Spectrum from a film containing a mixture of monomer and excimer species (Fleetham and Li, 2014).

$\eta_{\text{ext}} = 15.7\%$  with  $\eta_P = 27.3 \text{ lm/W}$ ,  $\text{CRI} = 80$ , and  $\text{CIE} = (0.37, 0.40)$ , corresponding to  $\text{CCT} \approx 4600 \text{ K}$  at a luminance of approximately  $500 \text{ cd/m}^2$ .

The design of monomer/excimer WOLEDs depends on the control of the dynamics leading to the generation of excimers in a molecular mixture. The mechanism by which the energy is transferred to the excimer state is different for neat and doped films. In neat films, excitons are first generated on the monomer, and are subsequently transferred to the excimer state. The formation rate of optically generated triplet excimers from adjacent excited and unexcited monomers follows:

**Figure 6.104** EL spectra normalized to the peak monomer intensity of a PHOLED with the structure: ITO:PEDOT:PSS/NPD (30 nm)/TAPC (10 nm)/x % Pt-17:26mCPy (25 nm)/PO15 (20 nm)/LiF/Al. The spectral regions for monomer and excimer emission are shown. Inset: Molecular structural formula of Pt-17 (Bakken et al., 2012).

where  $k_X$  is the rate of formation of the triplet excimer,  $k_{XP}$  is the rate of excimer phosphorescence,  $^3M^*$  is the excited monomer triplet state,  $^1M$  is the ground state, and  $^3E^*$  is the excited triplet excimer state in the solid film. If the formation is via electrical injection, a neutral charge transfer complex is formed by the combination of an anion and cation precursor pair:

where  $k_{ACX}$  is the rate of excimer formation from the charge transfer couple,  $M^-$  and  $M^+$ . Following analyses similar to that developed for exciton dynamics in Section 6.3.5, the rate equations for excimer formation in a neat film are (D'Andrade and Forrest, 2003)

$$\begin{aligned} \frac{d^3M^*}{dt} &= -k_{ph}(^3M^*) - k_{nr}^M(^3M^*) - k_X(^1MM^*) + G \\ \frac{d^3E^*}{dt} &= k_X(^1M^3M^*) - k_{XP}(^3E^*) - k_{nr}^E(^3E^*) \end{aligned} \quad (6.85)$$

where  $k_{nr}^M$  and  $k_{nr}^E$  are the non-radiative decay rates of the excited monomer and excimer, respectively, and  $G$  is the generation rate of triplet monomers due to the intersystem crossing of photogenerated monomer singlet states on the phosphor. As previously (cf. Eqs. 6.54 and 6.55), in these rate equations,  $M$  and

$E$  represent monomer and excimer concentrations (which differs from their representations as states in Eqs. 6.83 and 6.84). The solutions to Eq. 6.85 at  $G = 0$  are

$$\begin{aligned} {}^3M^*(t) &= A_1 \exp(-k_1 t) \\ {}^3E^*(t) &= A_2 \exp(-k_1 t) + A_3 \exp(-k_2 t) \end{aligned} \quad (6.86)$$

where  $A_1$ ,  $A_2$ , and  $A_3$  are determined by initial conditions, and the decay rates,  $k_1$  and  $k_2$ , are given by

$$\begin{aligned} k_1 &= k_{ph} + k_{nr}^M + k_X({}^1M) \\ k_2 &= k_{XP} + k_{nr}^E \end{aligned} \quad (6.87)$$

Triplet energy transfer between adjacent molecules is by thermally activated diffusion with an activation energy of  $E_a$ , giving (Baldo and Forrest, 2000)

$$k_X({}^1M) = k_X^\infty \exp[-E_a/k_B T], \quad (6.88)$$

where  $k_X^\infty$  is the monomer–excimer transfer rate at  $T \rightarrow \infty$ . When  $E_a \ll k_B T$ , excimers are formed by exothermic transfer of the excited state from the monomer, whereas for  $E_a > k_B T$ , the formation is endothermic. Hence, the relative emission intensities from excimer to monomer should change significantly with temperature, and the lifetime of the monomer should follow Eq. 6.87. Equation 6.88 also implies that the formation of triplet excimers is monomer-concentration dependent.

