An alternative two-color WOLED uses a TADF molecule that serves the dual purpose of a blue emitter, and as a host to a high efficiency yellow Ir-based phosphor (Cho et al., 2015). The very high efficiency of both the blue TADF molecule, DCzIPN at 16.4% and the yellow Ir complex, PO-01, results in a high WOLED efficiency as well. The orange and blue emitting sections in the EML are separated to prevent rapid energy transfer from DCzIPN to PO-01 in the mCP host. Excitons are generated at both the ETL/EML and HTL/EML interfaces. A fraction is harvested on the TADF emitter, and the remainder diffuse to PO-01. The WOLED has a maximum external efficiency of 21% achieved at 100 cd/m<sup>2</sup> with CIE color coordinates of (0.31, 0.33), which is near to the isoeenergetic point of (0.33, 0.33). However, the color coordinates are intensity dependent with the greatest blue spectral content at an intermediate luminance of 1000 cd/m<sup>2</sup> due to shifts in the position of the emission zone due to exciton formation moving between the ETL to the HTL sides of the EML. Also, as is characteristic of two-color WOLEDs, there is only weak emission in the green. Thus, while the CIE coordinates are nearly ideal, the CRI is too low for high quality illumination sources (Cho et al., 2015).

Given the results in this section, it is unclear whether TADF-based WOLEDs or those employing excimer/excplex emission will have the high performance necessary to be useful in general lighting applications. However, the simplicity of single or even double dopant WOLEDs is an attractive means for lowering cost.

### 6.5.5 Stacked and striped phosphorescent WOLEDs

We found in Section 6.4 that RGB OLEDs can be arranged in a stack with each color element individually addressed to achieve any desired color, including white with a bias-selectable CRI and CCT (Shen et al., 1997, Gu et al., 1999, Parthasarathy et al., 1999). Alternatively, the potential of the internal contacts can be allowed to float, as in Fig. 6.92d. In this configuration, both high efficiency and brightness are achieved, although dynamic color tuning is not possible.

The operating principle of the stacked WOLED is shown in Fig. 6.112. The SOLED consists of  $N$  emitting sub-elements comprising individual OLEDs that emit either the same or different colors. That is, the design of each element in the stack can be

**Figure 6.112** Comparison between (a) a single element OLED and (b) a stacked OLED, or SOLED. For a single element OLED, a current,  $I_0$ , at voltage,  $V_0$  generates luminance,  $L_0$ . For a three sub-element SOLED,  $I_0$  generates three times the luminance,  $3L_0$ , but requires voltage,  $3V_0$ .

independently designed and optimized to serve a particular function. The elements are separated by transparent *charge generation layers* (CGLs) consisting of a conducting medium that can inject charge of either polarity into the immediately adjacent sub-elements. The luminance emitted by each stacked element is additive. Hence, a single injected electron generates  $N$  photons, with a total external efficiency of:

$$\eta_{ext} = \sum_{i=1}^N T_{CGL,i} \eta_{int,i} \eta_{out,i}, \quad (6.96)$$

where  $T_{CGL,i}$  is the transmissivity of the CGL and the transparent contact of the  $i$ th element, and  $\eta_{int,i}$  is the internal quantum efficiency. Here  $i = 1$  is for the bottom sub-element, and  $i = N$  for the top element in Fig. 6.112b. Interestingly, there are different out-coupling efficiencies for each member of the stack since the optical field is different depending on position (see Section 6.6) (Bulovic et al., 1998a). We will show that the CGL transmissivity can approach 100%, allowing, in principle, the external quantum efficiency of a SOLED to exceed 100%.

The increased luminance comes at the expense of increased voltage. Thus, a current,  $I_0$ , at voltage,  $V_0$ , delivers a luminous intensity,  $L_0$ , for a single element

OLED. All other factors being equal, when placed in a stack of  $N$  elements,  $I_0$  results in  $NL_0$ , but at voltage  $NV_0$ . Thus, the power efficiency remains unchanged. This is an obvious restatement of the conservation of energy. The disadvantage of higher operational voltage and increased layer complexity notwithstanding, there are compelling advantages of using SOLEDs in lighting and displays:

- (i) The additive luminance leads to very high brightness at low current, particularly useful in lighting applications.
- (ii) Since a higher luminance is achieved at lower current densities, and since the operational lifetime of an OLED depends on current, the SOLED architecture results in a longer useful device life (see Section 6.7) (Zhang et al., 2014b).
- (iii) Lower current at a particular brightness leads to reduced operating temperature, which also extends device lifetime (Adamovich et al., 2012, Levermore et al., 2012).
- (iv) Reduced current operation reduces annihilation-based losses, resulting at higher efficiency at an equivalent current (and hence higher brightness) than a single element device.
- (v) The SOLED architecture allows for a flexible approach to device design. For example, white emission can be achieved by stacking individual white emitting devices (Kanno et al., 2006a, 2006b, Adamovich et al., 2012). Alternatively, red, green, and blue PHOLEDs (Liao et al., 2004, Qi et al., 2008, Chen et al., 2011), or any combination of a multicolor and monochromatic elements, can be stacked (Lee et al., 2008, Chen et al., 2011).
- (vi) The SOLED thickness is  $\sim Nd$ , where  $d$  is the thickness of each sub-element comprising the stack. The added thickness can result in reduced shorts between anode and cathode, and hence an increased manufacturing yield, although internal shorts between elements is not expected to differ from single element OLEDs.

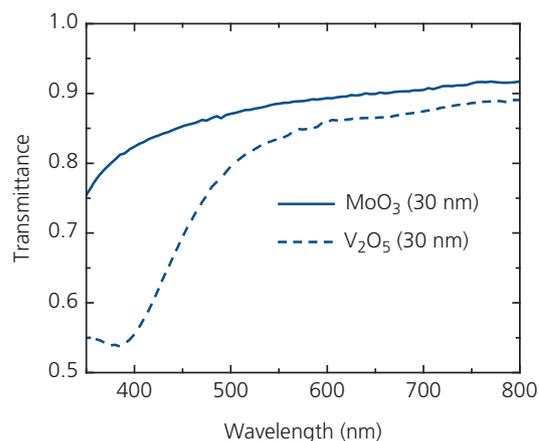

Since many approaches to achieving white emission already discussed are compatible with the SOLED architecture, a primary focus of SOLED research has been to develop transparent and electrically lossless CGLs. The earliest devices employed ITO, which stacks multiple TOLEDs in an integrated structure (Shen et al., 1997, Gu et al., 1999, Parthasarathy et al., 1999, Matsumoto et al., 2003). The energetic sputtering process is helpful in creating defects that promote electron injection into the ETL. However, as discussed in Section 6.4, significant damage and

shorting must be avoided by using a very low sputtering power, and the resulting slow deposition rate is inconvenient for rapid, high volume manufacturing.

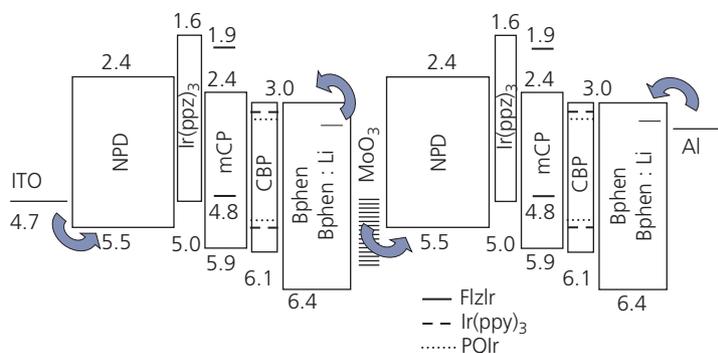

To avoid sputtering, compound CGLs comprising vacuum thermally deposited metal oxides such as  $V_2O_5$  (Matsumoto et al., 2003) or  $MoO_3$  (Kanno et al., 2006a, 2006b, Lee et al., 2008) used in conjunction with a doped organic electron injection layer have shown good performance. A comparison of the transmittance of these two oxides is provided in Fig. 6.113. For broad spectral bandwidth WOLEDs,  $MoO_3$  is a better choice due to its high transmittance from 85% in the deep blue, to >90% in the red.

A device structure comprising two RGB white emitting sub-pixel elements along with a 10 nm  $MoO_3/20$  nm BPhen:Li (1:1 molar ratio) CGL is shown in Fig. 6.114. The very deep  $MoO_3$  LUMO ( $-6.35$  eV below the vacuum level (Bao et al., 2010)) allows for rapid and efficient electron-hole recombination at its interface with the NPD HTL of the upper element. Similarly, the Li-doped BPhen in the CGL supplies electrons for injection into the lower element. The residual positive charge in the n-type Li-doped layer captures excess electrons in the  $MoO_3$ , thus completing the circuit with charges injected from the anode and cathode. While there is a large barrier between the  $MoO_3$  LUMO and the  $Li^+$  level, the excess charge induces energy level bending that allows for charge transfer until the Li and  $MoO_3$  are once more neutral (Lee et al., 2012).

The function of the CGL can be understood in terms of the energy level alignments shown in Fig. 6.115. The CGL in the device in Fig. 6.114 is illustrated in Fig. 6.115a.  $MoO_3$  has a deep LUMO that aligns with

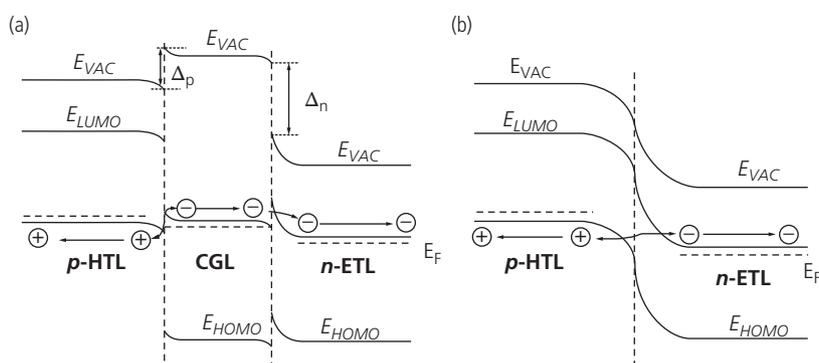

**Figure 6.113** Transmittance of 30 nm thick thermally evaporated layers of  $MoO_3$  and  $V_2O_5$  (Kanno et al., 2006a).

**Figure 6.114** Energy level diagram of a dual element WOLED using a compound  $\text{MoO}_3/\text{Bphen}:\text{Li}$  hole/electron injecting CGL. Numbers indicate HOMO and LUMO energies relative to vacuum of the various materials in eV. Arrows show the direction of charge injection (Kanno et al., 2006a).

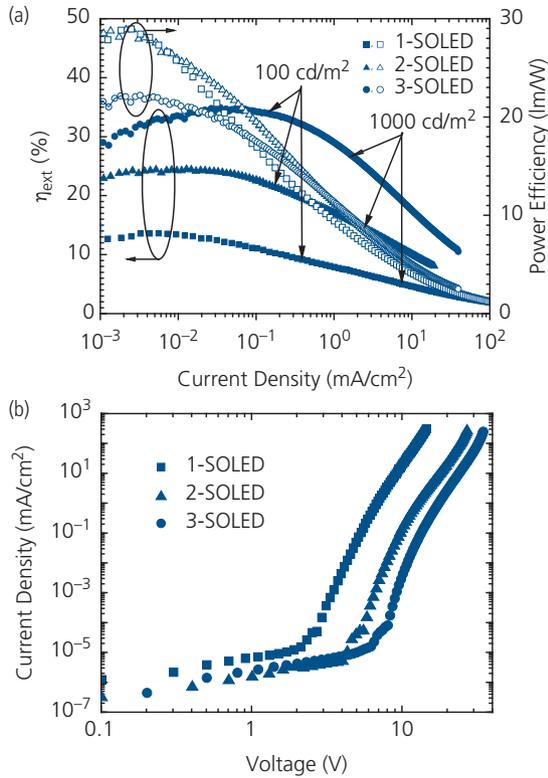

**Figure 6.115** Two types of CGLs used in multi-stage WOLEDs. (a) Charge generation via interface recombination at a CGL with a deep LUMO level. (b) Tunnel-junction CGL between a heavily doped p-HTL and n-ETL.

the n-doped ETL, forming an interface dipole of energy,  $\Delta_n$ . The LUMO alignment to the p-HTL permits efficient electron-hole recombination. The dipole plus energy level bending near the interface due to dopant charge depletion (i.e. electron injection from Li:BPhen into the adjacent OLED ETL) subsequently allows for electron-injection into the ETL of the second OLED in the stack. Alternatively, a highly doped p-n organic junction induces significant interface energy level bending, leading to tunneling of holes and electrons across the interface region. This case, shown in Fig. 6.115b, will be discussed further below.

Returning to the device in Fig. 6.114, each sub-element has the following structure: NPD (40 nm)/Ir(ppz)<sub>3</sub> (10 nm)/mCP:10 wt% FlzIr (20 nm)/CPB:3 wt% Ir(ppy)<sub>3</sub>:10 wt% PQIr/Bphen(20nm)/Li:BPhen (1:1 molar ratio) (20 nm). The EML is comprised of two sections: one with green and red phosphors in a CBP host, and the other with the blue phosphor (FlzIr) doped into mCP. Both elements use a combination EBL (BPhen) and hole blocking layer (Ir(ppz)<sub>3</sub>), the latter needed due to the very high LUMO energy of the blue dopant.

The stacked WOLED performance is shown in Fig. 6.116 (Kanno et al., 2006a). The peak  $\eta_{ext}$  moves monotonically to higher currents, and hence higher brightness, with the number of stages. As a result, the current density required to achieve a given luminance decreases as the number of sub-elements increases from 1, to 2, to 3. Both effects are due to reduced annihilation since the EML is effectively “spread out” among the multiple elements. Furthermore, the peak efficiency is approximately a linear function of the number of stacked elements. Thus, the peak forward viewing efficiencies from the glass surface are  $\eta_{ext} = 13.6, 24.7,$  and  $34.9\%$  for 1-, 2-, and 3-element SOLEDs. These efficiencies correspond to 1.8 and 2.6 times the efficiency of a single element device for the 2- and 3-element SOLEDs, suggesting that losses at each CGL are only  $\sim 10\%$ . As noted, conservation of energy requires that the power efficiency of multi-element devices not exceed that of a single stage OLED. This is clearly the case in Fig. 6.116a, where the power efficiency of each device is approximately equal.

In Fig. 6.116b we show the  $j$ - $V$  characteristics for the same three SOLEDs whose characteristics are

**Figure 6.116** (a) External quantum and power efficiencies of 1-, 2-, and 3-unit SOLEDs with the structure in Fig. 6.114. The currents needed to achieve luminances of 100 and 1000 cd/m<sup>2</sup> are indicated by arrows. (b) Current density vs. voltage characteristics of the devices in (a) (Kanno et al., 2006a).

summarized in Table 6.12. Since the applied voltage is approximately an integer multiple of the number of identical elements, we infer that the charge injection from the CGLs is nearly lossless. Indeed, the charge injection of the CGLs appears to be even more efficient than for the Al and ITO cathode and anode.

As noted previously, SOLEDs can exhibit noticeable microcavity effects due to the numerous dielectric layers comprising the stacks. These effects can be ameliorated by varying the thickness of the layers, thereby changing the optical path lengths (and hence the optical intensity profiles) within the stacks. The influence of stacking on the EL spectra of the devices in Figs. 6.114 and 6.116 is shown in Fig. 6.117. As elements are added to the stack, the peak emission moves from the blue, to the green, and then back to the blue for 1-, 2-, and 3-element devices, respectively. Since the emission zone in each element is also current dependent, the spectra vary with current, as shown in the inset, Fig. 6.117.

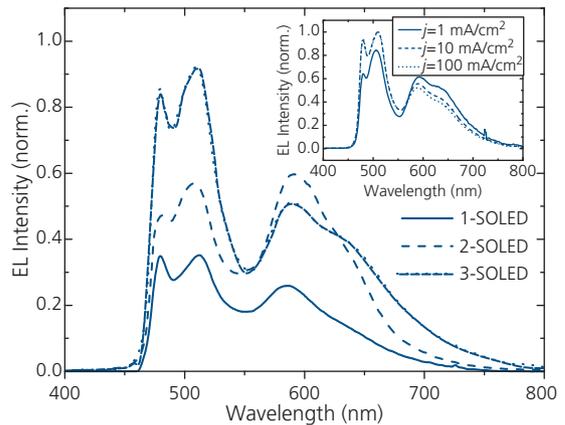

The MoO<sub>3</sub>/BPhen:Li compound CGL has been adapted to many different stacked structures. For

example, a significantly improved color rendition has been achieved by stacking fluorescent/phosphorescent white elements having structures and materials sets similar to that in Fig. 6.100. A 3-SOLED device with such a hybrid sub-element had a total efficiency of  $\eta_{ext} = 57\%$ ,  $\eta_p = 22$  lm/W and CIE coordinates of (0.38, 0.44), corresponding to CCT  $\approx$  4100 K with CRI = 82 at a luminance of 1000 cd/m<sup>2</sup>. This device showed an almost optically and electrically lossless CGL. The peak external efficiencies were 1.9 and 2.85 times larger for the 2- and 3-SOLEDs compared to the single element devices, corresponding to only a 5% loss at each stage. Similarly, the change in voltage drop across the device also scaled nearly linearly with the number of elements (Kanno et al., 2006b).

A different architectural approach using the MoO<sub>3</sub>/BPhen:Li CGL places three different color WOLEDs in a stack, as shown in Fig. 6.118a. One element (nearest the cathode) has a red-emitting EML consisting of PQIr doped CBP, followed by the green emitting Ir(ppy)<sub>3</sub>:CBP element, and a blue emitting FIr6:UGH2 element (Qi et al., 2008). This is an “RGB” structure,

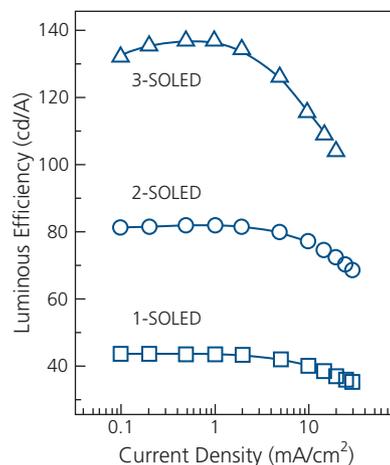

**Figure 6.118** (a) Energy level structure of an RGB phosphorescent WOLED. (b) Spectra depending on ordering of the sub-elements. BGR or RGB corresponds to the pixel ordering from cathode to anode (Qi et al., 2008).

where the first letter corresponds to the element nearest the cathode. The sub-pixel ordering is critical in managing microcavity effects to obtain the desired output spectrum. In Fig. 6.118, the color balance of the BGR SOLED is improved compared to the RGB SOLED, with CRI values for the two devices of 79 and 63, respectively. Due to the larger content of green and red emission, however, the RGB device has the highest quantum and power efficiencies of  $\eta_{ext} = 36\%$ , and  $\eta_p = 21$  lm/W and CIE coordinates of (0.45, 0.36), corresponding to  $CCT \approx 2450$  K with  $CRI = 63$ . This is a very warm white, with characteristics that fall short of acceptable for lighting applications, although further optimization is undoubtedly possible.

Lithium used in the CGLs in Fig. 6.118 can diffuse through the layers as the device ages. For this reason, other n-type dopants such as  $Cs_2CO_3$  have been used as the electron donor (Lee et al., 2008), as well as devices whose CGL comprises a combination of strong n-type donors such as LiF and Ca in mixtures with thin cathode metals Al and Ag (Sun et al., 2005).

Metal oxide/Li-doped organic CGLs are simply p-n junctions that efficiently inject electrons and holes into the adjacent OLED elements. Fully organic doped p-n tunnel junctions (Fig. 6.115b) have also been found to be an effective CGL architecture. The first such example used an n-type layer consisting of 1.2 vol.% Li doped into electron conducting  $Alq_3$  or TPBI, combined with a p-type,  $\alpha$ -NPD layer doped with 1 vol.%  $FeCl_3$  in both fluorescent and phosphorescent stacked devices (Liao et al., 2004). The organic junctions were used in green monochrome  $Ir(ppy)_3$ -based SOLEDs, with results in Fig. 6.119. The

**Figure 6.119** Luminous efficiency vs. current for 1-, 2-, and 3-element green phosphorescent ( $Ir(ppy)_3$ -based) SOLEDs with fully organic CGLs (Liao et al., 2004).

structure of the 3-SOLED was ITO/SA/EML/CGL/EML/CGL/EML/SC/Mg:Ag, with the 2-SOLED and 1-SOLED (single element) structures eliminating one or two EML/CGL units, respectively. Here, the separate units are EML = 30 nm NPD/20 nm 5 vol.%  $Ir(ppy)_3$ :CBP/20 nm TPBI; an anode side optical spacer unit to control microcavity emission spectra of SA = 60 nm NPD, and a cathode side optical spacer of SC = 40 nm TPBI. Also, CGL =  $Alq_3$ :Li/NPD:FeCl<sub>3</sub>. The CGLs are nearly lossless, with luminous efficiencies of 43.5, 81.7, and 136.3 cd/A at  $j = 1$  mA/cm<sup>2</sup> for the 1-, 2-, and 3-unit devices respectively. This corresponds to efficiency ratios of 1.9 and 3.1 for the 2-SOLED and 3-SOLED compared to the single element device. The voltages also nearly exactly double, and increase by 150% for comparable, fluorescent 2- and 3-element devices compared to the conventional OLED.

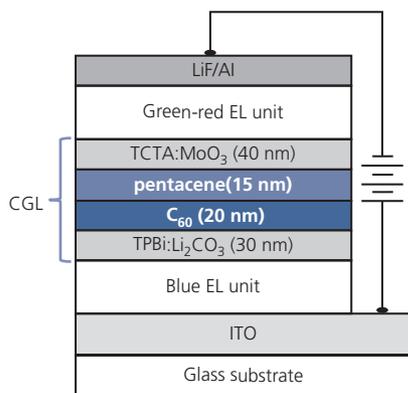

An organic that has similar frontier orbital energy alignments as  $MoO_3$  is HATCN, with a LUMO energy of  $-6.0$  eV (from the vacuum level) and a HOMO at  $-9.9$  eV (Kim et al., 2009). This can be used in an all-organic CGL with a multilayer structure of p-HTL/HATCN/n-ETL, which is analogous to charge injecting junctions using  $MoO_3$  (Liao et al., 2008, Lee et al., 2012).

A CGL that is a hybrid combination of organic and inorganic compounds has been demonstrated in tandem white phosphorescent SOLEDs comprising a combination of a blue element stacked with a red/green emitting element (see Fig. 6.120). The green-red section employed  $Ir(MDQ)_2(acac)$  and  $Ir(ppy)_2(acac)$  for red and green, and  $Flrpic$  for the blue emitting element. The CGL p-n junction comprised a p- $MoO_3$  doped TCTA layer, and an n- $Li_2CO_3$  doped TPBI layer. These were separated by an interfacial region

consisting of a type II pentacene donor/ $C_{60}$  acceptor HJ. The rationale for the interface zone is its ability to transfer charge across the donor/acceptor junction. This results in a reservoir of holes on the p-side and electrons on the n-side that greatly increase the conductivity, and the opportunity for charges to recombine within the CGL even at high current densities. A consequence is that there is very little dependence of quantum efficiency on luminance up to  $>5000$   $\text{cd}/\text{m}^2$  (Chen et al., 2011).

The effectiveness of the hybrid HJ was assessed by comparing the performance of the device in Fig. 6.124 with an identical two stage SOLED lacking the junction. The pentacene/ $C_{60}$  CGL device had a voltage of 6.0 and 6.9 V at 100 and 1000  $\text{cd}/\text{m}^2$ , respectively, which is significantly lower with 6.7 and 8.3 V for the device lacking the layer. This has a significant impact on the power efficiency of the devices. At 1000  $\text{cd}/\text{m}^2$ , the device with the hybrid interface junction had  $\eta_{ext} = 45\%$ ,  $\eta_P = 45$   $\text{lm}/\text{W}$  and CIE coordinates of (0.39, 0.44), corresponding to  $CCT \approx 4000$  K with  $CRI = 78$ . These metrics are only slightly degraded from their values at ten times lower luminance (Chen et al., 2011).

We previously noted that color tunability afforded by a device with individual contacts to each element in the stack can be used to change the CRI, CCT, and color coordinates of a light source simply by changing the current drive across each of the stacked elements. This has numerous advantages, in that room lighting often has different requirements for different occasions or times of day. For example, to complement the human circadian rhythm, the workplace can benefit from lighting fixtures with a higher red content (i.e. lower CCT) in the mornings and evenings, and a cooler, bluer hue during mid-day hours. Also, color-variable lighting can set a mood or highlight objects within a space. For all of these reasons, color

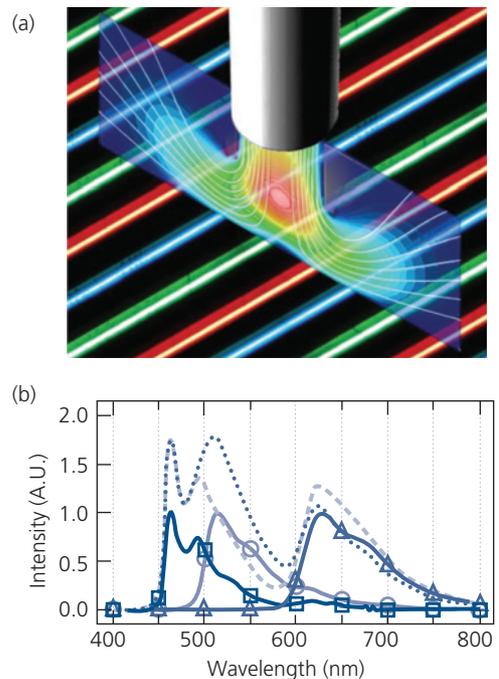

**Figure 6.120** A phosphorescent WOLED comprising a stack of green-red and blue emitting elements, along with a hybrid organic/inorganic compound CGL (Chen et al., 2011).

tunability afforded by OLED lighting makes it uniquely attractive to the consumer.

A difficulty in realizing color-tunable SOLEDs is fabricating and accessing low resistance contacts between the stacked elements. Illumination sources, however, are customarily viewed in the far field, obviating the need for the fabrication of small pixels that eases access to the interior contacts. Alternatively, the R, G, and B elements can be formed into long, laterally spaced stripes, as in Fig. 6.92f. This considerably eases both patterning and contacting of the individual color emission regions. Further, both stacked and striped PHOLEDs can achieve 100% internal efficiency in a white device, since the individual R, G, and B PHOLEDs can be separately optimized. While these approaches are more complex (and hence costlier) than two terminal WOLEDs, they provide the highest potential efficiency, and a wide range of color tunability.

A striped RGB WOLED has been fabricated by direct printing using organic vapor jet printing as described in Section 5.6.6 (Arnold et al., 2008). The device architecture and fabrication process are shown schematically in Fig. 6.121. Starting at the

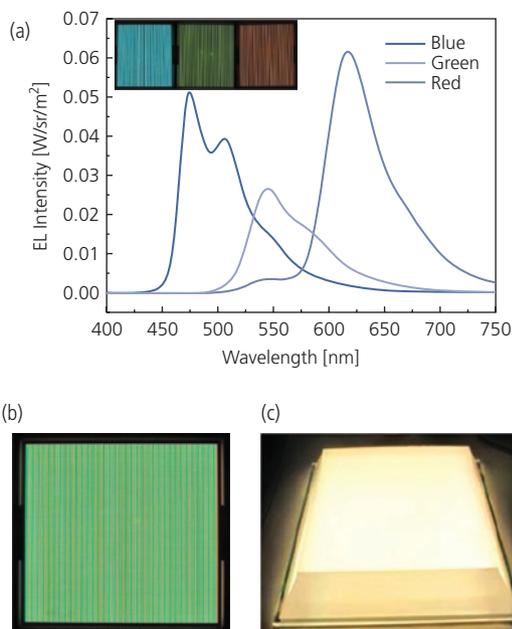

**Figure 6.121** (a) Conceptual view of direct printing of closely spaced R, G, and B PHOLED stripes by organic vapor jet printing to create a tunable color illumination source. The nozzle and its organic vapor flow field are shown above the stripes. (b) Spectra of the three PHOLEDs (solid lines), including two different white spectra obtained by differentially tuning the emission intensities from the PHOLEDs (Arnold et al., 2008).

ITO-coated glass substrate, the NPD HTL is blanket-deposited by vacuum thermal evaporation across the entire substrate. Then the separate EMLs are sequentially printed by volatilizing the dopants and hosts in a dilute, hot  $N_2$  gas stream and carried through a nozzle that directs the dopant/host mixture onto a substrate that is linearly translated at a rate ranging from 3 to 15 mm/s. The substrate is returned to the vacuum deposition chamber where the BPhen EBL,  $Alq_3$  ETL and LiF/Al cathodes are deposited through striped shadow masks to pattern the PHOLEDs. The R, G, and B EMLs consisted of the commercial, red emitting Ir-dopant RD-15, green emitting Ir(ppy) $_3$  doped in CBP, and blue emitting FIr6 doped into mCP within the OVJP print-head apparatus.

The emission spectra of the three parallel striped PHOLEDs are shown in Fig. 6.121b, along with white spectra with color coordinates of (0.33, 0.33) (dashed line) and (0.40, 0.31) (dotted line) accessed by differentially tuning the current of the individual stripes. The source appears as a single hue (including white) in the far field, or in the near field by placing the stripes behind a ground glass light diffuser. For the devices shown, the peak efficiency of the source at coordinates of (0.40, 0.31) was  $\eta_{ext} = 12.1\%$ ,  $\eta_P = 11.9$

**Figure 6.122** (a) Emission of the separate R, G, and B striped PHOLEDs of the 15 cm  $\times$  15 cm panel shown in the inset, with each of the individual striped PHOLEDs turned on independently. (b) All green pixels turned on simultaneously. (c) The lighting panel using a thick light extraction block plus color diffuser to give a uniform white appearance (Weaver et al., 2014).

lm/W. These values are comparable to those obtained using analogous vacuum-deposited PHOLED stripes (Arnold et al., 2008).

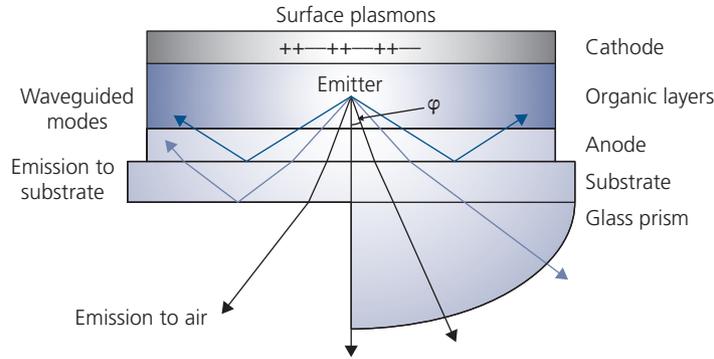

A similar striped device was fabricated using high efficiency phosphorescent dopants deposited entirely by VTE. The 15 cm  $\times$  15 cm panel in Fig. 6.122a employed a thick, light-extracting block and diffuser. Figure 6.122b shows only the green stripes turned on. Without the light extraction block, the striped WOLED had  $\eta_P = 41$  lm/W at 1000 cd/m $^2$ , with color coordinates of (0.476, 0.433), CRI = 90, and CCT = 2700 K. The light extraction block in Fig. 6.122c increased the output efficiency by a factor of 1.53, leading to an efficacy of 63 lm/W at 1000 cd/m $^2$ , with drive voltages of 3.0 V, 2.7 V, and 4.2 V for the R, G, and B stripes, respectively (Weaver et al., 2014). These results suggest that striped PHOLED designs are suited for producing both highly efficient and attractive color tunable lighting sources.

## 6.6 Light outcoupling

In the foregoing sections, we have seen that the internal efficiency of PHOLEDs can be as high as 100%. However, the external efficiency on flat glass substrates is limited to approximately 20% due to TIR. The fraction of light emitted from the dielectric substrate surface from a Lambertian source is  $\sim 1/2n^2 \approx 0.2$ , where  $n = 1.5$  is the refractive index of glass (Greenham et al., 1994). Hence, there is considerable benefit to be gained if the light trapped within the OLED is extracted. There are four primary sources of loss illustrated in Fig. 6.123 that decrease  $\eta_{out}$  in Eq. 6.1: (i) *substrate modes*, due to light trapped in the substrate from TIR at the substrate/air interface, (ii) *waveguide modes* due to launching of light parallel to the substrate plane within the relatively high index of refraction layers comprising the device and the transparent anode, (iii) *surface plasmon polariton modes* (SPP) excited in the conductive contacts, and (iv) *lossy modes* due to material and contact absorption.

In this section, we discuss strategies to extract light from each of these loss channels. We will find that extracting substrate modes is the easiest, and can lead to a 100% increase in the outcoupled light intensity, followed by waveguide modes, and the most difficult to outcouple, surface plasmon modes. If outcoupled,  $\eta_{out}$  between 70–80% can be achieved which, combined with their potential  $\eta_{int} = 100\%$ , can make OLEDs the most efficient illumination sources available.

There are numerous solutions to outcoupling the trapped modes from OLEDs. We point out, however, that all *practical* solutions (i.e. those that are

**Figure 6.123** Optical paths launched by an emitting molecule within an OLED. Shown on the right bottom of the substrate is a glass lens or prism used to outcouple substrate modes that would otherwise be totally internally reflected (Brütting et al., 2013).

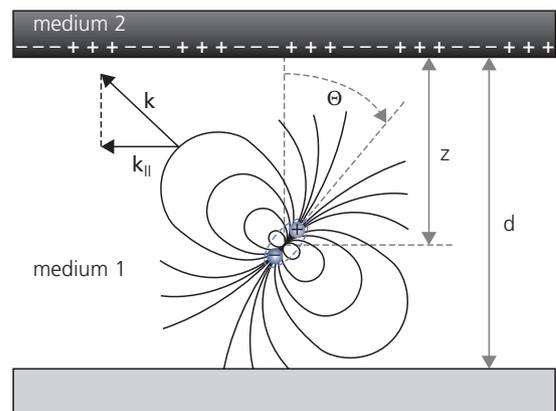

acceptable for incorporation in large area devices such as displays or lighting) should have the following properties:

- (i) The wavelength and intensity of the OLED should not be affected by the outcoupling scheme, and in particular, should not be a function of viewing angle.
- (ii) The solution should be minimally invasive of the OLED structure itself. That is, the ideal outcoupling scheme should not require changes to the OLED which is assumed to have been separately optimized to achieve maximum internal and luminous efficiencies, with the desired color coordinates and brightness. Placing additional constraints on the OLED design by an outcoupling scheme can possibly result in a decrease in performance.
- (iii) The solution should be inexpensive, allowing for minimal cost impact when used over the large areas required by both displays and lighting applications.

### 6.6.1 Theory of outcoupling

In its simplest terms, we view an OLED as an optical cavity comprising a dielectric in which there is an emitting molecule (medium 1) bounded on one surface by a reflective, metal contact (medium 2). Of course, the OLED is considerably more complicated than this simple two layer picture, but the bilayer embodies the essential physics needed to calculate the output spectrum and angular power distribution. Including the additional layers that more accurately represent an OLED is a simple matter that will be described later.

In Fig. 6.128 we show a radiating dipole (i.e. the emitter molecule) at angle  $\Theta$  and position  $z$  in an

**Figure 6.124** Illustration of a radiating molecular dipole at angle  $\Theta$  in the optical cavity of thickness  $d$  formed by an OLED. The direction of propagation is  $\mathbf{k}$ , with in-plane component  $k_{||}$ . A mirror forms the top cavity surface and a semi-reflecting layer forms the bottom surface (Brütting et al., 2013).

optical microcavity of thickness  $d$  formed by the OLED. The dipole radiation field results in propagation whose directions are defined by the vector  $\mathbf{k}$ , with component  $k_{||}$  along the substrate plane, and  $k_{\perp}$  perpendicular to the plane. When the dipole oscillates near an interface between two materials, it transfers energy to that interface (i.e. it excites a plasmon), resulting in a reflected electric field, modifying both the dipole frequency and lifetime. The interaction of the dipole and its field within a cavity is known as the Purcell effect. The reflected electric field,  $\mathbf{F}_R$ , is strongest near a highly reflective medium (i.e. at the interface with a metal mirror versus at a dielectric discontinuity). The field modifies the OLED emission. There are two related situations to consider: one in which the interface is weakly reflecting in an OLED with two transparent contacts, and the second more common scenario where one surface is a reflective metal cathode or anode contact.

Following the procedure of *Chance, Prock, and Silbey* (CPS), the equation of motion for a dipole of moment,  $\mathbf{p}$ , oscillating at natural frequency,  $\omega$ , in a microcavity is given by (Chance et al., 1974, 1978)

$$\frac{d^2\mathbf{p}}{dt^2} + \omega^2\mathbf{p} = \frac{q^2}{m^*}\mathbf{F}_R - \frac{1}{\tau_0}\frac{d\mathbf{p}}{dt}, \quad (6.97)$$

where  $m^*$  is the effective mass of the dipole and  $\tau_0$  is the natural damping (i.e. radiative) time of the oscillation in the absence of the mirror. Now both the dipole and the field oscillate at the same frequency, and have the same vector dependence since one is the image of the other. Equation 6.97 has the following solutions:

$$\mathbf{p} = \mathbf{p}_0 \exp(-i(\omega + \Delta\omega)t - t/2\tau) \quad (6.98a)$$

and

$$\mathbf{F}_R = \mathbf{F}_0 \exp(-i(\omega + \Delta\omega)t - t/2\tau), \quad (6.98b)$$

where  $\Delta\omega$  is the frequency shift and  $\tau$  is the lifetime in the presence of the mirror. In the limit of  $\Delta\omega \rightarrow 0$ , which is characteristic of weak microcavities, then substituting Eq. 6.98 into Eq. 6.97 gives

$$\frac{1}{\tau} = \frac{1}{\tau_0} + \left[ \frac{q^2}{2p_0 m^* \omega} \right] \text{Im}(F_0) \quad (6.99a)$$

and, likewise, to first order, the frequency is shifted by

$$\Delta\omega \approx \frac{1}{8\omega\tau^2} - \frac{1}{4\omega_0\tau_0\tau} - \frac{q^2}{2m^*\omega_0 p_0} \text{Re}(F_0). \quad (6.99b)$$

Generally, the frequency shift is sufficiently small that it is ignored in treatments of the weak microcavity effects typically encountered in OLEDs. From these two expressions, we see that the radiative rate is related to the out-of-phase electric field, and the frequency shift to the in-phase components of the reflected field.

The total field within medium 1 is the superposition of the dipole field and that reflected from the mirror. The field is calculated by considering a dipole in a homogeneous dielectric medium with permittivity,  $\epsilon_0\epsilon_r$ . Then the *Hertzian vector* is given by

$$\mathbf{\Pi} = \frac{\mathbf{p}_0 \exp(ik_1 r)}{4\pi\epsilon_0\epsilon_r r}, \quad (6.100)$$

where  $r$  is the distance from the dipole to the point of observation, and  $k_1$  is the component of the wavevector parallel to  $\hat{\mathbf{r}}$  in medium 1. Then, the electric field is given by

$$\mathbf{F} = k_1^2 \mathbf{\Pi} + \nabla \nabla \cdot \mathbf{\Pi} \quad (6.101)$$

and the magnetic field by

$$\mathbf{H} = -i\omega \nabla \times \mathbf{\Pi}. \quad (6.102)$$

Since the dipole field is cylindrically symmetric (see Fig. 6.124), we can solve this in terms of Bessel functions of the zeroth order,  $J_0$ . Then the expression for the Hertzian vector is (Wasey and Barnes, 2000)

$$\mathbf{\Pi} = \frac{i\mathbf{p}_0}{4\pi\epsilon_0\epsilon_r} \int_0^\infty \frac{u}{l} J_0(u\rho) \exp(il|z|) du, \quad (6.103)$$

where the integral is over the variable,  $u = k_{\parallel}/k_1$ ,  $k_{\parallel}$  is the in-plane wavevector, and  $l = (k_1^2 - u^2)^{1/2}$  is the wavevector for propagation perpendicular (i.e. in the  $\hat{\mathbf{z}}$ -direction) to the plane of the cavity ( $k_z$ ). For this expression, we use the cylindrical coordinate system,  $(\rho, \phi, z)$ . Over the domain,  $0 \leq u \leq 1$ , energy is radiated into the half-space below the mirror. In a multilayer system, waveguide modes can also be excited for particular angles of emission. At  $u > 1$ , non-radiative, evanescent SPP modes are excited, and when  $u$  becomes large at small separations between the dipole and medium 2, lossy non-radiative surface waves are generated.

With the modified emission rate, we can proceed with our determination of the reflected field. An isotropically oriented dipole (which is not always the case for emitting molecules in OLEDs, see Section 6.6.5) can have its components decomposed into directions parallel ( $\parallel$ ) and ( $\perp$ ) perpendicular to the plane, yielding

$$\frac{1}{\tau_{\parallel,\perp}} = \frac{1}{\tau_0} (1 - \eta_{int}^0 z_{\parallel,\perp}^0), \quad (6.104)$$

where  $\eta_{int}^0$  is the internal quantum yield of the dipole in medium 1 without the metal mirror. The parameters  $z_{\parallel,\perp}$  are given by (Barnes, 1998)

$$z_{\perp} = 1 - \frac{3}{2} \text{Im} \int_0^\infty \frac{u^3}{l_1} (1 - r_{1,2}^p) \exp(-i\beta) du \quad (6.105a)$$

and

$$z_{\parallel} = 1 - \frac{3}{4} \text{Im} \int_0^\infty \frac{u}{l_1} \left[ (1 + r_{1,2}^s) - (1 - u^2)(1 + r_{1,2}^p) \right] \times \exp(-i\beta) du, \quad (6.105b)$$

where  $r_{1,2}^{s,p}$  are the Fresnel reflection coefficients for  $s$ - and  $p$ -polarized light at the interface between media 1 and 2,  $l_1$  is the value of  $l$  in medium 1, and  $\beta$  is the phase difference between the emitted and reflected plane waves. This treatment can be extended to consider multiple layers based on transfer-matrix or

dyadic Green's function formalisms to account for the reflection at each interface, or depending on the value of  $u$ , excitation of guided modes within a particular medium (Chance et al., 1978, Celebi et al., 2007, Setz et al., 2011).

Equation 6.104 gives the decay rate due to a dipole oriented either parallel or perpendicular to the mirror. For an isotropic dipole orientation, the total observed damping rate is simply

$$\frac{1}{\tau} = \frac{2}{3\tau_{\parallel}} + \frac{1}{3\tau_{\perp}}, \quad (6.106)$$

where there are two possible in-plane ( $x, y$ ), and one out-of-plane ( $z$ ) orientation.

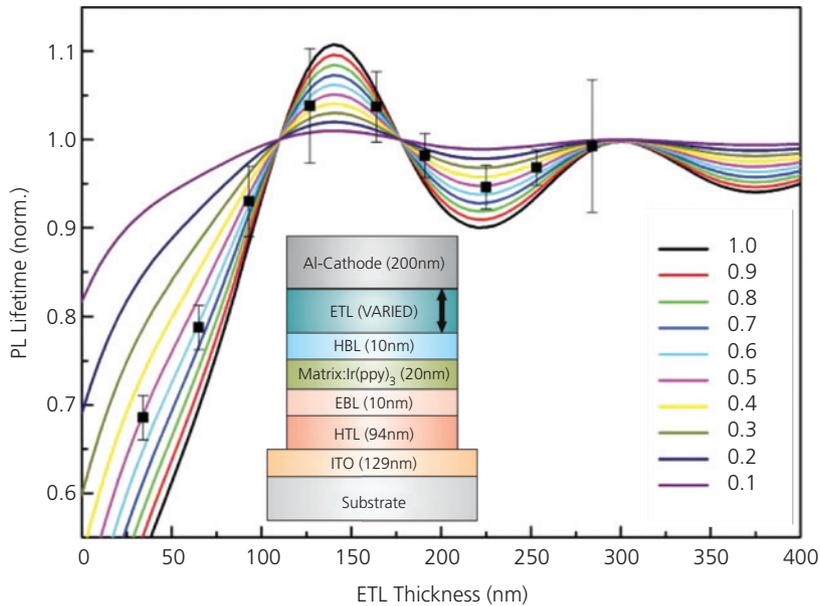

The modification of the emission rate with distance can be dramatic, as shown by the data points for the normalized PL lifetime for Ir(ppy)<sub>3</sub> emission in the PHOLED in Fig. 6.125 (Setz et al., 2011). Depending on the distance as determined by a dielectric spacer to the contact (in this case the ETL), the radiative lifetime is considerably shorter for dipoles near the mirror surface, to  $\tau > \tau_0$  at  $\sim 150$  nm distant from the mirror. For this device, the minimum distance from the emitting molecule to the cathode is 10 nm, determined by the hole blocking layer thickness. However, as the dipole distance is decreased, then  $\tau \rightarrow 0$  (Amos and Barnes, 1997). The oscillations, which arise from the phase differences between the superposed dipole and reflected fields, are damped as the distance from the

dipole to the mirror increases. The peaks occur at field maxima, that is, where the reflected and the emitted fields are in phase. The damping results since the reflected field intensity also decreases with distance. At very small dipole-to-mirror distances, however, the lifetime vanishes due to efficient excitation of SPPs in the metal. The solid lines in Fig. 6.125 are fits to the data based on CPS theory. Each line corresponds to a different emitter efficiency,  $\eta_{int}^0$ . As the emitting molecule becomes increasingly efficient, the oscillations are stronger due to the increased interference from the superimposed reflected field. The best fit to the data corresponds to  $\eta_{int}^0 = 0.5$ , where the CPS theory accurately approximates the observed optical emission.