From the foregoing, we can find the lifetime of the monomer exciton vs. temperature,  $T$ , using

$$\frac{k_1(T)}{k_1(T_0)} = \frac{k_{ph} + k_{nr}^M + k_X({}^1M)}{(k_{ph} + k_{nr}^M + k_X^\infty \exp[-E_a/k_B T])}, \quad (6.89)$$

with steady state solutions to Eq. 6.85 of

$${}^3M^* = \frac{G}{k_{ph} + k_{nr}^M + k_X({}^1M)}, \quad (6.90)$$

$${}^3E^* = \frac{k_X({}^1M)}{k_{ph} + k_{nr}^M + k_X({}^1M)} \times \left[ \frac{G}{k_{XP} + k_{nr}^E} \right]. \quad (6.91)$$

The monomer emission intensity is proportional to  $k_{ph}({}^3M^*)$ , and follows (D'Andrade and Forrest, 2003)

$$L^M(T) = \frac{A_4 (k_{ph} + k_{nr}^M)}{(k_{ph} + k_{nr}^M + k_X^\infty \exp[-E_a/k_B T])}, \quad (6.92)$$

where  $A_4$  is a constant. Given that  $k_r^E [{}^3E_0^*]$  is proportional to the excimer emission intensity, and assuming that the PL efficiency of the excimer is

temperature independent, the emission intensity of the excimer is

$$L^X(T) = \frac{A_5 \exp[-E_a/k_B T]}{(k_{ph} + k_{nr}^M + k_X^\infty \exp[E_a/k_B T])}, \quad (6.93)$$

where  $A_5$  is a constant. Note that the low efficiency of excimer diffusion due to exciton self-trapping reduces quenching from TTA compared with monomer-based electrophosphorescent systems.

In the solid state, monomers must be nearest neighbors to form an excimer. We have seen that solid films of square planar molecules with close  $\pi$ – $\pi$  ligand contact should promote the formation of excimer species, even in lightly doped films. Further, the rate equations above suggest that the ratio of excimer-to-monomer emission depends on the monomer concentration.

Varying the doping concentration of an excimer-forming molecule thus controls the excimer-to-monomer emission intensity ratio. The PL and absorption of the host and guest molecules, respectively, must overlap for efficient Dexter and Förster energy transfer to occur between the two species (see Section 3.8). The rate equations for excimer formation processes in a doped system are thus

$$\begin{aligned} \frac{d^1H^*}{dt} &= -k_{nr}^H({}^1H^*) - k_{ET}({}^1M^1H^*) + G \\ \frac{d^3M^*}{dt} &= -k_{ph}({}^3M^*) - k_{nr}^M({}^3M^*) - Qk_X({}^1M^3M^*) \\ &\quad + k_{ET}({}^1M^1H^*) \\ \frac{d^3E^*}{dt} &= Qk_X({}^1M^3M^*) - k_r^E({}^3E^*) - k_{nr}^E({}^3E^*) \end{aligned} \quad (6.94)$$

where  $k_{nr}^H$  is the non-radiative decay rate of the excited host,  ${}^1H$  is the singlet host state concentration,  $k_{ET}$  is the rate at which the exciton is transferred from the host to the dopant molecule, and  $Q$  is the probability that two dopant molecules are nearest neighbors. At doping levels where all host emission is quenched, the radiative decay rate of the excited host state is assumed to be negligible compared to the transfer rate of the exciton from the host to the dopant molecule.

For neat films,  $Q = 1$ , and for doped films,  $Q = 1 - (1 - f)^C$ , where  $C$  is the number of possible lattice positions around one molecule that can lead to the formation of an excimeric pair (i.e. the coordination number), and  $f$  is the mole fraction of the dopant. This assumes that dopant molecules are randomly dispersed without a tendency to form clusters. Apparently,  $Q = Cf$  for small dopant

concentrations. The excimer and monomer emission intensities are then:

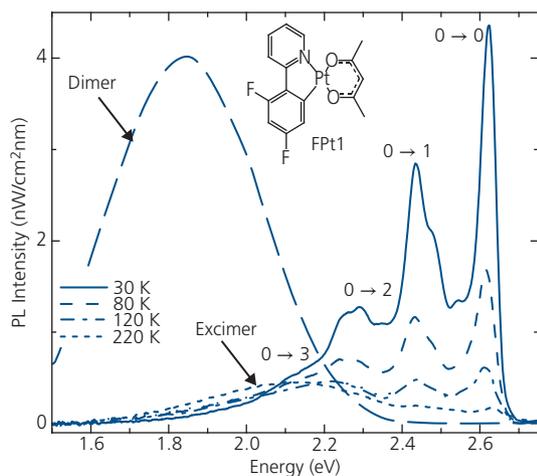

$$L^M = \frac{k_{ph}}{k_{ph} + k_{nr}^M + Qk_X(^1M)} \cdot \left[ \frac{k_{ET}(^1M)G}{k_{nr}^H + k_{ET}(^1M)} \right]$$

$$L^X = \frac{k_r^E}{k_r^E + k_{nr}^E} \cdot \left[ \frac{Qk_X(^1M)}{k_r^M + k_{nr}^M + Qk_X(^1M)} \right] \cdot \frac{k_{ET}(^1M)G}{k_{nr}^H + k_{ET}(^1M)}$$

$$\frac{L^X}{L^M} = \frac{k_r^E}{k_r^E + k_{nr}^E} \cdot \left[ \frac{Qk_X(^1M)}{k_{ph}} \right]$$
(6.95)

The ratio  $L^X/L^M$  varies as  $Q^1M$ , and for small dopant concentrations,  $Q$  varies linearly with concentration. The excimer-to-monomer emission intensity ratio should, therefore, exhibit a quadratic dependence with  $^1M$ .

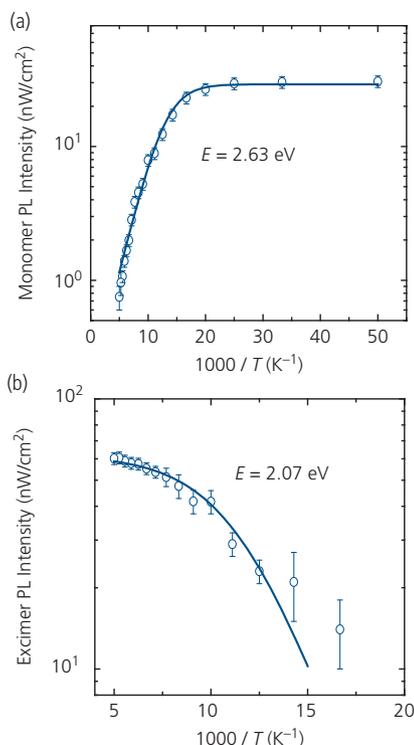

This model has been applied to understand the dynamics of the monomer–excimer emitting phosphor, FPt1 (D’Andrade et al., 2002a, D’Andrade and Forrest, 2003), shown in the inset, Fig. 6.105. The PL spectra of a neat thin film of FPt1 are shown as a function of temperature, along with the EL spectrum of a PHOLED with a 30 nm thick, neat FPt1 EML. At low temperatures, the excimer emission at 2.07 eV is completely dominated by monomer emission with a clearly resolved vibronic progression whose corresponding transitions are labeled. This contrasts with the highest temperature spectrum where only weak excimer emission is observed.

**Figure 6.105** PL spectra of a planar FPt1 molecule (molecular structural formula in the inset) at several temperatures. The monomer emission vibronic transitions from the triplet to the ground state are labeled, as well as the excimer emission which is most prominent at 220 K. Also shown is the room temperature dimer EL spectrum from an FPt1 PHOLED. The EL intensity is not normalized to the PL intensity shown on the ordinate (D’Andrade and Forrest, 2003).

The room temperature PHOLED EL spectrum shows none of the features found in the PL spectrum. Instead, only a broad peak, red-shifted to 1.84 eV associated with dimer emission is observed. Recall from Section 3.6 that excimers and dimers differ in that the former has no bound ground state. It results from an excitation shared by two nearest neighbor molecules that form a new, coupled eigenstate. In contrast, the dimer is stable in both the ground and the excited state, and results from the weak  $Pt \cdots Pt$  interactions between adjacent molecules. These weak bonds are considerably more stable than the excimer interactions, thus accounting for the significant red shift between the excimer and dimer spectra.