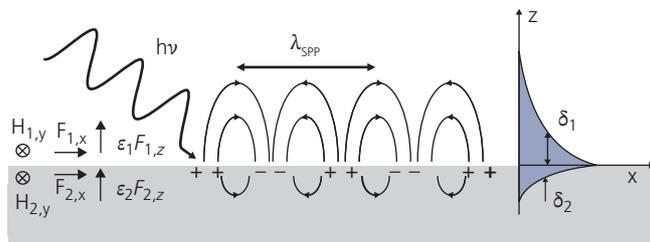

An SPP mode is schematically illustrated in Fig. 6.126. Light incident on the metal couples to the charge at its surface, inducing a charge density wave that is trapped at the metal/dielectric interface. The resulting  $p$ -polarized mode has wavelength,  $\lambda_{SPP}$ . The dispersion relationship of these modes is

$$k_{SPP}/k_0 = \sqrt{\frac{\epsilon_1(\omega)\epsilon_2(\omega)}{\epsilon_1(\omega) + \epsilon_2(\omega)}}, \quad (6.107)$$

where  $\epsilon_{1,2}(\omega)$  is the complex relative dielectric constant of medium 1, 2 at frequency  $\omega = k_{\parallel}/c$ . The field from the SPP evanescently penetrates a short distance,  $\delta_2$ , into the metal mirror. Resistance in the metal leads

**Figure 6.125** Oscillations in the lifetime of Ir(ppy)<sub>3</sub> emission calculated (lines) as a function of spacer (i.e. ETL) thickness between the emission layer and the Al cathode for the device structure shown in the inset. Measurements shown by squares. Each curve corresponds to a different internal efficiency,  $\eta_{int}^0$ , for Ir(ppy)<sub>3</sub> emission. The best fit to the optical model corresponds to  $\eta_{int}^0 = 0.5$ . After Setz et al. (2011) and Brütting et al. (2013).

**Figure 6.126** Schematic illustration of a surface plasmon polariton excited by dipole emission at energy  $h\nu$ . The SPP wavelength is  $\lambda_{SPP}$ , and its penetration depth is  $\delta_2$  into the metal mirror (medium 2) and  $\delta_1$  into the dielectric (medium 1). The permittivities of the two materials are shown, with  $\epsilon_1 = \epsilon_0\epsilon_{r1}$ , for example.

to losses. As the distance from the radiative dipole to the metal decreases, the coupling increases, resulting in a significantly increased loss, as observed in Fig. 6.125. However, the field can penetrate into the metal layer if its thickness is  $d \ll \delta_2$ , and hence can be extracted from the opposite (unilluminated) metal surface.

With the solutions for the electric field in Eqs. 6.100–6.103, the Poynting vector,  $\mathbf{S} = \mathbf{F} \times \mathbf{H}$  yields the energy flux, from which we obtain the total (integrated) power emitted by the dipole at wavelength  $\lambda$ , viz.

$$P_{tot}(\lambda) = \frac{\tau_0}{\tau} = [1 - \eta_{int}^0(\lambda)] + \eta_{int}^0(\lambda) \int_0^{\infty} P(k_{||}, \lambda, z) dk_{||}. \quad (6.108)$$

The first term in Eq. 6.108 is for transverse magnetic (TM, i.e.  $p$ -polarized) radiation emitted by dipoles oriented parallel to the substrate plane, and the second term includes both TM and transverse electric (TE, i.e.  $s$ -polarized) radiation emitted by perpendicular dipoles.

Thus, the power is equal the ratio of the rates for emission with and without the mirror. The rate within the cavity is  $1/\tau = 1/\tau'_r + 1/\tau_{nr}$ , where  $\tau'_r$  is the modified lifetime in the absence of non-radiative relaxation at rate  $\tau_{nr}$ , and  $1/\tau_0 = 1/\tau_r + 1/\tau_{nr}$  is the analogous expression in the absence of the mirror.

If the emission spectrum of the dipoles is  $S(\lambda)$ , the total emitted power is found by integrating over  $\lambda$ :

$$P_{tot} = 1 + \eta_{int}^0 \left\{ \int_0^{\infty} \int_0^{\infty} S(\lambda) P(k_{||}, \lambda, z) dk_{||} d\lambda - 1 \right\}. \quad (6.109)$$

More simply, the integral is the Purcell factor,  $PF$ , giving

$$P_{tot} = 1 + \eta_{int}^0 (PF - 1). \quad (6.110)$$

This modifies the cavity lifetime:  $1/\tau' = PF/\tau_r$ , that is, the Purcell factor is the ratio of the radiative rate in a

cavity to the natural lifetime of the emitter. Since the efficiency is given by  $\eta_{int}^0 = \tau_{nr}/(\tau_r + \tau_{nr})$  with a similar expression for  $\eta_{int}$ , then Eqs. 6.108–6.110 yield the quantum efficiency of the dipole in the cavity:

$$\frac{\eta_{int}}{\eta_{int}^0} = F \frac{\tau}{\tau_0} = \frac{PF}{1 + \eta_{int}^0 (PF - 1)}. \quad (6.111)$$

In analyzing the OLED spectrum, it is useful to decompose the power dissipated into its various modes, as well as the total output power as determined using Eq. 6.108. This can be accomplished by calculating the fraction of optical power emitted into each channel (i.e. the various waveguide and substrate modes) bounded by the allowed wavevectors,  $k_1$  and  $k_2$ :

$$P_{mod} = \eta_{int}^0 \int_0^2 \int_{k_1}^{\infty} S(\lambda) P(k_{||}, \lambda, z) dk_{||} d\lambda. \quad (6.112)$$

Then it is straightforward to determine the total external quantum efficiency from the microcavity via

$$\eta_{ext} = \eta_{int} \eta_{out} = \frac{P_{air}}{P_{tot}}, \quad (6.113)$$

where  $P_{air}$  corresponds to modes that escape the cavity within the domain  $0 \leq k_{||} \leq k_0$ , where  $k_0$  is the wavevector in free space.

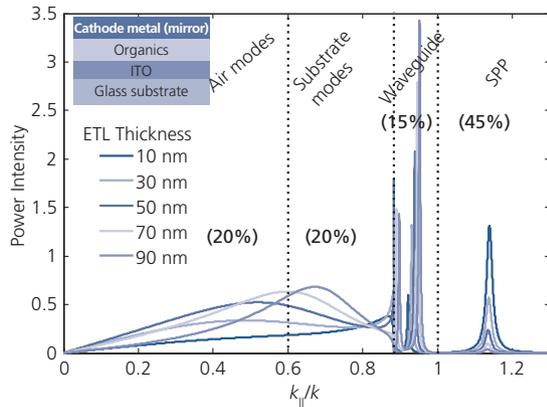

The results of a calculation of the emitted power intensity vs.  $k_{||}/k$  as a function of ETL thickness (and hence the distance from the emitting molecules from the reflective metal cathode) for an OLED using this formalism is shown in Fig. 6.127 (Chance et al., 1978, Neyts, 1998, Celebi et al., 2007). The in-plane wavevector provides the power coupled separately into SPP, waveguide, substrate, and air (radiative) modes. Note that the actual power radiated into air modes is reduced by Fresnel reflections for  $s$ -polarized waves at the substrate (glass, with index  $n_s = 1.5$ )/air interface, given by

$$r_{sa}^s = \frac{n_s \cos \theta_s - n_a \cos \theta_a}{n_s \cos \theta_s + n_a \cos \theta_a}, \quad (6.114)$$

where the subscripts  $s$  and  $a$  refer to the substrate and air, respectively, with  $n_a = 1$ . For  $p$ -polarization:

$$r_{sa}^p = \frac{n_a \cos \theta_s - n_s \cos \theta_a}{n_a \cos \theta_s + n_s \cos \theta_a}. \quad (6.115)$$

The reflectivity of the substrate is  $R_{sa}^{s,p} = |r_{sa}^{s,p}|^2$ .

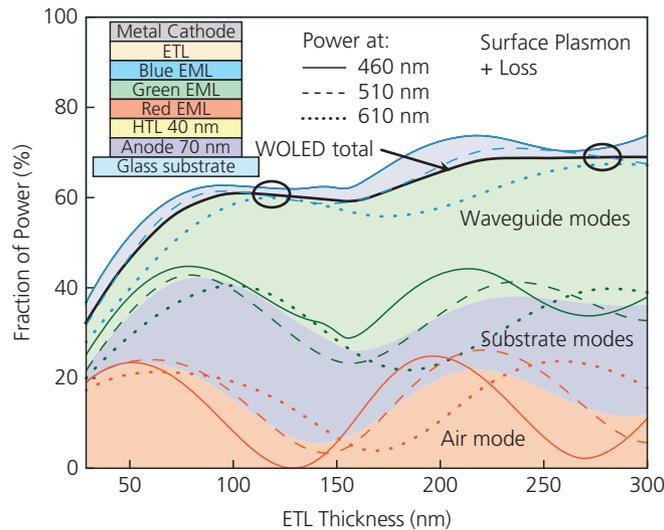

**Figure 6.127** Calculated power at  $\lambda = 510$  nm vs. in-plane wavevector for the structure shown in the inset. The refractive index of the organic layers is  $n = 1.7$ , ITO  $n = 1.85$ , and for the Al cathode, the complex index is  $\tilde{n} = 0.9 + i6.9$ . The detailed structure is glass substrate/ITO 70 nm/HTL 40 nm, EML 15 nm, and the ETL thickness is varied to space the dipole at different distances from the cathode. All emitting molecules are assumed to be at the EML/HTL interface.

As the spacer layer (i.e. the ETL) thickness between the emitter and the cathode increases, coupling to non-radiative SPP modes decreases. A much weaker modal dependence can also be found by varying the HTL and ITO anode thicknesses, although this does not significantly affect the excitation efficiency of SPPs. The waveguide, comprising the organic OLED stack and the ITO, supports at least two (TM, TE) modes. The number of modes depends on the total thickness of the organic layers, where more waveguide modes are expected in thick, stacked WOLEDs, for example.

The area under the various peaks is the integrated power within that particular mode. The broad SPP modes represents up to 45% of the power, whereas the very narrow waveguide modes trap only 15% of the power, with an additional 20% trapped within the substrate. As we show below, propagation in the substrate and waveguide modes is not lossy, and hence can be outcoupled if the in-plane propagating wave can be directed into out-of-plane radiative modes.

The calculated integrated powers of several WOLED optical modes as a function of ETL thickness ( $d_{ETL}$ ) are decomposed in Fig. 6.128. The EML is separated into three, stacked R, G, and B emitting zones. The lines show the total emission from each zone, and the color bands show their average. We find that the air modes are approximately equal at 20% of the emission at the first and second cavity maxima at  $d_{ETL} = 60$  nm and 220 nm. The substrate and waveguide mode

**Figure 6.128** Power dissipation vs. ETL thickness for the WOLED structure in the inset. The lines explicitly show the power for three different wavelengths corresponding to the peaks in the blue, green and red spectra of the phosphor dopants, Flrpic, Irppy<sub>3</sub> and PQIr, respectively. The bands give the total output power that is the average of the combined WOLED spectrum in the ratio of B:G:R of 0.45:0.63:1 to yield  $CRI = 0.91$ . The black line is the total power coupled into the three lossless propagating modes. Optical constants for each layer are as in Fig. 6.127. The emitter molecules are placed in the center of each EML whose thicknesses are 10 nm. The ellipses note the ETL thicknesses where the intensities of all three wavelengths are equal, providing an undistorted white color.

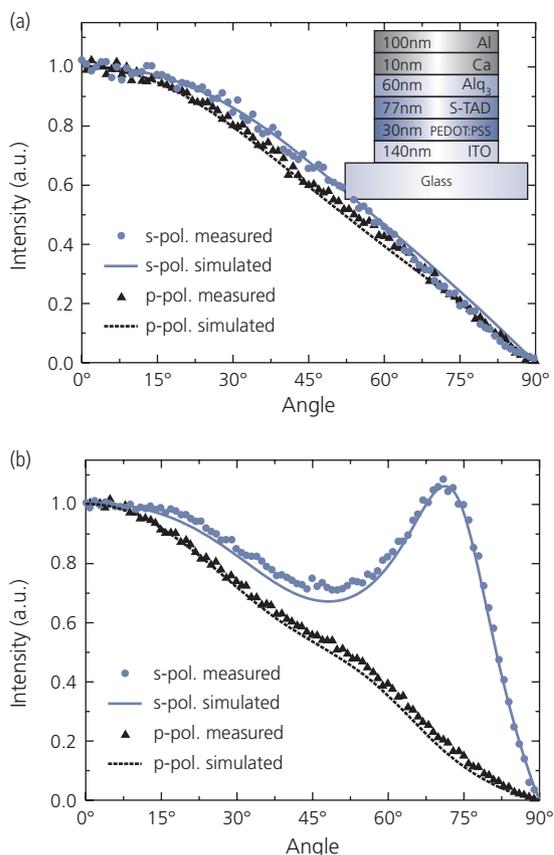

contributions are small when  $d_{ETL} \rightarrow 0$ , since a large fraction of the light is coupled into a combination of SPP and lossy metal modes as the dipoles approach the cathode. These losses are smallest for the blue emitters located at the largest optical distance (defined by the wavelength,  $\lambda_0/n$ ) from the mirror. As  $d_{ETL}$  increases, the waveguide (comprising the ITO, ETL, and the EMLs) can support a larger number of modes. Without outcoupling, an increasing amount of power, therefore, is trapped in the waveguide, as indicated by its increase at the expense of the other contributions. Finally, as the ETL thickness increases, coupling to SPPs and lossy metal modes decreases as predicted by CPS theory. In all cases the metal cathode contributes the largest loss, which is never less than 30% of the total, even at very large  $d_{ETL}$ . Also, such a large  $d_{ETL}$  may be impractical due to the series resistance that thick layers contribute, reducing the luminous power efficiency more rapidly than can be compensated by the increased external quantum efficiency.

Interestingly, there are at least two values of  $d_{ETL}$  where the total power from the three non-lossy modes is equal across the visible spectrum. These points at 120 nm and 275 nm are indicated by ellipses in Fig. 6.128. At these “isoenergetic” points, the emitted color is the same as that of the dipoles in a completely non-lossy, dielectric medium. It is at these thicknesses that the WOLED has a  $CRI = 0.91$  with an emission that is native to the molecules themselves. Interestingly, good color balance occurs at points where the air mode is near its minimum. By moving away from the isoenergetic points, the ratio of R to G to B is changed, thereby changing the WOLED  $CRI$ , CIE coordinates, and  $CCT$ .

The air and substrate optical modes can be conveniently measured using a cylindrical lens attached to the substrate, as on the right in Fig. 6.123 (Frischeisen et al., 2010). A detector in the far field is rotated through angles from 0 to 90°, measuring the emission intensity and its polarization at each angle. The ratio of light emitted by the vertical to horizontal dipoles is then obtained from the polarization of the emitted radiation following:

$$\Theta = \frac{TM_{\parallel}}{TE_{\perp} + TM_{\perp} + TM_{\parallel}}, \quad (6.116)$$

leading to  $\Theta = 0.33$  for random alignment and  $\Theta = 0$  for all molecular TDMs oriented parallel to the substrate plane (i.e. dipole emission is in the perpendicular direction, cf. Eq. 6.105) (Schmidt et al., 2011). The emission from horizontally aligned TDMs relative to the substrate plane is thus decomposed into transverse electric ( $TE_{\perp}$ ) and magnetic ( $TM_{\perp}$ ) modes

**Figure 6.129** *s*- and *p*-polarized emission from the device in the inset (a) without and (b) with a cylindrical lens used for extracting substrate modes, as illustrated in Fig. 6.123. Data are represented by points, theory by lines (Brütting et al., 2013).

using a polarization filter, whereas the vertically aligned TDM emits into the ( $TM_{\parallel}$ ) mode.

A fit of the foregoing optical analysis to the angular emission intensity is shown in Fig. 6.129a for the OLED in the inset. The emission profile obtained using a cylindrical lens attached to the glass substrate is shown in 6.129b. The optical model accurately replicates the observed emission pattern. In this case the orientation of the  $Alq_3$  dipoles is isotropic, although we will see below that this is not the case for many molecular species. Note that the *s*-polarized emission is due to  $TE_{\perp}$ , whereas *p*-polarization collects both  $TM_{\parallel}$  and  $TM_{\perp}$  emission.

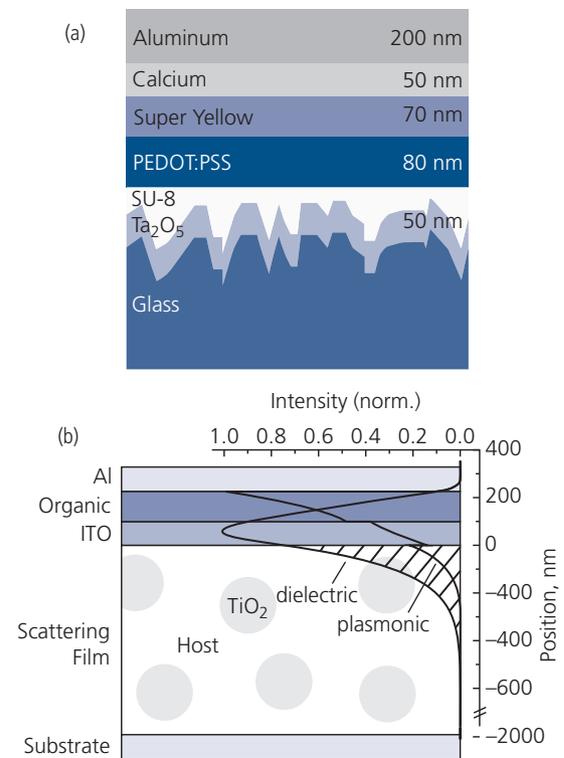

Now that we have developed an accurate and predictive optical model based on microcavity effects in OLEDs, we are prepared to discuss strategies used in efficiently outcoupling light from substrate and waveguide modes, as well as means for minimizing or even eliminating coupling to lossy metal contact modes. In keeping with our guiding principles for effective and practical outcoupling schemes, we will limit the following discussion to

those techniques that are (i) easily and cost-effectively applied over large areas, (ii) are largely wavelength- and angle-independent, and (iii) minimally intrude into the OLED structure itself. The principal methods are roughly categorized into those that outcouple substrate, waveguide and SPP modes, although several methods can extract more than a single type of emission. The following sections are divided by the primary extraction mechanism of a given approach.

### 6.6.2 Substrate mode outcoupling

Efficient substrate light outcoupling methods seek to reduce TIR at the substrate-air interface. These modes account for 20% of the power trapped in the substrate of bottom emitting devices such as in Figs. 6.127 and 6.128. One simple extraction method is to roughen the emitting surface to create a region whose index is intermediate between the substrate (typically glass or plastic) and air. Roughening on a scale of the emitting wavelength provides an anti-reflection coating as well as a layer that isotropically scatters internal reflections, thereby giving reflections from the metal cathode additional opportunities to be incident at this interface within the TIR cone. This angle is defined by Snell's law as  $\sin\theta_{TIR} = 1/n_s$  where  $\theta_{TIR}$  is the half angle for TIR. Reflections from the cathode result in  $\sim 5\text{--}10\%$  loss on each bounce. If the textured surface is far from the emission zone (due to an optically thick substrate), it creates a diffuse image of a pixel, although this would not necessarily be a disadvantage to a white illumination fixture. Roughening results in  $\sim 20\%$  increase in external efficiency (Zhou et al., 2011), representing only a small fraction of the total power in the substrate modes.

The scattering layer can be placed immediately beneath the transparent anode with significantly improved outcoupling compared with substrate back surface roughening. Methods of surface roughening include creating voids beneath the transparent anode (Fig. 6.130a) or embedding high refractive index scattering inhomogeneities in a low index matrix, also beneath the anode (Fig. 6.130b). The rough surface does not support waveguiding, and hence scatters light into the substrate. The texture in Fig. 6.130a can be produced by sandblasting, etching or grinding. The uneven surface shown is coated with a 50 nm thick layer of high index ( $n = 2.1$ )  $\text{Ta}_2\text{O}_5$  that spreads the guided modes into the roughened regions. The surface is subsequently planarized with a 200 nm thick layer of the low index polymer to prevent the surface irregularities from penetrating into the OLED active region. It is likely that internally reflected emission also scatters

**Figure 6.130** (a) Random roughness of a high index scattering layer below a transparent anode (Riedel et al., 2010). (b) Embedded high index  $\text{TiO}_2$  nanoparticle scattering layer in the same location. The lines represent dielectric and plasmonic mode intensity distributions (Chang et al., 2013a)

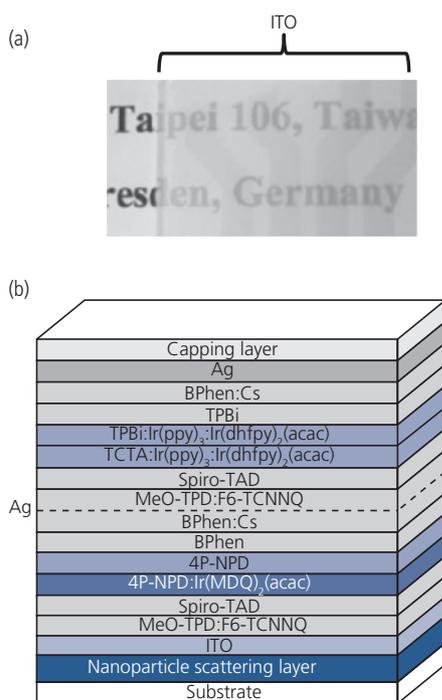

off of these features, whose scale is on the order of the wavelength of light (e.g. sandblasting results in a root mean square (rms) roughness of 200 nm, and a peak-to-valley height of 900 nm; Riedel et al., 2010), giving the trapped radiation multiple opportunities to couple into air modes. The best improvement of outcoupling of  $< 40\%$  was achieved using sandblasting. This falls short of extracting all of the substrate modes, which would approximately double the light output (see Fig. 6.128).

Significant improvements in outcoupling are achieved dispersions of  $\text{TiO}_2$  ( $n = 2.2$ ) nanoparticles (with mean diameters of 240 nm) in a low index ( $n = 1.5$ ) polymer positioned immediately below the transparent anode, as shown in Fig. 6.130b (Chang et al., 2013a). This dispersion has an effective index that approaches the weighted average of the volume concentrations of the spheres and matrix. As in the case of the roughened surfaces, the nanoparticle scattering layer (NPSL) primarily re-scatters internally reflected light, while also redirecting substrate modes to  $\theta < \theta_{TIR}$ . The power distribution of these two modes is shown in Fig. 6.130b.

The NPSL results in haze and image blurring (see Fig. 6.131a), making this suitable for lighting but not

for displays. The layer has been used for increasing outcoupling of a three-color stacked WOLED structure in Fig. 6.131b. This is a semitransparent device since the cathode comprises only 20 nm thick Ag layer capped with 50 nm thick layer of Spiro-TAD that acts as an anti-reflection coating. The total external efficiency is measured by capturing light from both top and bottom surfaces which is in the ratio:  $L_{\text{bottom}}/L_{\text{top}} = 1.5:1$ . Devices without the NPSL have  $L_{\text{bottom}}/L_{\text{top}} = 1.9:1$ . The WOLED efficiency was improved from 22% (32 lm/W) for the control, to 33% (46 lm/W) for the WOLED with the NPSL. This suggests that scattering results in a 50% increase in substrate mode outcoupling. By applying a hemispherical substrate outcoupling lens, the efficiency is increased further to 46% (62 lm/W). This indicates incomplete scattering of waveguided light into the substrate by the high index NPSL.

Scattering can also be enhanced by creating low index voids in a film that is attached onto the bottom (emitting) surface of the substrate (Koh et al., 2015). To create the voids, a high index ( $n > 1.7$ ) polyimide layer is immersed in an *antisolvent* that is miscible in the solvent used to cast the polymer, producing a porous

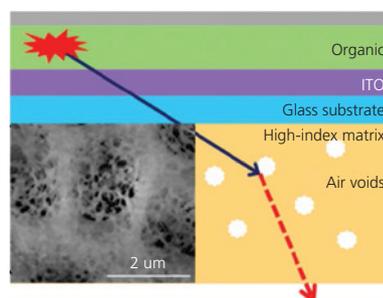

**Figure 6.131** (a) Translucent nanoparticle scattering layer on a glass substrate. The film scatters light from the printed sheet, leading to some image blurring. (b) Transparent stacked WOLED with a NPSL used to increase light outcoupling. The phosphors used for light emission are red =  $\text{Ir}(\text{MDQ})_2(\text{acac})$ , green = blends of  $\text{Ir}(\text{ppy})_3$  and  $\text{Ir}(\text{dhfp})_2(\text{acac})$ , and blue emission uses the fluorophore 4P-NPD (Chang et al., 2013a).

structure that scatters the substrate modes as shown in Fig. 6.132. The  $\sim 2\ \mu\text{m}$  thick film contains a high density of cavities a few microns in diameter. The films are slightly hazy, similar to the high index sub-anode film of Fig. 6.131. This scheme increases outcoupling by nearly 80%, which corresponds to nearly half of the trapped emission compared to a similar device on a flat glass substrate. Furthermore, the emission is nearly perfectly Lambertian.

We have seen that the light trapped in substrate modes is almost entirely extracted using a large spherical or cylindrical lens (Madigan et al., 2000). The diameter of the lens, however, must be even larger than the OLED itself, which adds considerable thickness to a device. For displays, substrate thicknesses of only 0.3–0.5 mm are desirable, thus severely limiting the utility of this approach. Furthermore, the single lens must be centered over the emitting area, extending  $30\text{--}45^\circ$  beyond the edge of the pixel to fully capture all of the light. This solution can be simplified for lighting by replacing the lens with a large trapezoidal outcoupling block (D'Andrade and Brown, 2006, Horst, 2007), or with trapezoids whose minor surface is equal to the pixel size itself (Gu et al., 1997b). However, none of these methods are practical given their complexity (and hence high cost), bulkiness or weight.

Micro lens arrays (MLAs) have proven to be a simple and effective means for outcoupling a majority of the substrate modes (Möller and Forrest, 2001, Sun and Forrest, 2006, 2008a). The microlenses themselves are much smaller than the pixel size, and are placed on the far (emitting) surface of the substrate. They can also be attached to the surface of top emitting OLEDs with equal effect. The enhanced outcoupling results from presenting a curved surface whose index is approximately matched to the substrate, as shown in Fig. 6.133a. Emitted light incident on the microlens

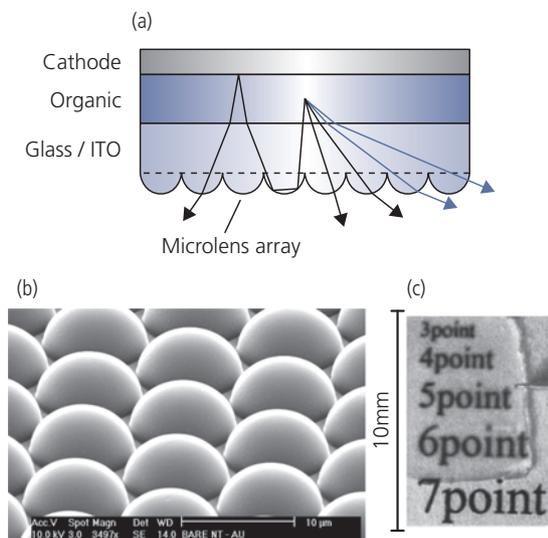

**Figure 6.132** Schematic of scattering from voids in a film attached to the emitting glass substrate surface of an OLED. The micrograph at the left shows the blister-like cavities in the high index polyimide film (Koh et al., 2015).

hemisphere at angles  $> \theta_{TIR}$  on a flat surface finds itself at  $< \theta_{TIR}$  at the curved lens/air interface, and hence can escape. Additionally, light emitted at  $\theta \gg \theta_{TIR}$  may be back scattered into the device, is once more reflected by the metal contact, and then can exit the substrate as shown in Fig. 6.133a. This path leads to some loss on reflection, hence the MLAs are  $< 100\%$  efficient.

An example array consisting of hexagonally close packed,  $10\ \mu\text{m}$  diameter polydimethylsiloxane (PDMS) hemispheres is shown in Fig. 6.133b. A disadvantage of MLAs is that they slightly blur the image. Figure 6.133c shows the image of a printed sheet partially covered by a MLA on a  $0.35\ \text{mm}$  thick glass substrate. Image blurring is apparent for 5 pt. type and below, although the lenses used to produce the images had a muffin-tin rather than spherical shape that has superior performance (Möller and Forrest, 2001).

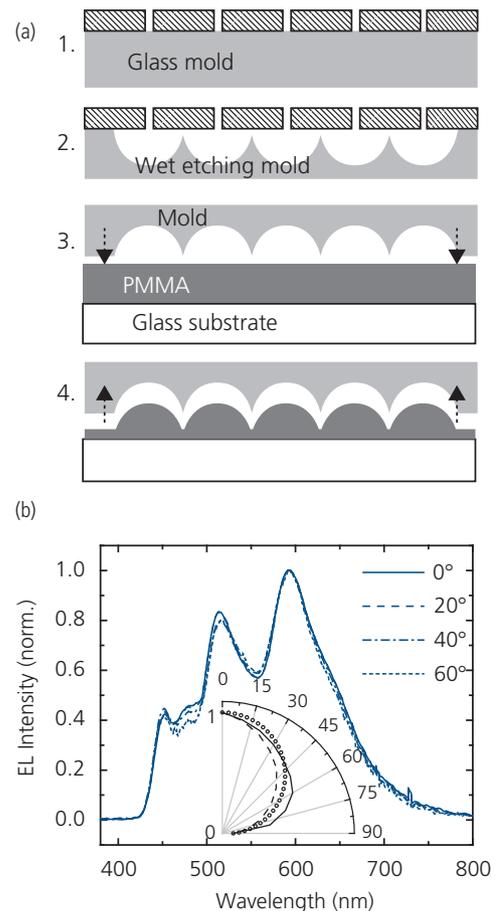

An attractive feature of MLAs is the ease (and hence low cost) with which they can be produced in large sheets in batch or roll-to-roll processes. A reusable mold is fabricated as shown in Fig. 6.134a on either a plate or a roller. (1) A photoresist mask (hatched layer in the figure) with small  $\sim 1\ \mu\text{m}$  diameter circular openings on a hexagonal lattice with a  $10\ \mu\text{m}$  pitch is applied to the surface of a glass sheet. (2) The glass is

**Figure 6.133** (a) Principle of operation of the microlens array. Blue rays correspond to substrate angles  $\theta > \theta_{TIR}$  whereas black rays are at  $\theta < \theta_{TIR}$  (Brütting et al., 2013). (b) Micrograph of a hexagonal array of  $10\ \mu\text{m}$  diameter hemispherical PDMS microlenses (Sun and Forrest, 2008a). (c) A film of  $10\ \mu\text{m}$  diameter muffin-tin shaped microlenses on top of a printed sheet showing minor image blurring (Möller and Forrest, 2001). Reprinted from Möller, S. & Forrest, S. R. 2001. Improved light outcoupling in organic light emitting devices employing ordered microlens arrays. *J. Appl. Phys.*, 91, 3324, with the permission of AIP Publishing

isotropically etched using an HF solution to form hemispherical openings that touch each other on their peripheries. (3) The mold is then pressed into a soft PDMS film which is subsequently thermally cured, and (4) the mold is removed, leaving the MLA film for subsequent attachment to the OLED substrate surface (Sun and Forrest, 2006).

The emission spectrum from the fluorescent/phosphorescent WOLED in Fig. 6.100 (Sun et al., 2006) is nearly independent of viewing angle, as shown in Fig. 6.134b, and the power distribution in the far field is approximately Lambertian (see inset), although the emission at wide viewing angles is enhanced compared with a conventional WOLED on a flat glass substrate. It is found that the PDMS arrays result in a 1.7 times enhancement in outcoupling efficiency compared to a flat glass substrate (Sun and Forrest, 2008a). This is close to the calculated

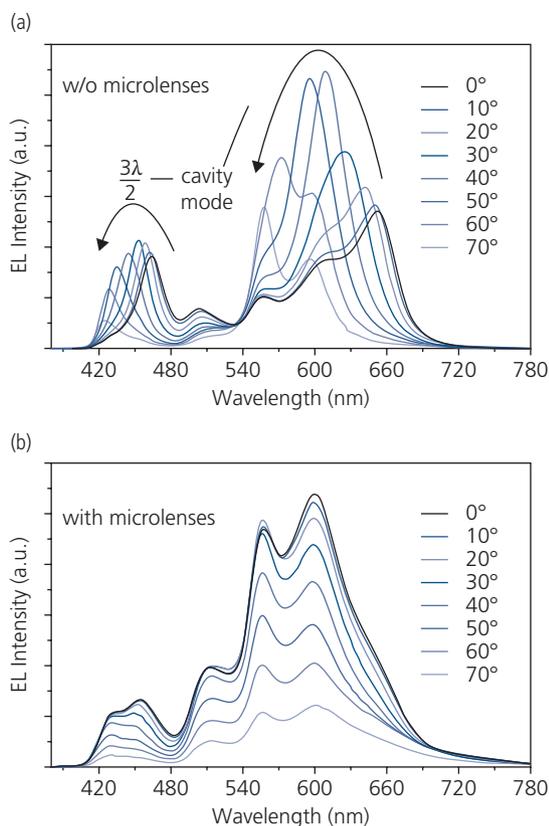

**Figure 6.134** (a) Process for forming polymer microlens arrays. (b) Emission spectrum from a fluorescent/phosphorescent WOLED as a function of viewing angle. Inset: Polar emission pattern for a device with (solid line) and without (dashed line) a microlens array (Sun and Forrest, 2006).

maximum enhancement of  $\sim 1.8$  times for this lens and substrate combination.

MLAs attached to the surface of a top emitting OLED significantly improve outcoupling while eliminating image blurring (Yang et al., 2007, Thomschke et al., 2012). One feature of the top surface MLA is that it acts as an effective light diffusing medium, thus reducing microcavity effects arising from the metal contacts on both top and bottom OLED surfaces. Optical outcoupling and light diffusion has been demonstrated with a tandem WOLED comprising a thick bottom Ag contact, and a semitransparent cathode using a 15 nm thick Ag film. The bottom element in the stack comprised a 10 nm thick yellow emitting EML with 8 wt% Ir(ppp)<sub>3</sub> in TCTA. This combination assists energy transfer to a yellow 1 wt% Ir(dhfp)<sub>2</sub>(acac) phosphor. The top blue/red 4P-NPD/Ir(MDQ)<sub>2</sub>(acac) EML was separated from the bottom device with a CGL comprising an ultrathin (0.5 nm) Ag nanoparticle layer embedded in n- and p-doped conducting layers. Without the MLA, the spectrum showed two distinct peaks (see Fig. 6.135a). Since the

blue and red lumophores are co-doped into a single layer, the blue emission has a peak at the  $m = 1$  (corresponding to  $3\lambda/2$ ) optical order centered at 460 nm (normal incidence). The red is at the  $m = 0$  order centered at  $\lambda = 660$  nm. The yellow emitting element also is at the  $m = 0$  mode at approximately 600 nm. The positions of the two EMLs within the cavity are adjusted by the thicknesses of the doped HTL and ETL in the blue/red element. There is a strong microcavity resonance associated with this device, as apparent from the spectral dependence on viewing angle in Fig. 6.135a (Thomschke et al., 2012).

A high index ( $n = 1.71$ ) MLA with a 10  $\mu\text{m}$  pitch was attached via lamination to the top contact with an intervening 200 nm thick NPD layer with approximately the same index of refraction as the MLA. Two effects are observed in Fig. 6.135b. The first is the almost total absence of spectral shifts with viewing angle; the microcavity effects have essentially been eliminated. Furthermore, the clear articulation of the cavity modes at  $3\lambda/2$  and  $\lambda$  disappear due to  $m = 0$  and 1 modal mixing. The net effect is a high CRI = 86 at CIE = (0.516, 0.420) for a device with an external efficiency of 22.8% and  $\eta_P = 25.2$  lm/W. This is nearly a 1.4 times increase in efficiency compared to a device without the microlenses. This demonstration provides evidence that MLAs are effective for extracting both waveguide and substrate modes, whether they are placed on the top or substrate OLED surface.

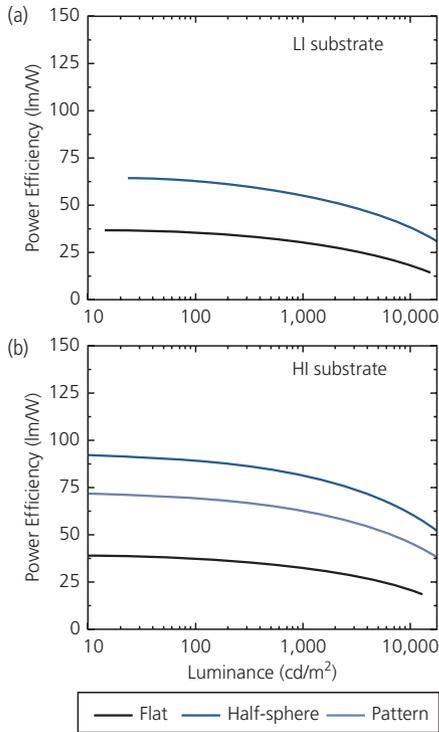

**Figure 6.135** The spectra and viewing angle dependence of a tandem, blue/red + yellow top emitting WOLED (a) without and (b) with a high index polymer microlens array attached to the top emitting surface (Thomschke et al., 2012).

### 6.6.3 Waveguide mode outcoupling

Modal analysis indicates that 20–30% of the OLED emission excites waveguide modes supported in the organic and ITO layers. Due to the small but non-negligible loss in the ITO with complex index of refraction of  $\tilde{n} = 1.95 + i0.0035$  (Chang et al., 2013a), these modes must be outcoupled into the substrate to limit attenuation. Thick organic and/or ITO layers can support high order TM and TE modes. Thus, waveguide mode trapping is more severe in multi-layer WOLEDs than in thinner, monochrome pixels.

Unlike substrate modes, outcoupling of waveguide modes requires structures that are in close proximity to, or even within the OLED active layers themselves. Many solutions are complex, and can reduce device performance and manufacturing yield or increase fabrication costs. It is not possible to directly measure the contribution of waveguide modes to the total power since they propagate parallel to the substrate plane. Indeed, SPPs also propagate in the in-plane direction, and may at least partially be outcoupled using the same strategies as those employed to extract guided

**Figure 6.136** Power efficiency vs. luminance for the WOLED in Fig. 6.94 on a (a) low index (LI) and (b) high index (HI) glass substrate. The black line is with no substrate mode outcoupling, dark blue is with index-matching fluid and a hemispherical lens, and light blue is with an array of pyramidal structures cut into the emitting substrate surface (Reineke et al., 2009).

modes. However, the SPP mode attenuation length is far shorter due to the large contribution of the imaginary part of the complex index of refraction by the metal layer.

The outcoupling of guided modes requires scattering into the substrate, followed by a second substrate light extraction scheme described in the previous section. A straightforward means for outcoupling guided modes is to use high index of refraction substrates instead of glass. If the substrate index is greater than that of the organic layers (typically  $n \sim 1.7$ ), the guided modes evanescently couple into the substrate (Nakamura et al., 2005, Gaertner and Greiner, 2008, Mladenovski et al., 2009), as shown for WOLEDs using high index MLAs in Fig. 6.135. The emitting layer of the OLED should be sufficiently far from the cathode to avoid excitation of lossy or SPP modes in the metal contact. Unfortunately, high index glasses are generally more costly than conventional substrate glass.

Enhanced waveguide mode outcoupling using high index N-LAF 21 Schott glass substrates ( $n = 1.78$  compared to  $n \approx 1.7$  for the organic active waveguide layers) is observed for the WOLED structure in Fig. 6.94, with results in Fig. 6.136. Absent substrate mode outcoupling enhancements (black lines), the peak power efficiency is approximately the same for the high and low index substrates, since in the former case, the increased outcoupling of waveguide modes is offset by the increased TIR at the substrate/air interface. Using *index-matching fluid* (IMF) between the substrate and a spherical lens extracts all of the substrate modes. Using this combination of extraction schemes, the power efficiency at 1000 cd/m<sup>2</sup> (dark blue line), increases by greater than two, to 81 lm/W for the high index substrate, but only to 55 lm/W for the conventional glass substrate. The high index substrate was further modified by cutting an array of large pyramids (0.55 mm pitch, 90° angle) into its emitting surface, which has effects similar to using microlenses. That is, the angled surfaces effectively increase the escape cone of light trapped by TIR on flat surfaces (Nakamura et al., 2005, Gaertner and Greiner, 2008). The enhancement leads to 63 lm/W, which is a significant improvement over that obtained for the low index substrate with complete substrate mode outcoupling. The spectra of both devices are nearly identical, since extracting waveguide modes does not change the device optical properties as long as the high index medium is non-absorbing.

Gratings or two-dimensional (2D) photonic band gap structures placed within or near to the OLED active region offer additional opportunities for waveguide mode outcoupling (Lee et al., 2003, Do et al., 2004, Ishihara et al., 2007, Zhou et al., 2014a). A grating placed near the emitting dipole scatters the propagating mode at an angle that is a function of wavelength. While a grating can efficiently scatter guided modes into the substrate, its energy dispersive nature requires that the outcoupled radiation pass through a diffuser to remove chromatic and angular dependences. Microlenses, roughened surfaces, or multilayer coatings can all serve this purpose.

Gratings comprise wavelength-scale features patterned over large substrate areas, resulting in potentially high manufacturing costs. Patterning can use nanoimprint lithography (Ishihara et al., 2007, Zhou et al., 2014a, 2014b) or, as in Fig. 6.137a, interference lithography (Matterson et al., 2001, Bocksrocker et al., 2012). The latter entails the interference of two beams split from the same laser source, and projected onto the substrate to expose a layer of photoresist (Fig. 6.137b) with a grating pattern of the appropriate

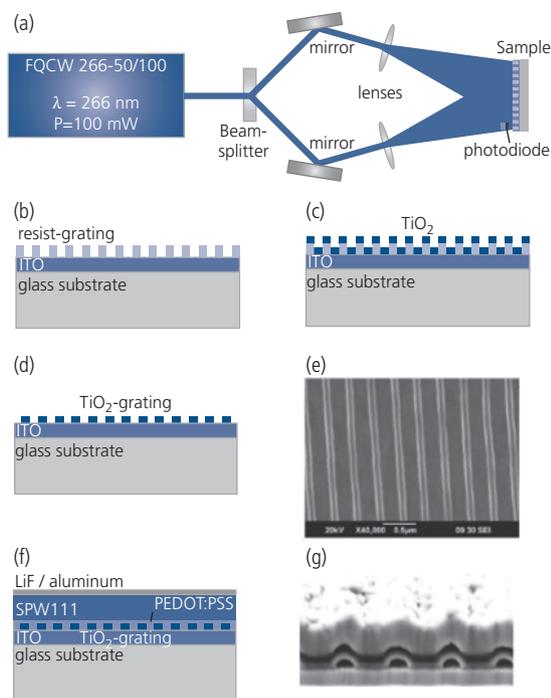

period. Next, a high index layer (e.g.  $\text{TiO}_2$  with  $n = 2.2$ ) is evaporated onto the photoresist surface (Fig. 6.137c), which is subsequently lifted off to leave behind the high index grating (Fig. 6.137d and e). Since the grating lies in only one direction, at most it can only outcouple 50% of the light emitted by vertically aligned dipoles that radiate isotropically within the plane. This problem is eliminated using 2D gratings, or photonic crystals that are produced by rotating the substrate by  $90^\circ$  and repeating the exposure and development steps (Lee et al., 2003, Do et al., 2004, Ishihara et al., 2007).

The grating is planarized with PEDOT:PSS and then the WOLED is completed by depositing the organic layers and cathode contact (Fig. 6.137f). Figure 6.137g shows a cross-section of the somewhat nonplanar device and grating. This minor surface ripple is actually helpful in outcoupling light, since  $k_{\parallel}$  waveguide modes scatter at each encounter with the undulations (Koo et al., 2010). In addition, the ripples reduce the efficiency of coupling to SPP modes, and can scatter them into the waveguide and substrate modes (Hobson et al., 2002).

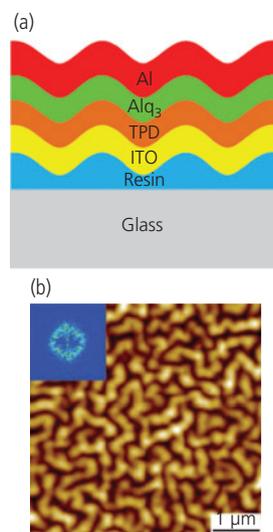

Modes that are coupled into the substrate either escape or are reflected back to the grating at the substrate/air interface. The backward travelling wave modes can recouple into the waveguide. The depth of

the grating determines its scattering efficiency. In the example of Fig. 6.137, it was found that the 15 nm deep grating was less likely to recouple back-scattered light than one with 35 nm depth. To eliminate chromatic and angular dispersion and minimize recoupling light into the waveguide, an MLA can be deposited on the substrate surface. The combination of microlenses formed by thermally reflowing an array of polymer pillars and a 15 nm deep grating resulted in a factor of four improvement in outcoupling (104% enhancement from the gratings and 94% from the microlens diffuser) compared to an identical WOLED on a flat glass substrate. Furthermore, the emission was found to be approximately Lambertian across the visible spectrum when the grating was paired with the lens array (Bocksrocker et al., 2012).