The excimer dynamics are obtained from the temperature dependence of the relative monomer and excimer PL intensities, as shown in Fig. 6.106. The data show the intensities of the highest energy monomer feature in Fig. 6.105 (i.e. the  $^3M^*(0 \rightarrow 0)$  transition) and the excimer ( $^3E^*$ ) as a function of temperature. The monomer intensity increases as temperature is

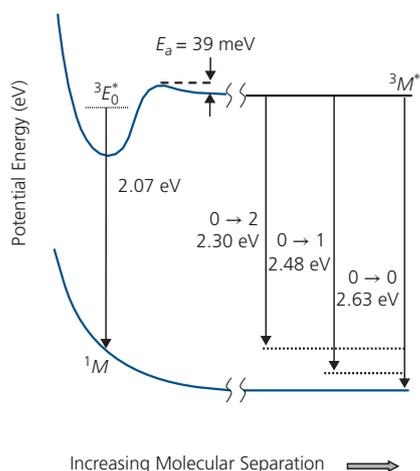

**Figure 6.106** (a) Integrated intensity of the  $^3M^*(0 \rightarrow 0)$  monomer emission spectrum of a FPt1-based PHOLED, and (b) the  $^3E^*$  spectrum vs. inverse temperature. Lines are fits to Eqs. 6.92 and 6.93 in steady state (D’Andrade and Forrest, 2003).

reduced, until it saturates at  $T < 40$  K. At the same time, the excimer peak decreases with temperature until its intensity is overwhelmed by the monomer emission, again at approximately 40 K.

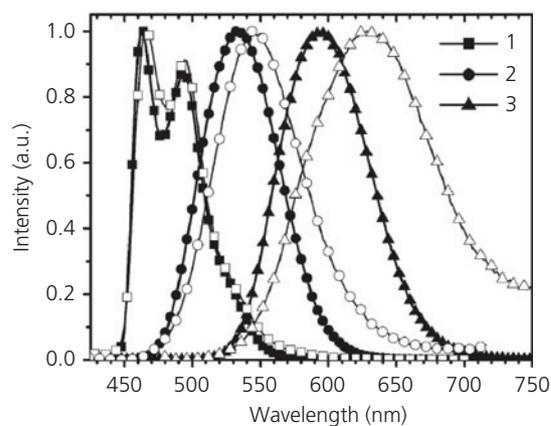

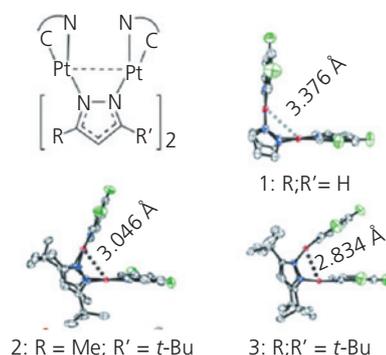

The seemingly opposite response to temperature of the excimer and monomer intensities suggests that these processes are linked, that is, the monomer excitation transfers more rapidly to the excimer state as temperature increases. The foregoing analysis leading to the temperature dependences of the luminance in Eqs. 6.92 and 6.93, therefore, should give us insight into the energy transfer process. Indeed, the solid lines in Fig. 6.106 are fits to these equations, yielding activation energies of  $E_a = 35$  meV for  $L^M(T)$ , and 39 meV for  $L^X(T)$ . Interestingly, even the magnitudes of these temperature variations are approximately equal, with  $k_X^\infty / (k_{PI} + k_{tr}^M) \approx 185$  in both cases. This strongly suggests that the two states are coupled. Following the model of excimer-monomer coupling presented in Figs. 3.44 and 3.45 (Birks, 1975; Nasu, 1987), there is apparently an activation energy barrier between monomer and excimer manifolds, as shown in Fig. 6.107. As triplets on individual monomers diffuse toward each other, they encounter a barrier due to Pauli exclusion and Coulomb repulsion of their orbitals. At a critical approach distance, their wavefunctions are shared to form an excimer state that is stabilized relative to the individual monomers. This results in a red shift of the emission energy as large as 560 meV. Analyses of the data are consistent with an energy barrier between these two states of 37 meV that inhibits excimer formation as temperature is decreased. As

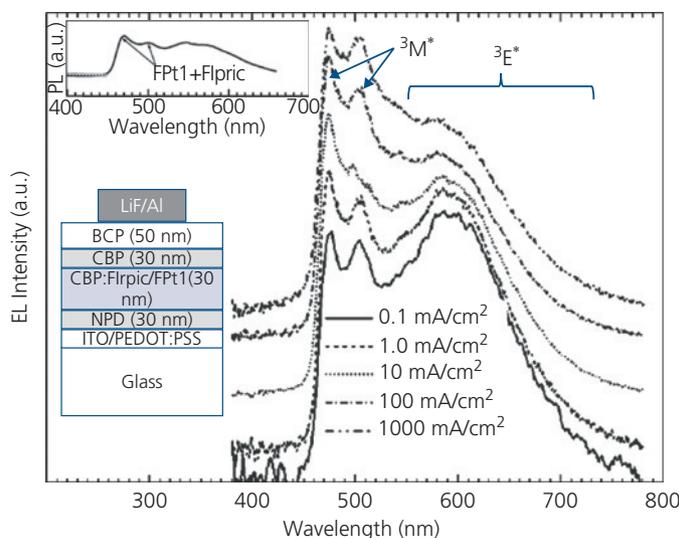

**Figure 6.107** Energetic landscape of FpT1 showing the excimer and monomer transition energies, as well as the 39 meV activation energy barrier separating the states (D'Andrade and Forrest, 2003).

noted above, a more stable Pt···Pt dimer state is identified in the EL spectra that results in an even greater red shift, to 1.84 eV.

A demonstration of the control of Pt···Pt dimerization, and hence the  $^3\text{MMLCT}$  interactions is based on a series of binuclear Pt complexes shown in Fig. 6.108, where the relative opening angle between adjacent ligands is varied by modifications of the steric bulk of the bridging pyrazolate (Ma et al., 2005, 2006). This series of molecules was introduced in Section 3.7.3 (Fig. 3.79) in the context of spin-orbit coupling. The complexes have the general formula  $\text{C}^{\wedge}\text{N}(\mu\text{-pz}')_2\text{PtC}^{\wedge}\text{N}$  (here,  $\text{C}^{\wedge}\text{N} = 2\text{-}(2,4\text{-difluorophenyl})\text{pyridyl}$ ,  $\text{pz}'$  for compound **1** =  $\mu$ -pyrazolate, **2** = 3-methyl-5-*tert*-butylpyrazolate, and **3** = 3,5-bis(*tert*-butyl)pyrazolate). The opening angle determines the Pt···Pt bond length, and hence the strength of the  $^3\text{MMLCT}$  transition. As the Pt atoms are spaced more closely together, the dimer becomes increasingly stable, resulting in a larger red shift as seen in both the WOLED

**Figure 6.108** (from top left) Molecular structural formulae of the three binuclear Pt complexes shown. The Pt···Pt separation distances shown are adjusted by varying the steric bulk of the functional groups on the bridging pyrazolate: Me = methyl; *t*-Bu = *tert*-butyl. The lower figure shows that the EL spectra for PHOLEDs (filled symbols) using dopants **1**, **2**, and **3** are blue shifted compared to their PL spectra in solid solutions of polystyrene (open symbols) (Ma et al., 2006).

**Figure 6.109** EL spectra of an FpT1+Flrpic OLED at several current densities. The monomer and excimer contributions to the spectra are noted. Upper inset: PL spectrum of the CBP + 6 wt% FpT1 + 6 wt% Flrpic blend. Lower inset: Schematic of the PHOLED structure. After D'Andrade et al. (2002a).