Random wavelength-scale buckling of a film deposited onto the flat substrate surface that provides a rippled surface on which the OLED layers are deposited can be used to avoid high resolution grating patterning over large substrate areas (Koo et al., 2010, Lee et al., 2014). The advantages of such corrugations are two-fold: they do not require photolithography over larger areas, and the nanostructures are isotropic, which means that they are equally effective in outcoupling light propagating in either the  $x$  or  $y$  in-plane directions. The buckling in Fig. 6.138 is produced by

**Figure 6.137** Fabrication steps of a  $\text{TiO}_2$  grating within the anode contact of a WOLED for extracting waveguide modes. See text for a description of the procedure (Bocksrocker et al., 2012).

depositing a 10 nm thick Al film on a PDMS layer heated to 100°C. After deposition, the bilayer cools. The buckles are formed to relieve strain induced by the differences in thermal expansion between PDMS and Al. The depth of the corrugations is  $D \approx \Lambda \sigma^{1/2}$ , where  $\sigma$  is the compressive stress exerted by the metal on the polymer, and  $\Lambda$  is the periodicity of the features. A decrease in  $\Lambda$  results in a proportionate decrease in the corrugation depth, and consequently the outcoupling efficiency is also decreased. The depth is increased by making successive, buckled film masters. The second master is created by spinning a layer of PDMS onto the original Al/PDMS bilayer, and repeating the process to obtain single-, double- and triple-cast masters. To form the devices in Figure 6.138a, a UV-curable resin is spun on to the glass substrate, and then the PDMS master is pressed into its surface, thereby transferring the buckled pattern. This is followed by deposition of the OLED layers.

This process results in  $D$  from 40 to 70 nm, leading to a characteristic buckling length of  $\Lambda = 400$  nm. Outcoupling enhancements of  $\sim 2$ – $4$  times (with the larger enhancements at longer wavelengths) compared to a conventional, Alq<sub>3</sub> device are observed. The ripples outcouple waveguide as well as a fraction of the SPP modes, due to the rapid change in waveguide and contact angles relative to the substrate plane. A disadvantage of this scheme is that it

disturbs the planar morphology of the OLED structure. As a result, the current at a given voltage is increased compared with a planar device due to local thinning of the active region (Koo et al., 2010).

A method for waveguide mode outcoupling that does not require high resolution lithography, and hence is wavelength and viewing angle independent is the use of *low index grids* (LIGs) in the OLED active region, as illustrated in Fig. 6.139a (Sun and Forrest, 2008a). A region with an index lower than the organic layers is placed within the active region, thereby scattering light into the substrate modes. The grid structure is 2D, leading to outcoupling of all in-plane modes, independent of propagation direction. The primary requirement for the grid periodicity is that the low index regions are sufficiently closely spaced to avoid excessive waveguide mode attenuation, but are far enough apart to prevent chromatic dispersion. Beyond this, there are no conditions on grid shape. Since the low index dielectric region is placed within the OLED active layers, the regions over the grid lines are non-emissive. This reduces the total luminance but not the luminescent efficiency, since both the electrically active current and light emitting device areas are similarly reduced. Typical grid dimensions are a dielectric region width of  $w_{LIG} = 1$   $\mu\text{m}$  and a spacing of  $w_{org} = 6$   $\mu\text{m}$ , requiring an increase in pixel size of  $\sim 25\%$  to achieve the same luminance as a device lacking the grid.

**Figure 6.139** Low index grid (LIG) outcoupling structure. (a) Schematic of the device as well as the half-sphere used for calculating the total output power. (b)–(e) Simulated power intensities through the curved surface of the simulation domain for vertical and horizontal emitting dipole orientations, with and without the LIG. (b) Vertical, and (c) horizontal dipole, no LIG. (d) vertical and (e) horizontal dipole with LIG. In (c) and (e) the full range of values is not shown. The vast majority of light is in the white center of the disk. Dashed lines show the azimuthal angles of  $\theta = 30^\circ$  and  $60^\circ$  (Slootsky and Forrest, 2009).

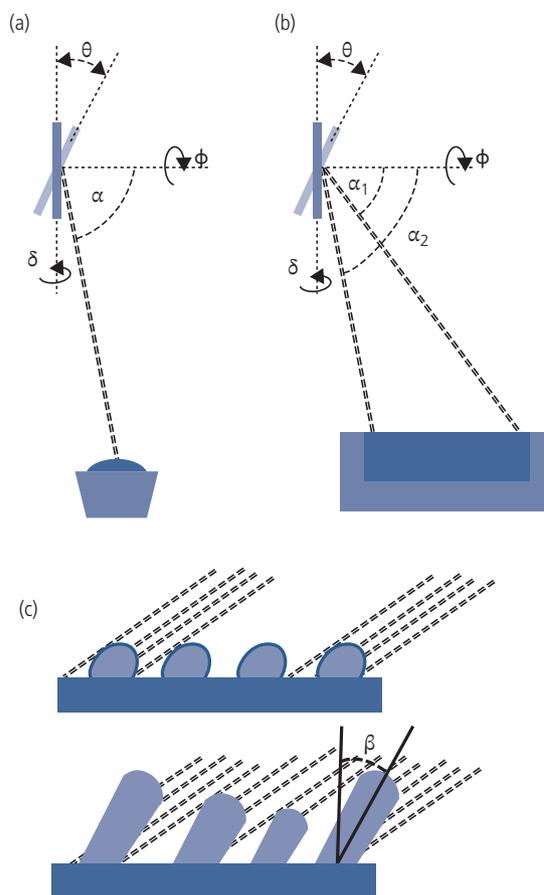

Full-wave modal analysis of the guided light shows the effectiveness of a silica grid ( $n_{GRID} = 1.45$ ) in coupling vertical dipole emission into the azimuthal direction. Polar plots of the emission intensity calculated for vertically and horizontally aligned dipoles in a conventional OLED are shown in Fig. 6.139b and c, respectively (Slootsky and Forrest, 2009). Emission from vertical dipoles is weak, with a considerable amount of equatorial propagation along the waveguide longitude at an angle of  $\theta = 90^\circ$ . Emission from horizontal dipoles, on the other hand, is almost completely along the azimuth, as expected. The LIG placed within the organic ( $n = 1.75$ ) and above the ITO ( $n = 1.8$ ) guiding layers efficiently scatters the vertical dipole emission from the first grid cell (Fig. 6.139d) while leaving the horizontal dipole emission largely unperturbed (Fig. 6.139e). The dielectric discontinuities scatter waveguide light into the substrate with such high efficiency that light scattered from second nearest neighbor cells contribute only negligibly to the total emission intensity.

The LIG concept was demonstrated using the fluorescent/phosphorescent WOLED structure in Fig. 6.100 along with a 100 nm thick silica LIG with dimensions of  $w_{LIG} = 1 \mu\text{m}$  and  $w_{org} = 6 \mu\text{m}$ . The LIG device exhibits an enhancement of 1.32 in outcoupling compared to a conventional device, which exceeds that predicted from modal calculations since the SPP modes are also partially scattered by the uneven waveguiding region. Using a MLA with the conventional device, an enhancement of 1.68 is realized, and combining both of these coupling strategies, the efficiency is increased by a factor of 2.3 to achieve  $\eta_{ext} = 34\%$  and a peak luminance power efficiency of 68 lm/W. Due to the large dimensions of the LIG, the broad white emission spectrum is unchanged from that of the analogous conventional device (Sun and Forrest, 2008a).

Considerable benefits can be realized by reducing the refractive index of the LIG. Indeed, very low index LIGs with  $n_{LIG} = 1.10\text{--}1.15$  have been achieved by depositing 100 nm thick  $\text{SiO}_2$  at a highly oblique angle ( $80\text{--}85^\circ$ ) relative to the substrate plane. *Oblique angle* or *glancing incidence deposition* results in nucleation of the film at random positions around the substrate. Due to the angle of the substrate plane to the direction of the evaporated flux, the nucleation centers cast shadows on regions more distant from the source. This increases the rate of deposition on the islands which then further shadow the area behind them, leading to a porous film similar to an aerogel (Xi et al., 2005, Barranco et al., 2016).

The oblique angle deposition process used in optical coatings for both OLEDs and OPVs can be

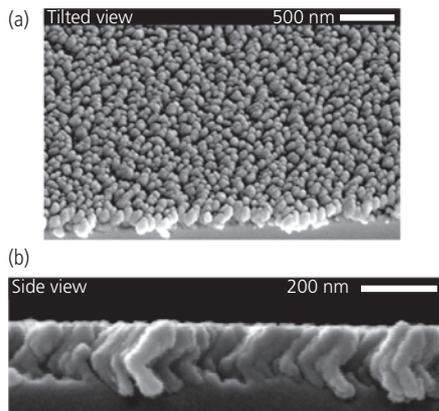

understood from the illustration in Fig. 6.140. A point source (Fig. 6.140a) results in more defined shadowing, and hence narrower pillars than an extended source due to the range of arrival angles between  $\alpha_1$  and  $\alpha_2$  in Fig. 6.140b. The pillar tilt angle,  $\beta$ , is determined by the angle of the substrate to the source,  $\theta$ , and  $\alpha$ . The index of the resulting film equals the volume average of the indices of the deposit and the voids. Results of the e-beam deposition of low index  $\text{SiO}_2$  at  $\alpha = 80\text{--}85^\circ$  and  $\theta = 0$  forming the LIG is shown in Fig. 6.141. The top image (Fig. 6.141a) shows a highly porous film, comprised of densely packed pillars of nearly the same diameter. The side view in Fig. 6.141b shows that the pillars have a kink midway along their length. This results since the substrate was rotated around an angle of  $\phi = 180^\circ$  after the first  $\sim 50$  nm of  $\text{SiO}_2$  was deposited. The index of refraction of the film was  $n = 1.10\text{--}1.15$ . Using porous grids with the same dimensions as the device in Fig. 6.139, outcoupling enhancements of approximately a factor of

**Figure 6.140** Oblique angle deposition from (a) a point and (b) an extended evaporation source. (c) Illustration of shadowing leading to pillars from randomly located growth nucleation sites (Barranco et al., 2016).

two compared to conventional devices on flat substrates were observed (Slootsky and Forrest, 2010).

The structure of Fig. 6.139 penetrates the device active region, which can lead to losses in manufacturing yield due to shorts. Alternatively, the grid can be located beneath the ITO anode and the OLED layers, as shown in Fig. 6.142a. The grid can have either a higher or lower index than the medium in which it is embedded, since light is scattered as a result of the index discontinuity that it encounters as it propagates in-plane (Qu et al., 2015). The evanescent tail of the guided modes penetrates beyond the

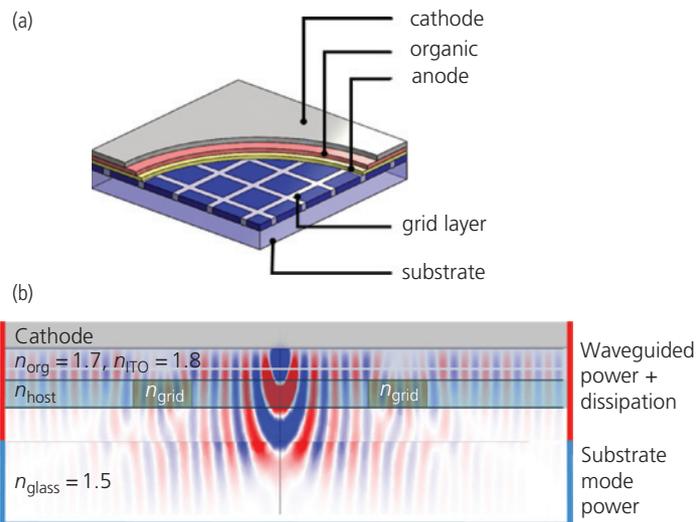

**Figure 6.141** (a) Top and (b) side view SEM images of  $\text{SiO}_2$  forming a low index grid used in OLED outcoupling (Slootsky and Forrest, 2010).

ITO into the grid region in Fig. 6.142b, and then is scattered into substrate and air modes. With an index difference between the “host” and the grid of 2.2, the enhancement in outcoupled radiation can be as high as 1.4, decreasing with the index contrast. This 2D structure is effective in scattering all in-plane modes, and its efficiency is largely independent of the shape or the size of the grid. The sub-anode grid dimensions are limited by the same factors as for the LIG: it must be small enough to minimize propagation losses prior to encountering a grid line, and it must be sufficiently large (i.e.  $>1 \mu\text{m}$ ) to avoid chromatic dispersion accompanying a grating or photonic crystal structure. Since the grid is located close to the EML, there is no image blurring due to the “near field” scattering of light.

Sub-anode grids have been fabricated using either low index (air) or high index  $\text{TiO}_2$  grid lines, with similar results. Fabrication of the  $\text{TiO}_2$  grid is shown in Fig. 6.143. The buried grid has the advantage of not interfering with the OLED structure. However, a consequence of the resulting planar OLED is that the grid only scatters waveguide modes. The SPP modes, whose evanescent fields do not extend as far as the grid, remain unaffected, and their losses remain significant. The fraction of power in each mode as a function of ETL thickness in a PHOLED whose structure is: 70 nm ITO/2 nm  $\text{MoO}_3$ /40 nm CBP/15 nm 15 wt%  $\text{Ir}(\text{ppy})_3$  doped in CBP/65 nm TPBi ETL/1 nm LiF/Al is shown in Fig. 6.144. This device is deposited

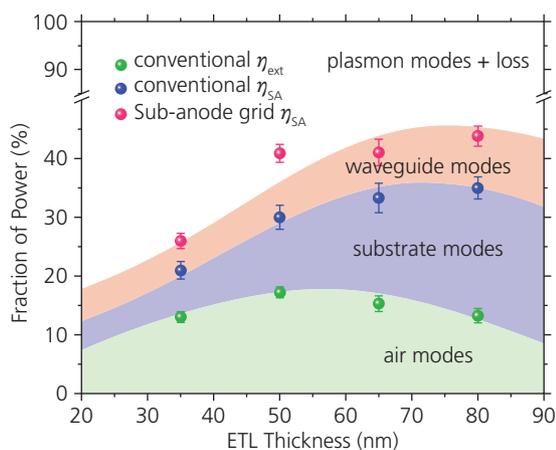

**Figure 6.142** (a) Schematic cut-away view of an OLED with a sub-anode grid (Qu et al., 2015). (b) Calculated wavefronts of guided light in the ITO and organic layers. Scattering of the wavefront from the index contrast presented by the grid results in an increase in substrate modes at the expense of waveguide modes.

**Figure 6.144** Power coupled into each mode of an Ir(ppy)<sub>3</sub> PHOLED vs. ETL thickness. Measurements of contributions from air and substrate modes are based on conventional PHOLEDs without, and with index-matching fluid between the substrate and detector surfaces, respectively. The waveguide modes are measured using an analogous PHOLED with a sub-anode grid, also using IMF (Qu et al., 2015).

Qu, Y., Sloatsky, M. & Forrest, S. R. 2015. Enhanced light extraction from organic light-emitting devices using a sub-anode grid. *Nature Photon.*, 9, 758

onto a 340 nm thick hexagonal TiO<sub>2</sub> grid, with grid line width of 1 μm and a hexagon side dimension of 3 μm. The calculation uses the Green's function analysis based on CPS theory in Section 6.6.1.

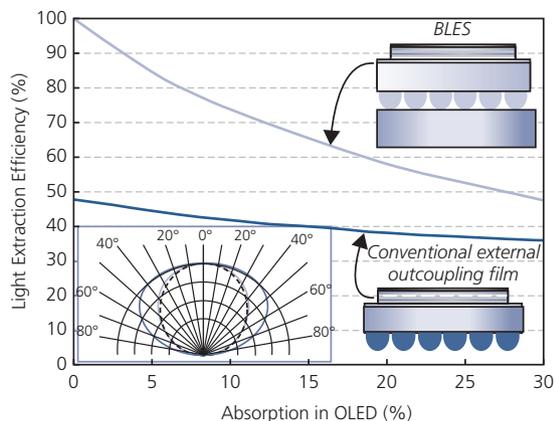

The power in the individual modes in Fig. 6.144 is measured as follows: (i) Air modes employ a conventional device and all of the radiation in the forward viewing direction is measured with a photodetector in the far field. (ii) Substrate modes are assigned to the difference in the output from the device in (i) and for that same device placed in contact with the photo-detector using a substrate IMF to outcouple all of the internally trapped modes. (iii) The device with an identical structure to (i) and (ii), except that it includes a sub-anode grid, is placed in contact with the detector using an IMF. The difference in output between (ii) and (iii) is assigned to waveguide modes. (iv) Plasmonic, internal efficiency and metal losses are assigned to the difference between (iii) and 100%. The calculations match well with the data (points in Fig. 6.144) for several different ETL thicknesses. Indeed, the sub-anode grid apparently extracts nearly 100% of the waveguide modes, resulting in an enhancement of ~ 1.45 times compared to the conventional device. This enhancement is independent of whether the grid has a low index (air) or high index discontinuity with the substrate, or whether it is a square or a hexagon. Furthermore, no systematic changes in the emission spectra are observed for any of these device variations, and the output intensity profile is found to be a nearly ideal Lambertian (Qu et al., 2015). However, approximately 50% of the power is lost to SPP and other sources, emphasizing that reduction of coupling to SPPs is essential in achieving high efficiency.

Another approach to outcoupling waveguide modes is to fabricate the thin OLED directly onto the flat surface of a high index film shaped into an MLA, and then attaching the entire unit onto the surface of the glass substrate. This so-called built-up light extraction substrate (BLES) is shown schematically in Fig. 6.145. The device comprises a high refractive index ( $n = 1.77$  at a wavelength of 550 nm) PEN film with a 10 μm diameter MLA with the same high index. This is attached to a glass substrate with a small air gap between the array and the glass. The planar surface of the PEN serves as a substrate for the growth of the OLED, including the transparent anode. In effect, this is simply an MLA mounted on a high index substrate, then placed on a glass substrate to enable further encapsulation. The calculated light extraction efficiency is plotted vs. residual OLED loss in comparison to a MLA on a low index (glass) substrate. The efficiency is enhanced by the BLES, particularly as the OLED losses due to absorption, SPP modes, etc. are reduced.

To test the efficacy of the waveguide mode extraction using the BLES, 1 cm<sup>2</sup> two unit (one comprising a red-green emitting, and the second a blue emitting

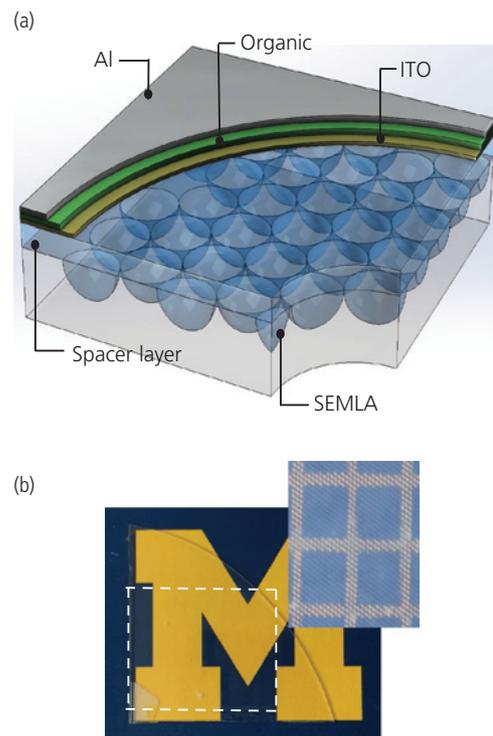

sub-element) white PHOLEDs were grown onto the BLES surface, and then mounted onto the glass substrate (Yamae et al., 2013). The BLES device had an efficacy of 114 lm/W and an operational lifetime of  $10^5$  h to half its initial luminance of  $1000 \text{ cd/m}^2$  due to the encapsulation provided by the glass slab (Komoda et al., 2012). The emission has  $CRI = 80$  and  $CCT = 2550 \text{ K}$  giving it a reddish cast. It was estimated that 50% of the light was extracted via this strategy. Note that the emission pattern in Fig. 6.145, inset, is non-Lambertian due to the tendency for MLAs to preferentially scatter into near in-plane angles (Möller and Forrest, 2001).

An improvement on the BLES that extracts nearly 100% of the trapped light in the active region into the air and substrate modes embeds the MLA completely within the glass substrate immediately beneath the bottom, transparent electrode (Qu et al., 2018). The sub-electrode microlens array (SEMLA) is shown in Fig. 6.146a. It comprises a high index ( $n_{\text{SEMLA}} = 1.8$ ) planar spacer layer on top of a hexagonal close-packed array of  $10 \mu\text{m}$  diameter hemispherical lenses. The SEMLA surface is smooth to eliminate optical scattering, and does not intrude into the device active region. Figure 6.146b shows a glass substrate containing the SEMLA structure (highlighted by dashed lines) on a printed background, with no apparent impact on image sharpness. The inset shows a microscopic image of a section of a glass substrate covered by the SEMLA. The substrate is patterned with a square grid with  $100 \mu\text{m}$  period and  $20 \mu\text{m}$  wide metal gridlines. The SEMLA has negligible impact on image resolution when magnified at this level.

**Figure 6.145** Light extraction efficiency vs. excess loss in the OLED for a built-up light extraction (BLES) microlens architecture and a conventional device on a glass substrate with a microlens array. Inset: Radiation pattern of the BLES (red line), a Lambertian source (black line) and a conventional OLED (green line) (Yamae et al., 2013).

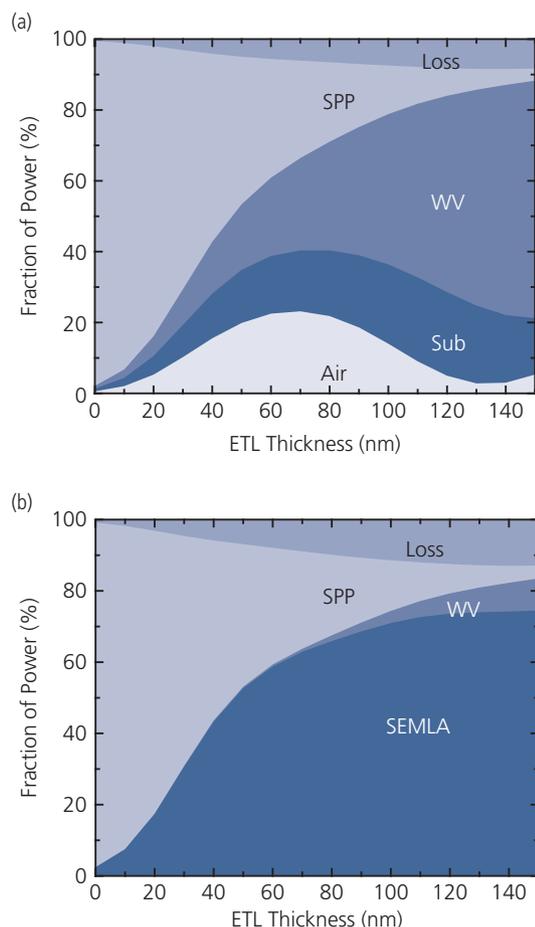

The high refractive index of the SEMLA extracts waveguide modes from the organic and ITO anode layers. Figures 6.147a and b show the calculated optical power distribution in devices with and without the SEMLA based on Green's function analysis, assuming that the spacer layer is semi-infinite. The device structure used in the calculation is: 40 nm ITO anode/40 nm HTL/20 nm EML/ETL/Al cathode. The waveguide modes are reduced to almost zero for an ETL thickness  $< 70 \text{ nm}$ . Indeed, the SEMLA extracts all radiated optical power except for the SPP modes. The optical power exits into the glass substrate from the high index hemispherical MLA. The light extraction from the SEMLA into glass ( $n_{\text{glass}} = 1.45$ ) is more efficient than from an external MLA ( $n_{\text{MLA}} = 1.4\text{--}1.5$ ) into air ( $n_{\text{air}} = 1$ ) due to reduced reflection at the lens/glass interface with its larger critical angle. Air gaps between the substrate and the MLA as in Fig. 6.145 increase reflections, and hence are avoided.