EL and PL spectra of these compounds in Fig. 6.108. The PL spectra are taken with the molecules mixed into a large energy gap polystyrene matrix. In the PHOLEDs, the complexes are doped at 8 wt% in mCP in an EML sandwiched between an NPD HTL, and a BCP EBL/Alq<sub>3</sub> ETL cap. When the ligand angle is 90° for compound **1**, there is very little Pt–Pt interaction, resulting in a nearly unchanged spectrum from the monomer <sup>3</sup>LC/<sup>3</sup>MLCT transition of the square planar (C<sup>^</sup>N)Pt complex itself. In contrast, **2** and **3** have considerably stronger Pt dimer interactions, resulting in increasingly larger red shifts of up to 200 nm in solid solution as the bond distance decreases to 2.834 Å. The differences in EL and PL spectra are attributed to different couplings to the host. The orbital interactions between **2** and **3** and mCP result in a hypsochromic shift compared to polystyrene, where such interactions are completely absent. The shifts are a result of the solid-state solvation polarization interactions discussed in Section 3.6.7. Further, compound **1** shows no such shift since the monomer excited state is confined to the ligands themselves.

While spectral shifts and broadening are precisely controlled by the ligand bulk, it does not result in sufficient spectral broadening to generate efficient white emission. In fact, only compound **1** generates excimer broadening in the presence of monomer emission at high doping concentrations (30–70%) due to the exposure of its ligands that allows for monomer coupling to nearby molecules. Unfortunately, the efficiencies of these white PHOLEDs are < 4%. When **3** is used as a dopant in **1**, the monomer

emission from the latter compound is mixed with the orange-red spectrum of the latter, giving broad red emission with 5.4% efficiency (Ma et al., 2006).

The foregoing analysis of excimers is general, and can be used to understand and ultimately optimize excimer-based PHOLED emission in neat systems, as well as in the often more efficient guest–host systems that can precisely control the excimer-to-monomer intensity ratio. The phosphor, FpT1, itself has proven to yield modestly efficient WOLEDs when combined with an additional blue phosphor, Flrpic, in a CBP host. The Flrpic is included to shift the spectrum toward the green to compensate for the strong red shift of FpT1 needed to achieve high efficiency. The PL spectra of the CBP + 6 wt% FpT1 + 6 wt% Flrpic blend is shown in Fig. 6.109, upper inset. The monomer emission features are apparent at 450–525 nm, whereas the broad excimer emission is seen at longer wavelengths. The WOLED EL spectra at several current densities employing this double-doped EML are provided in Fig. 6.109. Again, both the monomer <sup>3</sup>M\* and excimer <sup>3</sup>E\* features are readily resolved. The devices had slightly green CIE coordinates of (0.33, 0.44), resulting in CRI = 78 and CCT ≈ 5500 K. However, as is often the case with excimer-monomer devices, the forward viewing efficiencies were only η<sub>ext</sub> = 4% and η<sub>P</sub> = 4.4 lm/W (D'Andrade et al., 2002a).

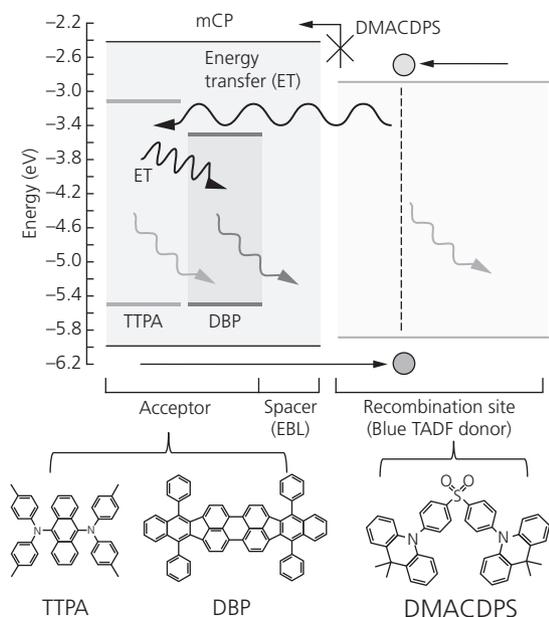

Among the most efficient single dopant monomer–excimer devices are those based on a symmetric tetradentate square planar Pt (Pt707) doped at 14 wt% into mCBP (Li et al., 2014). The monomer-to-excimer ratio is controlled by the concentration, as is the efficiency.