**Figure 6.146** (a) Schematic illustration of devices on a sub-electrode microlens array (SEMLA) substrate. (b) Image of a SEMLA substrate on a printed image, with the microlens side facing the image. The white dashed lines enclose the SEMLA structure area. Both green emitting PHOLEDs and WOLEDs were fabricated on SEMLA substrates, using an additional MLA attached to the bottom of the substrates to extract substrate modes. The performance characteristics of the green PHOLEDs with different substrates are shown in Fig. 6.148a. At 100  $\text{cd}/\text{m}^2$ , the SEMLA alone enhances  $\eta_{\text{ext}}$  from 25% for a PHOLED on a flat glass substrate, to 30%, representing improvement by an outcoupling enhancement factor of  $EF = 1.2$ . The outcoupling is further enhanced to  $EF = 1.9$  to  $\eta_{\text{ext}} = 47\%$  using an external MLA. Using IMF at the glass-air interface in conjunction with the SEMLA extracts up to 70% (an  $EF = 2.6$ ) of the total generated photons, compared with 51% for conventional glass, and 60% for sapphire substrates whose refractive index is similar to that of the SEMLA ( $n_{\text{sap}} = 1.77$ ). The most efficient device using the SEMLA reaches  $\eta_{\text{ext}} = 70\%$ . Similar enhancements are achieved for a WOLED fabricated on the SEMLA surface.

**Figure 6.147** Optical power modal analysis vs. electron transport layer (ETL) thickness on (a) a conventional glass substrate and (b) a SEMLA substrate (Qu et al., 2018).

The SEMLA eliminates microcavity effects, and hence does not induce spectral shifts even at viewing angles  $\sim 60^\circ$ . This is inferred from the angular intensity profile of the conventional device in Fig. 6.148b,

**Figure 6.148** (a) Measured  $\eta_{\text{ext}}$  vs. luminance of green emitting PHOLEDs on conventional flat glass (Con), SEMLA and sapphire (Sap) substrates. Measurements with no additional outcoupling at the substrate and air interface (air), with an external microlens array (MLA), and with index matching fluid (IMF) are indicated. (b) The angular luminosity distribution of WOLEDs on different substrates. Lamb. Indicates an ideal Lambertian emission pattern. (c) Enhancement factor ( $EF$ ) of green and white PHOLEDs on different substrates compared with conventional flat substrates with identical device structures. The  $\eta_{\text{ext}}$  are indicated. The circles and the pentagons denote the green and white PHOLEDs, respectively (Qu et al., 2018).

which is narrower than a Lambertian source, whereas the SEMLA-modified substrates show higher intensities at large viewing angles, bringing them closer to a Lambertian pattern. The similar enhancement factors of light extraction from both the green and white PHOLEDs are summarized in Fig. 6.148c, indicating that the SEMLA performs the same, independent of emission wavelength. The MLA outcouples  $\sim 70\%$  photons from the substrate and air modes combined. Outcoupling using an IMF or high index sapphire substrate in Fig. 6.148c shows that  $\sim 20\%$  photons remain trapped in the substrate using the SEMLA in combination with the MLA. Solutions to improve extraction from substrate modes are, therefore, necessary to fully exploit the advantages of efficient waveguide and surface plasmon mode outcoupling structures.

#### 6.6.4 Surface plasmon polariton mode outcoupling

Both SPP and waveguide modes can be coupled into glass modes by surface roughness near to the metal surface (Hobson et al., 2002). For example, patterning a grating onto the thin metal electrode is one means to extract SPP modes from the OLED surface (Gifford and Hall, 2002, Yates et al., 2006). As previously, the grating can be formed by interference or nanoimprint lithography on the substrate surface, followed by deposition of the several OLED layers and metal. If the metal cathode is semitransparent, with a grating periodicity,  $\Lambda$ , then in-plane modes can outcouple the SPP mode at both the dielectric interface and at the metal/air interface if it satisfies the Bragg condition:

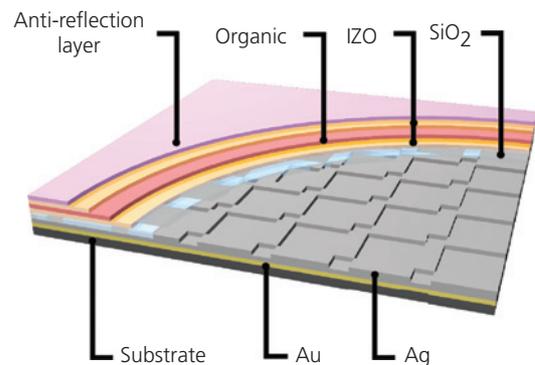

$$k_{\parallel}(\lambda) = \pm k_{SPP}(\lambda) \pm \frac{2\pi}{\Lambda}, \quad (6.117)$$

where  $k_{SPP}$  is the wavevector of the SPP mode at the metal-air interface (see Eq. 6.107). Modes satisfying Eq. 6.117 radiate from the top metal surface as long as the metal is thin enough to be semitransparent, that is, it is less than or on the order of the skin depth of the metal (Gifford and Hall, 2002). The signs in Eq. 6.117 are due to the two counter-propagating modes at each wavelength due to the mirror symmetry of the grating. Hence, the grating produces a splitting of the emission spectrum into both a red- and blue-shifted mode.

Since the SPP modes are lossy, their outcoupling efficiency is limited. Furthermore, this is another solution that disrupts the planar OLED structure. Alternatively, employing a very thick ETL avoids exciting SPP and metal loss modes altogether,

although increasing the layer thickness at some point leads to high device resistance. Replacing the metal contact with a less conductive transparent oxide almost completely eliminates both SPP and lossy metal modes. This solution has been implemented by growing a transparent PHOLED onto the surface of a planarized reflective Ag mirror beneath the WOLED bottom contact, as shown in Fig. 6.149. Employing a scattering structure within the substrate while retaining a planar surface allows freedom for optimizing the scattering layer dimensions without affecting the OLED electrical properties. The reflector is a patterned grid of raised rectangles coated with Ag. Similar to the LIG, the periodicity is on the order of several wavelengths to avoid angle- and wavelength-dependent effects. A planarizing dielectric layer fills the depressions and extends above the raised portions of the grid on which the electrodes and organic layers are deposited. The thick and thin spacer regions couple to different optical modes propagating beneath the transparent electrode (Qu et al., 2017).

The simulated modal power distributions vs. wavelength of the thick and thin regions between the grid surface and the transparent OLED bottom contact are shown in Fig. 6.150a and b (Gontijo et al., 1999). The calculations assume an OLED whose active region comprises a 130-nm-thick organic layer ( $n_{org} = 1.8$ ) sandwiched between 80-nm-thick transparent electrodes (50 nm IZO and 30 nm  $\text{MoO}_3$ ,  $n_{IZO} = n_{\text{MoO}_3} = 2$ ), with the EML placed 60 nm above the bottom electrode. A randomly oriented green emitting molecular dipole is placed at the position of the EML. The spacer refractive index is  $n = 1.5$ . The optical outcoupling efficiency is  $>20\%$  when spacer layer thicknesses are

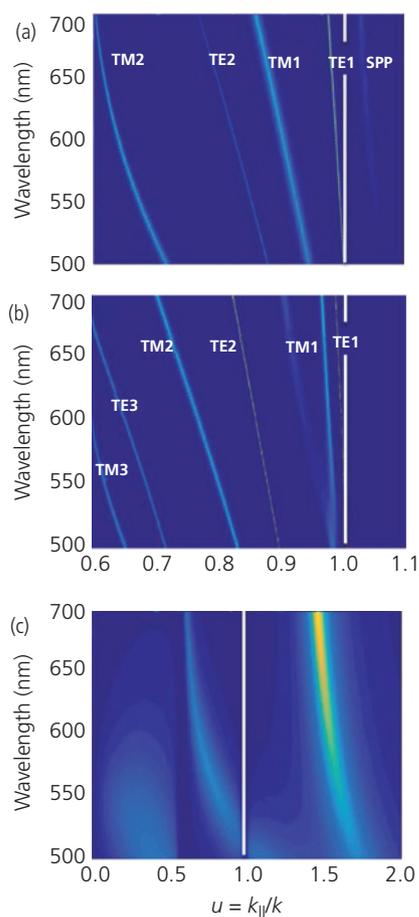

**Figure 6.149** Schematic cross-sectional view of a transparent OLED grown on a reflective sub-electrode grid (Qu et al., 2017).

65 and 245 nm in the thin and thick dielectric regions beneath the OLED, respectively.

The in-plane wavevector,  $k_{\parallel}$ , corresponds to light propagating in the organic layers with refractive index  $n_{org}$ , and the total wavevector is  $k$ . Modes with  $u = k_{\parallel}/k < n_{air}/n_{org}$  are radiative,  $n_{air}/n_{org} < u < 1$  are waveguided, and modes with  $u > 1$  are lost to SPPs. For the thin cavity regions (Fig. 5.150a), there are four waveguide modes, and a weak SPP mode. The thick cavity region (Fig. 5.150b) adds three more waveguide modes but has no SPP mode. Figure 6.150c shows the power distribution of a conventional top emitting OLED with the structure Ag/90 nm organic layers/20 nm semitransparent Ag

**Figure 6.150** The modal power distributions within the cavities found between the raised and depressed portions of the grid and the OLED in Fig. 6.149. Here,  $k_{\parallel}$  is the in-plane wavevector for light within the organic layers with refractive index,  $n_{org}$ . The total wavevector is  $k$ . The waveguide and SPP modes (at  $u > n_{air}/n_{org}$ ), of the cavities over the (a) gridlines and (b) depressions. (c) The power distribution of a conventional top emitting OLED optimized over the same spectral range. The vertical line corresponds to  $u = k_{\parallel}/k = 1$ . At higher  $k_{\parallel}$ , the waves are evanescent and lossy (Qu et al., 2017).

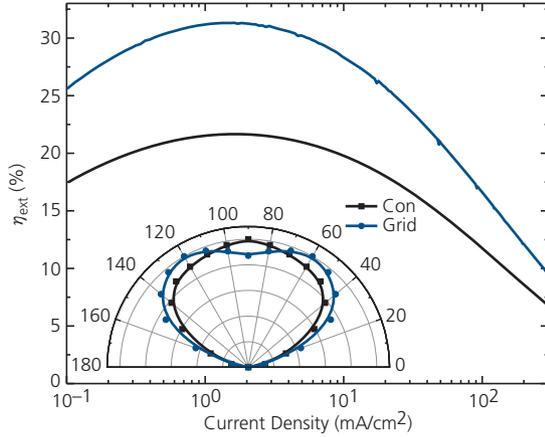

layer, with a 20 nm EML centered in the organic active region. This structure does not support any waveguide modes, but instead has two, intense SPP modes. The first SPP mode at  $u \approx 0.6$  and  $\lambda \approx 540$  nm propagates in the top thin Ag film. According to Eq. 6.107 and given  $n_{air} < n_{org}$ , this SPP mode lies at  $u < 1$  rather than  $u > 1$  for organic/metal SSPs. The second SPP mode at  $u > 1.5$  is along the Ag/organic interface lies at. Thus, compared to conventional OLEDs, metal-coated grid devices successfully suppress SPP modes while coupling power into the waveguide modes.

The scattering by the grid is a consequence of the mismatch between the waveguide modes supported by the two cavities above the grid lines and depressions, which can be estimated by the overlap of the wavevectors of these modes. The  $TE_1$  and  $TM_1$  modes in the thin  $SiO_2$  cavity regions (Fig. 6.150a) have some overlap with the  $TE_1$  and  $TM_1$  modes in the thick dielectric regions (Fig. 6.150b), and thus can propagate in plane. The modes that are not aligned between cavities are completely scattered into the substrate by the grid.

The sub-electrode reflecting grid for an OLED with the structure: glass substrate/50 nm IZO/30 nm  $MoO_3$ /30 nm BPhen: Li (molar 1:1)/30 nm BPhen/30 nm 8 vol.%  $Ir(ppy)_3$  in CBP/40 nm TAPC/30 nm  $MoO_3$ /50 nm IZO comprised an array of  $1 \mu m \times 3 \mu m$  raised rectangles surrounding  $3 \mu m \times 3 \mu m$  square depressions. The spacer thicknesses varied between 245 nm and 65 nm. The design is forgiving in that there is no pronounced sensitivity to either grid shape (it can be ordered, or random), or dimensions, as long as the feature sizes are larger than  $\lambda$  and less than  $\delta_{SPP}$ . As with the non-reflecting sub-anode grid structure, there is no image blurring due to the proximity of the mirror to the EML.

In Fig. 6.151 we show that  $\eta_{ext}$  is increased from 20% to 30% using the metallic scattering grid compared to a similar PHOLED fabricated on a substrate with a mirror but no grid. The angular intensity profiles of both devices are broadened from a Lambertian function. The peak intensity of the flat mirror device is normal to the surface, whereas the grid OLED intensity has a maximum at  $20^\circ$  from normal. This is due to microcavity effects that are inevitably encountered in top emitting OLEDs.

Although a significant efficiency enhancement is obtained using the reflecting grid, 60% of the optical power is still lost. In addition to the limited grid scattering efficiency due to the spacer thicknesses used, the scattered light incurs losses at each reflection from the mirror surface. A diffuser or MLA comprised of high refractive index materials added to the

**Figure 6.151** External quantum efficiencies of a top emitting PHOLED with a sub-anode mirror separated from the PHOLED by a 65 nm thick  $\text{SiO}_2$  spacer (black), and a metal-coated grid device (blue). Inset: Angular intensity profiles of the conventional and metal coated grid PHOLEDs (Qu et al., 2017).

top surface of the transparent OLEDs can reduce cavity resonances. Green's function analysis shows that a MLA on the device emitting surface could further improve the efficiency by >30% (Qu et al., 2017).

A final, potentially very low cost example that completely eliminates SPP modes replaces the bottom metal electrode in top-emitting WOLEDs with the ITO anode deposited on a highly reflective, diffuse dielectric such as used in the interior surfaces of integrating spheres. The structure design is illustrated in Fig. 6.152a. The rough dielectric reflector surface efficiently scatters the waveguided light emitted from a transparent OLED deposited on a planarizing, high refractive index ( $n_P=1.8$ ) polymer slab that extracts modes trapped in the OLED, while presenting a flat surface on which the OLED layers are grown. Unlike the other methods described in this section, the diffuser-based PHOLED requires no additional light extraction such as index matching layers or MLAs, making this a very simple design.

As illustrated in Fig. 6.152a, light emitted from the OLED exits either from the top, transparent ITO contact, or enters the waveguide layer where it propagates until it is incident on the rough dielectric reflector surface. There, the light is scattered into a Lambertian profile, and light within the TIR exit cone is emitted into the viewing direction. Light incident at angles greater than  $\theta_{\text{TIR}}$  at the polymer-air interface is returned to the diffuse reflector where it is scattered once again. This repeats until the light is either absorbed or scattered into the viewing direction. Since the light requires several bounces before exiting the device, the diffuser must have a reflectivity that

exceeds that of the metal, and losses in the transparent anode and polymer waveguide layer must also be small. Here, PTFE (Teflon<sup>®</sup>) is well suited for this purpose due to its nearly 99% reflectance across the visible.

The simplicity of fabrication is illustrated by the process sequence in Fig. 6.152b. The PTFE reflector is coated with the polymer waveguide on its surface. Next, a PDMS stamp attached to a glass handle is pressed onto the polymer for planarization, during which the polymer was cured by exposure to UV light prior to stamp removal. The resulting polymer waveguide layer was 0.25 mm thick. Following this procedure, the ITO anode, the OLED layers, and the transparent, top ITO cathode are fabricated by conventional methods.

For a lossless reflector and waveguide layer, the ratio of incident to scattered light power towards the viewing direction from a single diffuse reflection ( $R_S$ ) is determined using Snell's law, viz.  $R_S = (n_{\text{air}}/n_P)^2$ . Then, the ratio of the light intensity extracted into the viewing direction to that confined within waveguide layer ( $\eta_D$ ) following the path in Fig. 6.152a is (Kim et al., 2018)

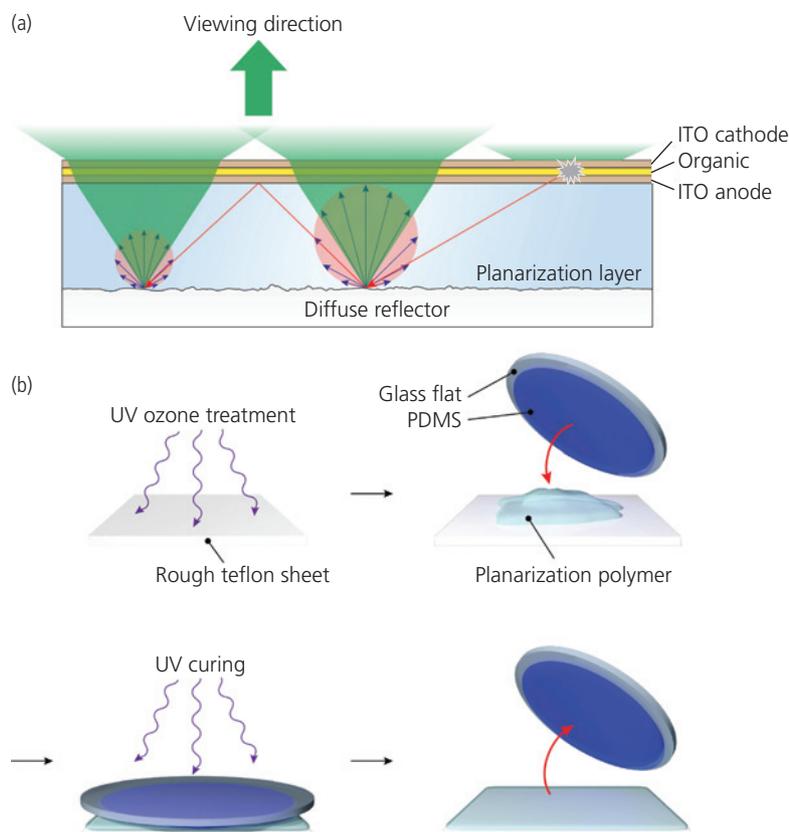

$$\begin{aligned} \eta_D &= R_S + (1 - R_S) \cdot R_S + (1 - R_S)^2 \cdot R_S + \dots \\ &= \sum_{n=0}^{\infty} (1 - R_S)^n \cdot R_S = 1. \end{aligned} \quad (6.118)$$

It follows that total outcoupling efficiency ( $\eta_{\text{out}}$ ) of the OLED is

$$\eta_{\text{out}} = \eta_{TA} + \eta_D \eta_S, \quad (6.119)$$

where  $\eta_{TA}$  is the fraction of light emitted from the top surface, and  $\eta_S$  is the fraction of light coupled into the slab waveguide. A diffuse reflecting, a green emitting PHOLED showed a peak  $\eta_{\text{ext}} = 37\%$ , whereas for comparison, a device using only a metal mirror had  $\eta_{\text{ext}} = 15\%$ . This substantial difference is due to the much larger losses introduced due to reflections from a metal mirror than a dielectric reflector. From Eq. 6.119, the light coupled into the waveguide layer shows  $\eta_{\text{out}} = \eta_{\text{int}} \eta_S \eta_D = 30\%$  and 8% for the diffuser and metal mirror structures, respectively, resulting in a 3.8-fold increase in extraction into the viewing direction via diffuse scattering.

The diffuser increases the *étendue* of the OLED, thus introducing emission outside of the PHOLED active area defined by the device contacts. Figure 6.153a shows the normalized radiated power intensity assuming a polymer waveguide loss of  $\alpha = 0.4 \text{ mm}^{-1}$ , a thickness of 240  $\mu\text{m}$ , and a  $(1 \text{ mm})^2$  device area. An image of the emission

**Figure 6.152** (a) Schematic illustration of the transparent OLED on the surface of a polymer waveguide/planarization layer on a diffuse dielectric reflector. The path of light emission from a region within the OLED (star) shows multiple reflections from the diffuse reflecting surface prior to escape from the top surface of the device. Direct emission from the surface is also shown at right. At each bounce, the light direction is randomized, resulting in a Lambertian emission profile (red ovals), some of which is reflected into the optical escape cone. (b) Fabrication sequence of the diffuser and polymer waveguide/planarization layer. After Kim et al. (2018).

from the PHOLED is shown in Fig. 6.153b, right, inset. The diffuse reflector isotropically redistributes the power, thus showing a nearly circular emission pattern. The measured radial intensity profile of the PHOLED following the trajectory of the horizontal dashed line in the simulated 2D intensity map is shown at the right in Fig. 6.153a. Integrating the radiated power outside the device active area indicates that approximately 55% of the total emission is emitted beyond the contact periphery. Given the broad dispersion of the light beneath the OLED area, this method results in considerable image blurring, making it useful only for lighting applications.

For large lighting fixtures, the fraction of emission in the tails vs. directly under the active area decreases exponentially with OLED diameter. Hence, in an extended lighting source, all the light eventually emerges via the top transparent OLED surface. The integrated modal power of air and substrate

modes after each reflection is given in Fig. 6.153c, showing that  $\sim 90\%$  of the light is emitted (including the direct emission from the top surface) after five bounces from the diffuse reflecting layer.

### 6.6.5 Outcoupling via molecular alignment

We illustrated several strategies in the previous sections that are effective in outcoupling up to 70% of the emission that is otherwise lost to surface plasmon and waveguide modes. A completely different approach to avoiding coupling to these loss channels is to align the TDMs of the emitting molecules parallel to the substrate plane. In this orientation, the emission is directed almost entirely perpendicular to the emitting surface, thus only exciting air and substrate modes. Equation 6.116 indicates that the degree of outcoupling is controlled by the ratio of TDM alignment in the vertical to the horizontal direction. That is, for  $\Theta = 0$ ,

**Figure 6.153** (a) Simulated radiant power for a PHOLED on a diffuse reflector substrate. (*left*) The black dashed line indicates the device active area. (*right*) Measured (circles) radial peak intensity profile along the white dashed line bisecting the PHOLED in (a) along with the ray tracing fit (line). Inset: Photograph of emission from the green, diffuse PHOLED. (c) Distribution of modal power in air and substrate modes following each reflection (Kim et al., 2018).

radiation is emitted normal to the substrate plane due to complete horizontal dipole alignment. The dipole radiation field due to vertical TDM orientation is shown in Fig. 6.154a. From electrostatics, the field intensity of a vertical dipole follows  $\sin^2 \alpha$  (Rao, 1994), where  $\alpha$  is the angle between the dipole vector and field direction (Rao, 1994). Thus, perfect dipolar orientation parallel to the substrate will excite both waveguide and SPP modes. These contributions will be far smaller than if the dipoles are randomly or vertically oriented.

The fraction of power emitted into each mode with different orientations for a green emitting device with  $\eta_{ext} = 1$  and the structure of: glass substrate/140 nm ITO/77 nm HTL/60 nm EML/ $d_{ETL}$  ETL/Ca:Al cathode are calculated using CPS theory with result in Fig. 6.155, where  $d_{ETL}$  is the ETL thickness. Complete horizontal dipole orientation (Fig. 6.155a) results in plasmonic loss only for  $d_{ETL} < 50$  nm. At larger ETL thicknesses where the metal cathode is in the weak fringe field of the dipole, the plasmonic losses nearly vanish. Of course, with increasing

ETL thickness, an increasing amount of energy is dissipated into waveguide modes. Horizontally oriented dipoles emit only  $\sim 20\%$  into air and another  $40\%$  into the substrate modes. The opposite situation obtains for predominantly vertical orientation in Fig. 6.155c. Here, plasmonic modes are dominant even for  $d_{ETL}$  as large as 150 nm, resulting in almost no emission into either air or even substrate modes. However, once the ETL is sufficiently thick, excitation of SPP modes is weakened and becomes negligible, yet the dominance of waveguide modes becomes even stronger than for random (Fig. 6.155b) or horizontal dipolar orientations, since the field intensity for vertical dipoles is almost entirely in-plane.

The external efficiencies of PHOLEDs as a function of molecular TDM orientation are summarized in Fig. 6.156. For this calculation, it is assumed that the 30 nm thick EML is spaced 40 nm from an Al cathode. The device is on a flat glass substrate with no further outcoupling employed. The PL quantum yield of an Ir(ppy)<sub>2</sub>acac molecule is  $\phi_{PL} = 0.94$ , corresponding to

**Figure 6.154** (a) Radiation field intensity distribution for a molecule with a vertical TDM (block arrow). (b) Schematic of the radiation fields from perfect horizontal ( $\Theta = 0$ ) to vertical ( $\Theta = 1$ ) TDM alignment. The TDMs are illustrated by ellipses, and the substrate plane is assumed to be parallel to the gray arrow at bottom (Courtesy, M. E. Thompson, 2018).

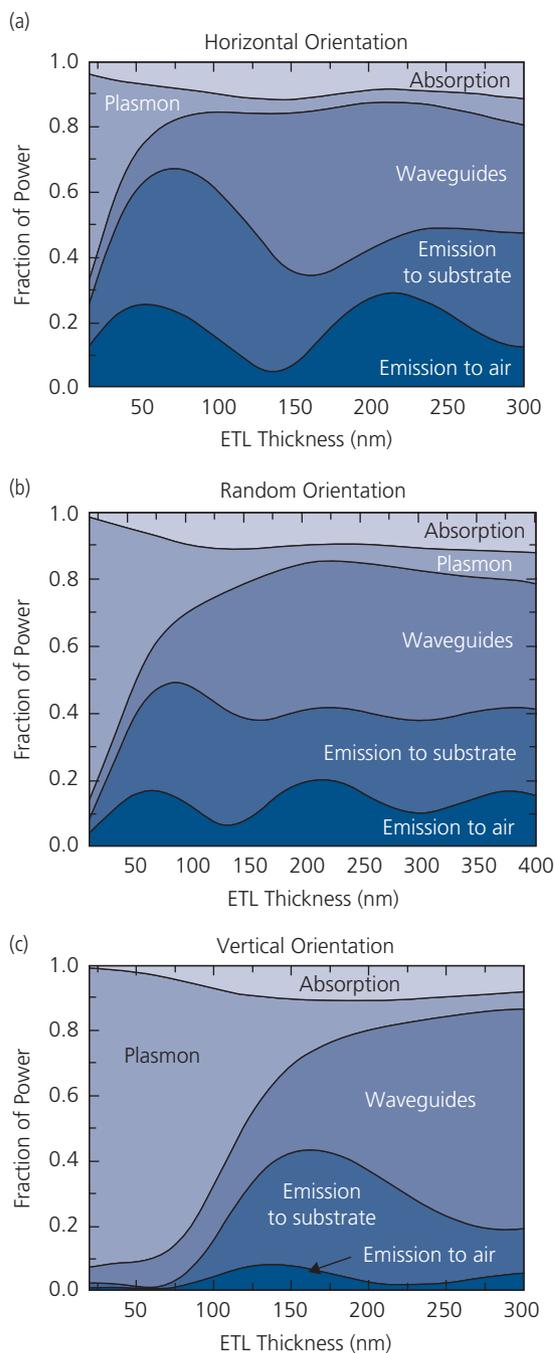

the horizontal dashed line. This analysis shows that for perfect horizontal TDM alignment and  $\phi_{PL} = 1$ , a maximum external quantum efficiency of 46% is possible.

The TDM orientation for the PHOLED was measured using the PL intensity vs. angle with results in Fig. 6.157. The fits employ independent ellipsometric measurements of the ordinary and extraordinary refractive indices ( $n_o$  and  $n_e$ , respectively) of host matrix (TCTA:B3PYMPM in this case). Then, the angle-dependent effective refractive index is

$$\frac{1}{n_{eff}^2} = \frac{\cos^2\theta}{n_o^2} + \frac{\sin^2\theta}{n_e^2}. \quad (6.120)$$

The best fit to the data yields an alignment principally in the horizontal direction, with  $\Theta = 0.23$ . Referring to Fig. 6.156, this should result in a PHOLED with  $\eta_{ext} = 29.7\%$ , which is consistent with the measured value of 30.2% (Kim et al., 2013b).

Preferential molecular alignment parallel to the substrate plane resulting in increased quantum efficiency has been observed in a wide range of fluorescent and phosphorescent materials. Early on, it was found that spin-cast polymer chains can align in the plane, resulting in increased outcoupling (McBranch et al., 1995). Linearly extended vacuum deposited small molecules also show a tendency to lie with their TDM parallel to the substrate (Frischeisen et al., 2010, Frischeisen et al., 2011), as do square planar Pt

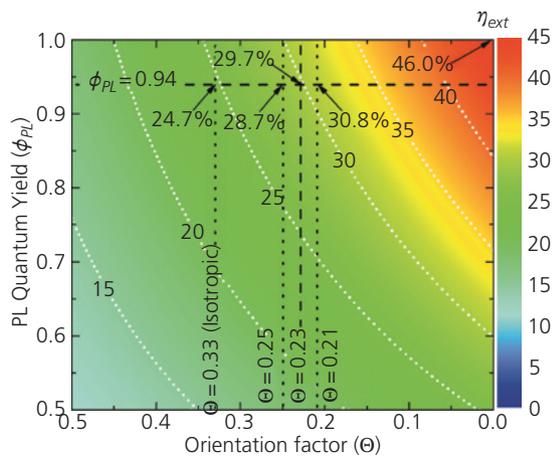

**Figure 6.155** Relative fraction of emitted power for different dipole orientations and the contribution from each OLED mode. It is assumed that  $\eta_{ext} = 1$  (Brütting et al., 2013).

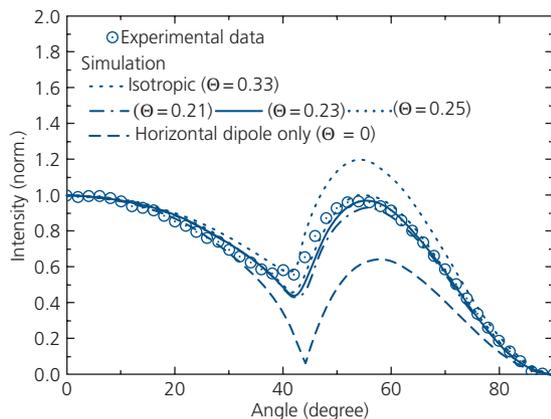

complexes (Wang et al., 2014a, Kim et al., 2016a, Ly et al., 2016). Also, the heteroleptic molecules,  $(C^{\wedge}N)_2IrX$ , where X is the ancillary ligand show alignment parallel to the substrate, independent of the host in which they are doped (Schmidt et al., 2011, Graf et al., 2014, Kim et al., 2014a, Kim et al., 2014b, Jurow

et al., 2016). In contrast, small molecular weight homoleptic phosphorescent dopants such as  $\text{Ir}(\text{ppy})_3$  whose dipole moments are isotropically distributed, show no tendency for preferred alignment (Graf et al., 2014, Kim et al., 2014b).

Several models have been advanced to explain the driving force that leads to molecular alignment. We have seen in Chapter 5 that ostensibly planar molecules grow into two preferred orientations relative to the substrate: flat lying or standing up. The different growth habits are a function of molecule/surface vs. molecule/molecule bond energies. That is, a strong molecule/surface binding due, for example to an extended molecular  $\pi$ -system, leads to a flat-lying

**Figure 6.156** External PHOLED quantum efficiency dependence on dipole orientation factor,  $\Theta$ , and PL quantum yield. For complete horizontal dipole alignment ( $\Theta = 0$ ), a maximum  $\eta_{\text{ext}} = 46\%$  is possible for a device on a flat glass substrate (Kim et al., 2013b).

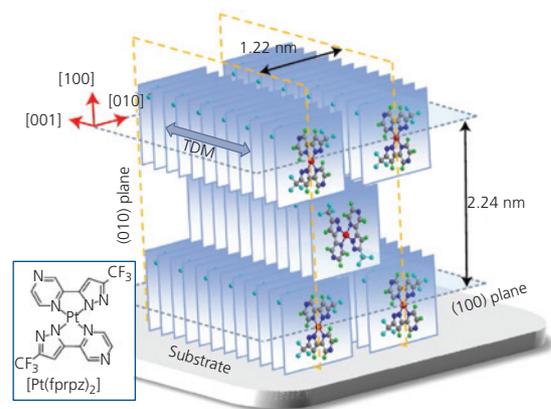

**Figure 6.157** PL intensity vs. angle for an EML comprising 8 vol.%  $\text{Ir}(\text{ppy})_2(\text{acac})$  in a 1:1 TCTA:B3PYMPM co-host. The data (circles) are fit (lines) to a dipole alignment factor of  $\Theta = 0.23$ . Also shown are expected angular dependences for  $\Theta = 0$  and 0.33 (Kim et al., 2013b).

motif. However, very strong intermolecular  $\pi$ - $\pi$  interactions may draw the molecules into standing perpendicular to the substrate to minimize energy. The preferred stacking habit is often determined solely by these interactions, or they can, to some degree, be controlled by the thermodynamic conditions used during growth. For example, the substrate temperature can be increased to drive vertical vs. horizontal alignment (Komino et al., 2014, Kim et al., 2019). Alternatively, spin-casting rather than vacuum deposition of films can lead to isotropic TDM orientations (Lampe et al., 2016).

The film growth habits leading to TDM orientation has been determined for the homoleptic 2-pyrazinyl pyrazolate Pt(II) complex,  $\text{Pt}(\text{fprpz})_2$ , using *grazing incidence wide angle x-ray scattering* (GIWAXS), with results given in Fig. 6.158. Strong intermolecular interactions result in a vertical molecular orientation relative to a fused silica substrate. This is induced by the  $^3\text{MMLCT}$  interactions whose excimer TDM lies in the substrate plane between adjacent molecules in a vertical stack. The resulting excimer emission has a peak wavelength of 740 nm. The horizontal alignment factor of  $\Theta = 0.87$  in the PHOLEDs with neat EMLs indicates near perfect horizontal alignment of the TDM, leading to  $\eta_{\text{ext}} = 24\%$  (Ly et al., 2016).

In neat films, planar molecular orientations appear to be driven by molecule/interface energies and growth kinetics. In contrast, orientation is largely independent of the host material for a number of homo- and heteroleptic pseudo-octahedral Ir-complexes. Table 6.13 lists a number of such complexes, all of

**Figure 6.158** Stacking habit of  $\text{Pt}(\text{fprpz})_2$  on a fused silica substrate. The TDM orientation of the excimer state is parallel to the substrate (blue block arrow). Inset: Molecular structural formula of  $\text{Pt}(\text{fprpz})_2$  (Ly et al., 2016).

which are approximately spherically shaped. However, the TDM vectors of molecules containing an aliphatic acetyl acetate (acac) group lie preferentially parallel to the substrate plane. Those without such a group (the three Ir complexes near the bottom of the Table) appear to have no preferred orientation.

It is noteworthy that the horizontal alignment factor is, thus, nearly independent of the static dipole moment of the molecules, or the host matrix shape or composition. Several theories have been advanced as to the source of this alignment. One model suggests that high molecular dipole moments lead to electrostatically driven aggregation of dopants, which tends to randomize the orientation (Graf et al., 2014). This potentially explains why Ir(ppy)<sub>3</sub>, with its comparatively large static dipole moment of 6.40 D exhibits a nearly isotropic TDM in the solid state. However, this apparently contradicts the observed preferred horizontal orientations of Ir(bppo)<sub>2</sub>(acac) (bppo = benzopyranopyridinone) and Ir(tBuCN-F)<sub>2</sub>(acac) with even higher dipole moments. It has been suggested that the large static dipole can lead to electrostatic guest–host interactions that align the aggregates at the growth interface. While host molecules are often approximately planar with a high aspect ratio, they have a very small or no dipole moment. Once again, Table 6.13 shows no apparent correlation

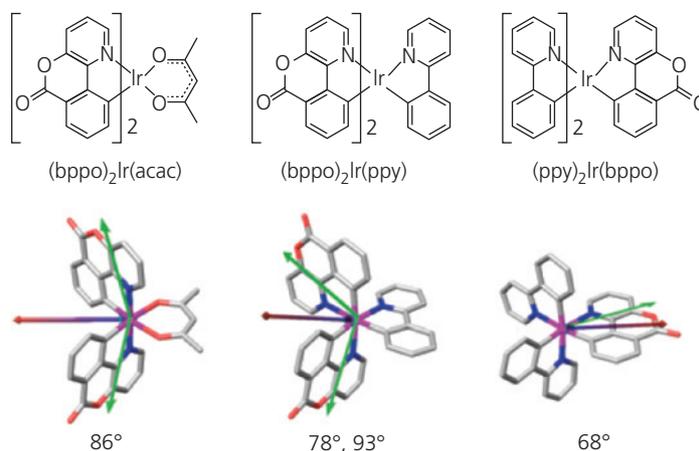

between host or dopant composition, which brings this model into doubt (Kim et al., 2014a).

To identify the molecular properties that drive orientation, the angular emission patterns of Ir-complexes with coumarin-based bppo ligands shown in Fig. 6.159 were measured. The carbonyl (C=O) groups are dipolar, allowing the molecules to cluster when doped at 20 vol.% in a CBP host. Their ground state (static) dipole moments range from 6.18 D for Ir(bppo)<sub>2</sub>(acac) to 8.44 D for Ir(ppy)(bppo)<sub>2</sub>. The broadened and quenched spectra with increasing doping concentration from 6 to 20vol.% indicate that aggregates are, in fact, formed.

Interestingly, only the PL spectra of Ir(bppo)<sub>2</sub>(acac) show preferential horizontal alignment with  $\Theta = 0.22$ . The other two bppo-based molecules form isotropically emitting films, with  $\Theta = 0.32$ – $0.33$ . This alignment morphology is independent of the angle between the TDM and the permanent molecular dipole vectors. Indeed, Ir(bppo)<sub>2</sub>Ir(acac) and Ir(bppo)<sub>2</sub>Ir(ppy) have a similar angle between these vectors, yet the former compound forms preferentially aligned, and the latter forms isotropic films when co-deposited with the common host, CBP, whose long axis lies in the substrate plane. Hence, it is unlikely that dipole-dependent guest–host interactions determine the degree of horizontal alignment.

**Table 6.13** Horizontal alignment factors and static dipole moments of several Ir-phosphors in various host matrices (Jurow et al., 2016)

Emitter molecule	Host	Orientation ( $\Theta$ )	Static dipole moment (D)	Reference

It has also been proposed that hosts with low *glass transition temperatures* ( $T_g$ ) may form clusters during or after deposition (Dalal et al., 2015). The glass transition temperature is where the amorphous material makes a transition from a hard glassy state to a more flexible (rubbery) viscous state. The dependence of molecular orientation on host composition, and the process used in depositing the films for a series of heteroleptic Ir-complexes containing aliphatic acetylacetonate ancillary ligands as well as the homoleptic Ir(ppy)<sub>3</sub> has been investigated, with results summarized in Fig. 6.160 (Lampe et al., 2016). The different hosts have a range of glass transition temperatures (and hence propensity for crystallization). They were co-deposited either from vacuum, or spin-casting with four Ir-complexes. Spiro2-CBP and PMMA have considerably higher  $T_g$  than either CBP or NPB, which are known to crystallize at temperatures as low as 50°C. With the exception of Ir(ppy)<sub>3</sub>, vacuum deposition results in preferred horizontal alignment in all hosts tested (open symbols). The alignment following spin casting, however does not show this preference. Solution processed guest–host blends result in an isotropic orientation of the TDM vectors, and in a few cases there is even a slight preference for vertical dipole alignment.

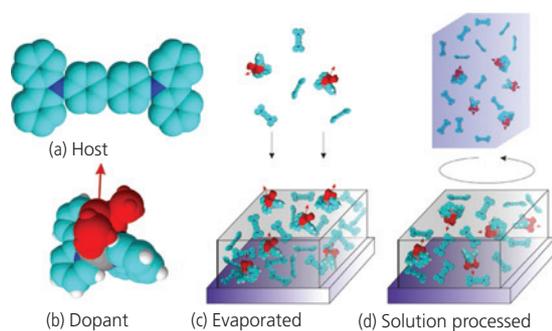

A consistent explanation of these phenomena is offered in Fig. 6.161. Deposition of a CBP:Ir(ppy)<sub>2</sub>(acac) layer occurs at the vacuum/solid interface of the film. At the growth interface, the aliphatic (acac) groups are presumably forced to orient toward vacuum while the phenylpyridine groups highlighted in red

lie along the molecular C2 axis extending from the Ir core. The molecules thus aligned adhere to the solid surface, thereby creating a preferred in-plane orientation of the TDM that is perpendicular to the C2 axis. In contrast, CBP arrives without a preferred orientation. This relative orientation of vectors is shown for Ir(bppo)<sub>2</sub>(acac) in Fig. 6.159. The orientation is presumably driven by a surface energy mechanism similar to that of molecules with hydrophobic and hydrophilic end groups in Langmuir-Blodgett thin film deposition (see Section 5.4.2). In this picture, the molecules deposited from solution in Fig. 6.161 lack a defined vacuum/solid interface, preventing them from finding a preferred emitter or host orientation (Jurow et al., 2016). While this is a plausible explanation for the horizontal alignment observed for Ir-complexes containing ancillary aliphatic groups grown by VTE, to our knowledge there is not yet a quantitative energetic model to support it.

The methods of alignment discussed above are thermodynamically driven, with the outcome dependent on the energetic relationship between the molecule and substrate surface. In Section 5.4.2, we showed that the energy topography of the surface can be modified by pretreatment and by templating. The various morphologies that can be achieved during growth on various surfaces are illustrated in Fig. 6.162. In the foregoing discussion we showed that blends of the guest and host can be random, or the host itself can drive the orientation of the dopants within the blend to maximize horizontal TDM alignment. The most directed approach is to initiate

**Figure 6.160** Horizontal TDM alignment factor for various host and dopant combinations. Filled symbols correspond to samples cast from solution, open symbols to co-deposition via vacuum thermal evaporation (Lampe et al., 2016).

**Figure 6.161** Molecular structures of the (a) CBP host and (b)  $\text{Ir}(\text{ppy})_2(\text{acac})$ . The acac group is highlighted in red, and the C2 axis vector between the Ir atom and this aliphatic group is shown (arrow). (c) Growth of a  $\text{CBP}:\text{Ir}(\text{ppy})_2(\text{acac})$  via vacuum thermal evaporation. At the growth interface, the acac groups orient toward vacuum, and the phenylpyridine groups adhere to the solid surface creating a preferred in-plane orientation of the TDM located perpendicular to the C2 axis (cf. Fig. 6.159). (d) Solution-processed films have no vacuum/solid interface, and hence randomize the TDM orientation (Lampe et al., 2016).

growth of the guest/host system on a pre-deposited *template layer*, thus ensuring that the desired alignment is forced on the subsequently deposited structure (right hand side of the figure).

An example of forced alignment by deposition on a structural template is shown for the square planar Pt complex, PtD shown in the inset of Fig. 6.163. The PtD was deposited by VTE on a bilayer of 1.5 nm PTCDA/1.5 nm NTCDA on sapphire. As shown previously,

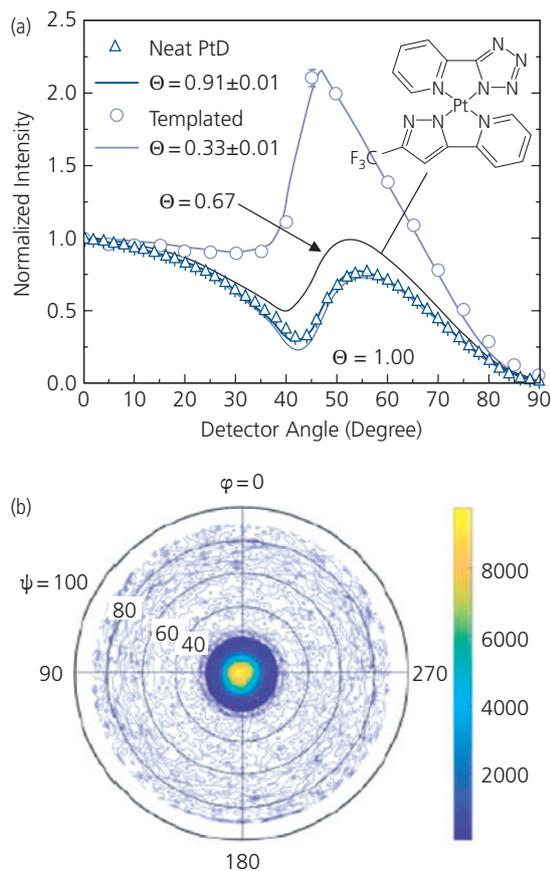

PTCDA self-organizes into planar stacks with monolayer flatness across a large area. However, the energy gap of PTCDA is small (2.2 eV), and hence it can quench excitons in the layer deposited on its surface. Thus, the wide energy gap NTCDA is deposited on the PTCDA film, thereby transferring the template structure to the subsequently deposited Pt-complex. The templated PtD shows a decreased horizontal orientation ( $\Theta_{hor} = 0.33 \pm 0.01$ ) of the PtD dimer whose TDM extends between Pt centers of adjacent molecules, compared to deposition on a bare fused silica substrate with  $\Theta_{hor} = 0.91 \pm 0.01$  (see Fig. 6.163a). Thus, the horizontal TDM for the neat film corresponds to PtD molecules orientated with their planes perpendicular to the substrate surface. To verify this spatial relationship, an X-ray pole figure of the (200) plane is provided in Fig. 6.163b. The film deposited directly on the sapphire substrate in shows the (200) diffraction peak ( $2\theta = 8.2\text{--}8.5^\circ$ ) at a radial angle of  $\psi = 0^\circ$ , suggesting that (200) plane lies parallel to the substrate. Note that the (200) plane is perpendicular to the molecular stacking axis along the (020) plane. There is a striking contrast between the TDM orientations with and without the exogenous template, from parallel to nearly completely vertical relative to the substrate plane, respectively (Kim et al., 2019).