The devices exhibit  $\eta_{ext} = 17.7\%$  and  $\eta_P = 24.0 \text{ lm/W}$  at  $1000 \text{ cd/m}^2$ , making them competitive with many multi-monomer emitting phosphor devices. Further, their CIE coordinates are (0.37, 0.42) (corresponding to  $CCT \approx 4550 \text{ K}$ ), although the low  $CRI = 70$  makes these devices unsuitable for high quality lighting applications.

### 6.5.4 WOLEDs employing TADF emission

In this section we discuss two WOLEDs based on TADF that have been engineered to achieve high efficiency. The first uses a blue TADF emitter that transfers a portion of its energy to conventional yellow and red emitting fluorescent materials (Higuchi et al., 2015). The second is based on a blue emitting TADF emitter used in combination with a yellow Ir-phosphor molecule (Cho et al., 2015). Both structures share many of the same operational principles as hybrid fluorescent/phosphorescent and phosphoresensitized fluorescent WOLEDs in Section 6.5.2.

The hybrid TADF/sensitized fluorescent device EML energy scheme is shown in Fig. 6.110. The EML consists of an electron and hole conducting blue emitting TADF molecule, DMACDPS, located in the exciton generation region. Its peak wavelength is 480

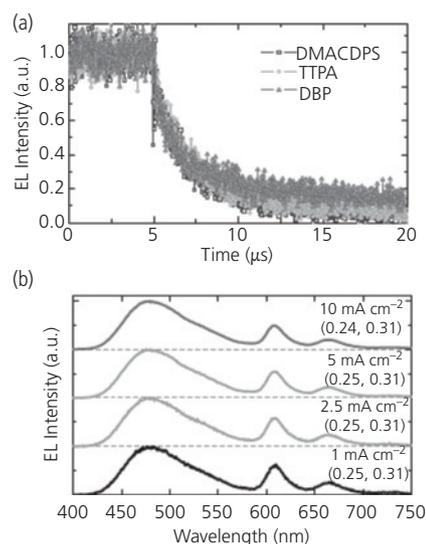

**Figure 6.110** Energy level scheme for a TADF/fluorescent hybrid WOLED. The excitons are primarily generated in the TADF zone, where electrons are blocked from entering the mCP host by a 0.5 eV energy barrier. A spacer layer separates the fluorophores, TTPA and DBP, from the exciton formation zone. Energy transfer (bold wiggly arrow) and emission (gray wiggly arrows) are shown (Higuchi et al., 2015).

nm, and when used alone as an emitting molecule, the blue OLED has an external efficiency of 15%. In the WOLED, the blue emitting/exciton formation zone is separated by a 2 nm thick mCP spacer, chosen for its high triplet energy to avoid recombination of the TADF molecular triplets. At the opposite side of the spacer, the mCP is doped at 1 wt% with red emitting DBP and 10 wt% yellow emitting TTPA. The spacer prevents direct singlet transfer to these molecules, which would inevitably result in a red OLED based solely on DBP emission. Rather, the spacer requires energy transfer from DMACDPS to TTPA to DBP. By maintaining a very low DBP concentration, a balance of blue, yellow and red emission is established.

The excitation processes of the various lumophores are verified by the transient response of the WOLED in Fig. 6.111a. Whereas the fluorescent emission from TTPA and DBP occurs on a timescale of 1–10 ns, all three WOLED spectra are governed by the phosphorescent lifetime of DMACDPS of  $\tau \approx 4 \mu\text{s}$ . Thus, the luminescence persists until all blue triplets have been converted to singlets, and subsequently radiatively recombine, or transfer to the fluorophores that emit at longer wavelengths.

The WOLED emission spectrum is relatively independent of current, as shown in Fig. 6.111b. This indicates that the process in Fig. 6.110 is indeed limited by FRET-based diffusion. While good spectral coverage across the visible is not achieved (hence resulting in a low CRI), the CIE coordinates are unchanged over a decade variation in current. The maximum

external quantum efficiency is 12.1% and  $\eta_P = 22.0$  lm/W, with CIE = (0.25, 0.31) at 1000 cd/m<sup>2</sup>, resulting in a green-blue cast (Higuchi et al., 2015).