In summary, molecular alignment appears to be an effective means to improve optical outcoupling by decreasing the efficiency of excitation of waveguide and SPP modes using many octahedral or dihedral phosphorescent complexes, as well as high aspect

ratio planar molecules used in fluorescent and TADF-based OLEDs. Alignment is controlled to a limited degree by the conditions used during growth (Ráfols-Ribé et al., 2018), material glass transition

temperature, spin casting, substrate structure, templating, etc., although the primary driving force for alignment is the molecular structure itself. The coupling to only substrate and air modes is limited by the spatially distributed emission pattern of the dipoles. Nevertheless, efficiencies in the absence of additional substrate outcoupling schemes can potentially be as high as 45%. The primary disadvantage of dipole alignment is that it requires that the molecular design and deposition process promote TDM alignment in the desired direction. Given the numerous other requirements placed on high performance molecules used in optimized display and lighting applications, also demanding that materials meet this additional design criterion might not always be possible.

### 6.6.6 Summary and prospects

In this section we have reviewed several criteria that should be met for effective outcoupling, and have shown a few ingenious approaches toward achieving that goal. We have found that extracting substrate modes is achieved using a dense array of microlenses that can be fabricated by molding polymers, followed by their attachment to the substrate. Extracting waveguide and SPP modes is considerably more challenging. Yet, the use of modified substrates (e.g. sub-anode grids), and transparent contacts are effective since they can eliminate exciting modes in the first place. Extracting  $\sim 70\%$  of the trapped light has been achieved, although not without adding complexity to the OLED design. Finally, we have shown that alignment of molecular transition dipoles parallel to the substrate plane can eliminate most waveguide and SPP modes, particularly for planar Pt-based phosphors and fluorescent molecules, as well as some Ir-complexes with non-emissive ancillary ligands.

Based on these findings, it appears likely that practical outcoupling schemes that outcouple 80% of the emitting power are possible. Since phosphorescent

complexes have shown up to 100% internal efficiency, achieving this goal will result in display and lighting appliances with  $\eta_{ext} = 80\%$ . Efficiencies of this magnitude are now leading to new, and perhaps unprecedented applications in efficient information displays and lighting.

## 6.7 Reliability of organic light emitters

Since the invention of efficient OLEDs, questions have been raised about their potential for practical use given the nearly universal observation up to that time that organic electronic device properties were unstable, that is, they rapidly change over time and often suffer from catastrophic failure soon after fabrication. This lack of reliability makes such devices unsuitable for practical applications, where the user of a smart phone, tablet or TV monitor reasonably expects their appliance to work trouble-free over many years. For this reason, quantifying and increasing the reliability of OLEDs has been the focus of considerable research over several decades. Today, OLEDs are beginning to dominate the entire display industry due, among other things, to the progress made in extending their operational lifetimes.

In this section, we review the methodologies employed in quantifying OLED reliability, and discuss metrics that must be met to qualify devices for display and lighting applications. This discussion lays out general techniques that are also useful for characterizing other electronic devices including OPVs and OTFTs in Chapters 7 and 8. Once the methods have been established, we will discuss the major failure mechanisms that are active in OLEDs. Device aging, or failure, falls generally into two categories: failure due to *extrinsic* or *intrinsic* mechanisms. Extrinsic causes for degradation are those whose origins are not an inherent property of the material or the device itself. Examples include catastrophic failure due to shorts via dust particles left on the substrate, material impurities or film inhomogeneities introduced during film preparation. In Chapter 5 we showed that extrinsic impurities have many deleterious effects on device operation, such as reduction in luminescence from non-radiative recombination, reduction in exciton and charge diffusion lengths, and most assuredly on device stability. Also, exposure to environmental contaminants such as moisture or oxygen in poorly or unpackaged devices falls into this category. In the following discussion, we generally assume that extrinsic sources of failure have been eliminated in environmentally protected devices that have been

fabricated by stable and proven processes, using materials that have been highly purified prior to use.

Intrinsic degradation is due to changes over time of the inherent properties of the materials used or the device architecture. While not always easily distinguished from extrinsic process, intrinsic processes include: (i) Degradation of contacts and heterointerfaces that changes the charge density and balance within the OLED structure, (ii) thermally induced morphological instabilities, (iii) dissociation and fragmentation of chemical species within the OLED, (iv) energy-driven degradation of blue phosphorescent and TADF emitters, and (v) exposure to environmental agents in OLEDs employing semipermeable (e.g. plastic) substrates.

### 6.7.1 Quantifying OLED long term performance and reliability

The lifetime of electronic devices is determined by first setting the criteria for failure. In OLEDs, this is typically defined as the time,  $t$ , it takes for the luminance ( $L(t)$ ) to reach a predetermined value lower than its initial luminance ( $L_0$ ), when the device is deemed to no longer be useful (i.e. it has failed). Then its *time to failure* or *lifetime* is denoted  $T_x$ , or alternatively,  $LT_x$ , where  $x$  is 100 times the ratio  $L(t)/L_0$  that corresponds to device failure. For example, if  $L/L_0 = 0.5$  is set as the failure criterion, then the time  $t'$  that it takes to reach this luminance corresponds to  $LT50 = t'$ . To put this value in context, the time to failure must be specified along with the test conditions that might affect its value, including  $L_0$ , temperature,  $T$ , ambient properties (e.g. humidity), etc.

The intended application sets the conditions that define failure. For example, displays are operated at  $\sim 100$  cd/m<sup>2</sup>, although we have shown in Table 6.10 that the actual pixel luminance on the display front plane can be nearly 60 times that value due to the small aperture ratio and differential aging of the R, G and B pixels. Furthermore, the eye is highly sensitive to small luminance differences between pixels. Hence, display pixels are commonly tested at  $L_0 = 1000$  cd/m<sup>2</sup>, and are assumed to fail once 5–10% of the initial luminance is lost. That is,  $LT95$  or  $LT90$  provides the failure criterion for information display pixels. The industrial metric for the lifetime of lighting sources, on the other hand, not only employs a different luminance and luminance loss criterion, but also a shift in color coordinates. Typically, OLED lighting sources are tested at  $L_0 = 3000$  cd/m<sup>2</sup>, and are assumed to have failed at  $LT70$ , with a maximum color shift of  $\Delta u = \Delta v \approx 0.03$ .

Since lifetime depends on multiple factors that vary from device to device, meaningful failure analysis must be done on a statistically significant population of devices, with the ultimate objective of predicting the operational lifetime of fresh devices manufactured by the same process as the test population. The measured lifetime that characterizes the population is specified as the *mean time to failure*, or *MTTF*, of members of that population. Other important quantities to measure include the *failure rate*, which is the number of failures per unit time, and *B(X) life* which is the time at which the probability for failure has reached *X%*. The statistical analysis of the failure of a population of devices independent of the specifics of the technology employed is known as a *Weibull analysis* (Weibull, 1939).

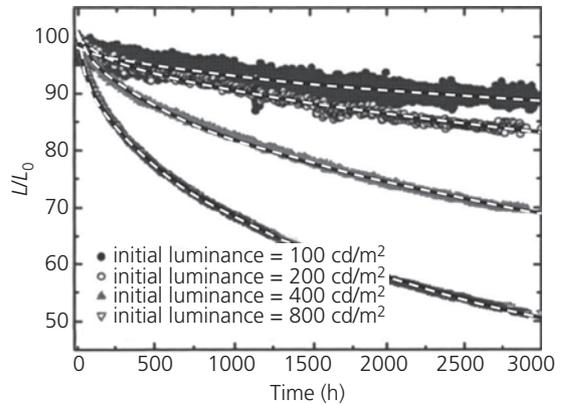

Several functions have been used to empirically model  $L(t)$  to predict the lifetime for a particular device architecture, materials set, and fabrication process. Given their parametric nature, the best models accurately fit the luminance for times relevant for practical device operation. These functions include the *stretched exponential*:

$$L(t)/L_0 = \exp\left[-(t/\tau)^\beta\right], \quad (6.121)$$

where  $\tau$  is the characteristic luminance decay time and  $\beta$  is the dispersion factor that determines the shape (or “speed”) of the exponential decay (Ishii, 2003, Féry et al., 2005). This is a particularly simple functional form, requiring only two fitting parameters. Furthermore, the value of  $\beta$  is largely independent of  $L_0$ , as shown by the data in Fig. 6.164 for a green emitting OLED fit using  $\beta = 0.53$  for  $L_0$  from 100 to 800  $\text{cd}/\text{m}^2$ .

There is no theoretical framework with which to predict the stretched exponential. If we assume that the luminance degradation arises from destruction of emitting molecules via reaction with other species such as excited states or polarons (Aziz et al., 1999), then the luminance depends on the concentration of surviving emissive molecules at time  $t$ . In this simple picture, we expect that  $L(t)$  would follow Eq. 6.121 with  $\beta = 1$ , that is, a simple exponential. Since typically  $\beta < 1$  as in the population in Fig. 6.164, the rate of degradation must depend on the depletion of more than one species. That is, it might be catalyzed by the addition of an excited state of a nearby emissive molecule, or an impurity. The number of nearby pairs, therefore, rapidly decreases at the early stages of life, slowing as the EML is left only with lone molecules that have no opportunity to react with appropriate species in their immediate neighborhood.

For long-lived devices, it is often inconvenient to wait until failure under the anticipated operating

**Figure 6.164** Luminance decay of an OLED for several values of  $L_0$  shown in legend. Data are shown by points, and fits (dashed lines) to a stretched exponential (Eq. 6.121) with  $\beta = 0.53$  for various  $\tau$  are shown by lines (Féry et al., 2005).

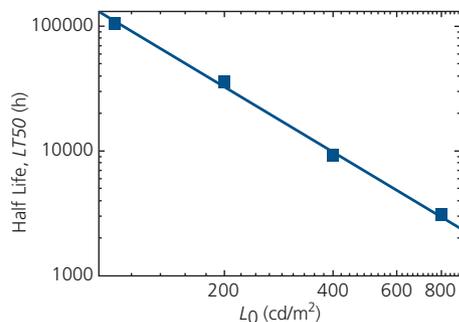

conditions to determine the  $LT_x$  of the population. Hence, the use of a functional form such as Eq. 6.121 is essential, but its accuracy in predicting  $LT_x$  depends on the accuracy with which  $\tau$  and  $\beta$  can be determined over the time the device is under test. Hence, we often quote the *extrapolated luminous lifetime*, which is the  $LT_x$  determined by extrapolating the actual measured time to the calculated lifetime of the population using a characteristic degradation function as the stretched exponential.

An alternative means for decreasing the time under test is to use *accelerated aging* methodologies. For example, for lighting applications, we require  $L_0 = 1000\text{--}3000 \text{ cd}/\text{m}^2$  and  $LT_{70} = 50,000 \text{ h}$ . For displays, the criteria are even more stringent: typically  $L_0 = 600\text{--}6000 \text{ cd}/\text{m}^2$  (depending on the pixel color, see Table 6.10) and  $LT_{90} = 10,000\text{--}30,000 \text{ h}$ , since only a few percent of differential aging between color pixels is easily discerned as a shift in hue (Laaperi, 2008). Hence, it is impractical to wait for such long times to directly measure the MTTF. There are two principal means for accelerating the aging of OLEDs: by increasing intensity (which, equivalently, corresponds to an increase in drive current), or by increasing the temperature.

Once again, the aging factors are empirically determined by measuring the changes in the slope of  $L(t)$  as either intensity or temperature conditions are varied. It has been found that the lifetime depends on the initial luminance following:

$$LT_x(L_0) = LT_x(L_{0st}) \cdot \left[\frac{L_{0st}}{L_0}\right]^n, \quad (6.122)$$

where  $L_{0st}$  is the initial luminance of the device under accelerated test conditions, which is greater than its value under normal operating conditions ( $L_0$ ), and  $n$  is

**Figure 6.165** Accelerated aging of the green OLED in Fig. 6.164 via increasing initial luminance,  $L_0$ . The data are shown by squares, and the power law fit using Eq. 6.122 with  $n = 1.7$  is shown by the line (Féry et al., 2005).

the acceleration factor that varies between 1.5 and 2.5 (Féry et al., 2005, Orselli et al., 2012, Zhang et al., 2014b). A plot of  $LT_{50}$  vs.  $L_0$  for the device in Fig. 6.164 is shown in Fig. 6.165. The data (squares) are fit by the straight line with  $n = 1.7$ . Note, that since  $L \propto j$ , we conclude that lifetime is determined by the total amount of charge that has passed through the OLED, and since  $n > 1$ , increasing the initial charge density results in more rapid generation of non-radiative defects than at lower charge densities. This is consistent with the model that aging is catalyzed by multiple excitations on a single molecule, or between neighboring molecules. Our discussion of energy-related degradation in Section 6.7.4 lends further support to this hypothesis.

Increasing the operating temperature can also accelerate aging. We might assume that the probability for destroying an emitting molecule is thermally activated, that is, the probability is  $P = \exp(-\Delta E_A/k_B T)$ , where  $\Delta E_A$  is the activation energy for the formation of non-radiative molecular species. As noted above, the probability is increased by the presence of other emitting molecules. Hence the energy for defect formation decreases as the number of emitting molecules,  $n_e$ , decreases (Féry et al., 2005):

$$\Delta E_A(n_e) = \Delta E_{A0} - K(n_{e0} - n_e), \quad (6.123)$$

where  $K$  is a constant, and  $n_{e0}$  and  $\Delta E_{A0}$  are the number of emitting molecules and the defect activation energy at  $t = 0$ . Then the rate of defect formation is

$$\frac{dn_e}{dt} = \frac{1}{\tau_r} \exp(-\Delta E_A(n_e)/k_B T) - K'n_e, \quad (6.124)$$

where  $K'$  is chosen to meet the boundary condition that  $dn_e/dt = 0$  at  $t \rightarrow \infty$ , and  $\tau_r$  is the radiative emission time for the molecules that competes with

defect formation. Solving Eq. 6.123 using Eq. 6.124 yields a thermally activated luminance decay time

$$\tau = \frac{\tau_r}{n_{e0}} \exp[(\Delta E_{A0} - Kn_{e0}^2)/k_B T]. \quad (6.125)$$

Hence, the luminance time constant,  $\tau$ , decreases with increasing  $T$ . From Eq. 6.121, this suggests that increasing temperature will accelerate the degradation in luminance. The dependence of the activation energy on the number of emitting centers in Eq. 6.125 thus yields the stretched exponential behavior of the luminance.

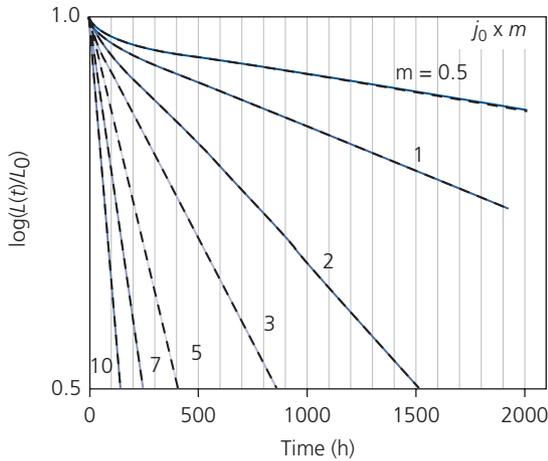

We have previously noted that, lacking an analytical theory for device degradation, the fits to  $L(t)$  are inherently empirical. Hence, other expressions have been used to approximate this decay, but none with as few parameters as Eq. 6.121 (Tsujimura et al., 2012, Yoshioka et al., 2014). In fact, the precision of the extrapolated lifetime using this simple expression has not always been acceptable (Meerheim et al., 2006, Orselli et al., 2012). To increase the accuracy over a long test period, a sum of exponentials can be employed, viz. (Yoshioka et al., 2014)

$$L(t)/L_0 = \lambda \exp(-t/\tau_1) + (1 - \lambda) \exp(-t/\tau_2), \quad (6.126)$$

where  $\lambda$ ,  $\tau_1$  and  $\tau_2$  are fitting parameters. The first term expresses the rapid initial decay, and the second fits the extended long-term decay. Hence,  $\tau_1 \ll \tau_2$  and  $\lambda$  depends on the relative magnitudes of these two aging regimes. Since most of the luminance loss occurs over the long term in reasonably high performance OLEDs, it is safely assumed that  $\lambda \ll 1$ . In fact, the physical assumptions leading to both Eqs. 6.121 and 6.126 are similar; that initial decay is more rapid than long term luminance loss due to an initially accelerated depletion of emitting molecules.

The use of Eq. 6.126 entails the separate fits to the early and late stages of luminance decay, with  $L(t)$  vs.  $j$  shown in Fig. 6.166 for a PHOLED with the structure: glass substrate/150 nm ITO/60 nm HATCN/30 nm Ir(ppy)<sub>3</sub> (6%):CBP/10 nm BALq/30 nm Alq<sub>3</sub>/1.6 nm LiF/150 nm Al. The sum of exponentials provides an accurate fit to the data at all current densities, with a reasonable expectation for predicting  $LT_{50}$  even at the lowest current densities examined. The rather small impact of early aging is observed at the lowest current densities ( $m \leq 2$ ), where adjustments at  $t < 200$  h were needed to assure that  $L(t)/L_0 = 1$  at  $t = 0$ .

The thermal activation of degradation following Eq. 6.125 is shown in Fig. 6.167 for the same green PHOLED. We observe that the data for the long term rate is thermally activated, independent of

**Figure 6.166** Luminance vs. time of a green PHOLED at several different current densities at  $T = 25^\circ\text{C}$ . Here,  $j_0 = 6 \text{ mA/cm}^2$  corresponds to  $L_0 = 1800 \text{ cd/m}^2$ . The data are shown by solid lines, and the fits to the sum of exponentials (Eq. 6.125) are dashed lines (Yoshioka et al., 2014).

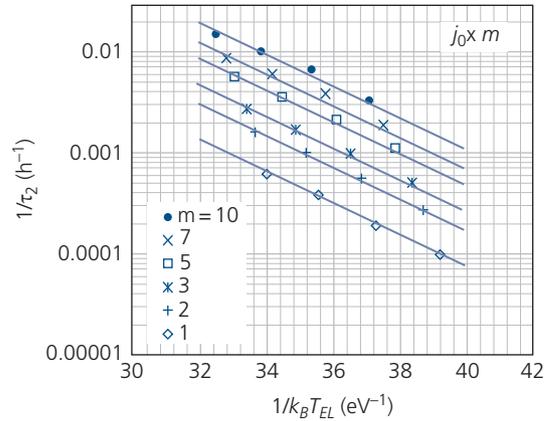

current density. The activation energy, which is also independent of  $j$ , is  $\Delta E_{A0} = 0.34 \pm 0.02 \text{ eV}$ . The thermally activated luminance decay suggests that increasing temperature can predictably accelerate the OLED aging. However, it is important that a single value of  $\Delta E_{A0}$  is associated with each failure mechanism. Hence, the aging temperature should not be so high as to introduce new degradation channels that are inactive under normal device operating conditions (i.e. employing  $T > T_{gr}$ , the glass transition temperature of the layers).

Combining the results of the data in Figs. 6.166 and 6.167, along with the sum of exponentials empirical analysis, we arrive at an expression for the long-term decay time constant of

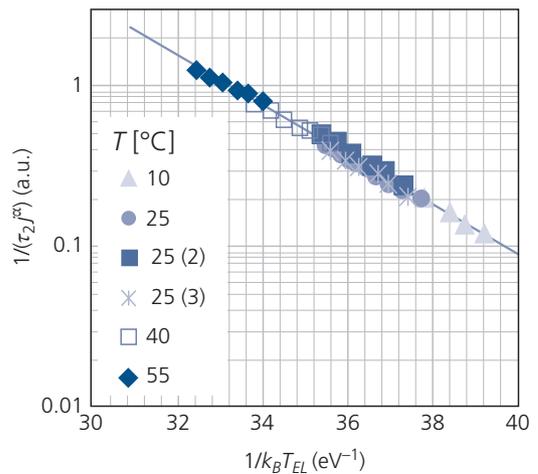

$$\frac{1}{\tau_2} = K'' j^\alpha \exp(-\Delta E_{A0}/k_B T), \quad (6.127)$$

where  $K''$  is a fitting parameter. The universality of Eq. 6.127 is illustrated by a plot of all the lifetime, current and temperature data of Figs. 6.166 and 6.167, in Fig. 6.168 using  $\alpha = 1.20$  and  $\Delta E_{A0} = 0.34 \text{ eV}$ . The observation that all the data fall on a single line implies that  $\Delta E_{A0}$  and  $\alpha$  are independent of the test conditions. Furthermore, these data support the conclusion that the luminance depends on the total amount of charge that has flowed through the device at a given time during its life cycle.

The test conditions used in obtaining reproducible and accurate data for the long term reliability of the devices must be carefully controlled. As noted previously, to achieve long lifetimes and reliable data

**Figure 6.167** Thermal activation of  $\tau_2$  in Eq. 6.126 at several current densities. Here,  $j_0 = 6 \text{ mA/cm}^2$  corresponding to  $L_0 = 1800 \text{ cd/m}^2$ .  $T_{EL}$  is the actual temperature of the organic layers as determined from the temperature dependent  $j$ - $V$  characteristics. The data are shown by points, and the fits to Eq. 6.125 (assuming  $K\tau_{A0}^2 \rightarrow 0$ ) are lines (Yoshioka et al., 2014).

**Figure 6.168** Universal dependence of the luminance loss of green PHOLEDs on current and ambient temperature ( $T$ ) following Eq. 6.127 (Yoshioka et al., 2014).

sets, the materials used must be purified, and the fabrication conditions are sufficiently stable to ensure there is little variation between device characteristics made on different processing cycles. Absent this stability of the fabrication process, the aging tests are likely to be tainted by minor, and relatively uninteresting variations between device populations whose presence will obscure the underlying sources of failure and result in errors in the extrapolated device lifetime.

Beyond process stability and materials purity, long-term reliability tests should have the following features:

- (i) A statistically significant population of devices should be examined to ensure reliable determination of  $LT_x$ . Since the random uncertainty of a parameter in a population of  $N$  devices is proportional to  $\sqrt{N}$ , a minimum number of devices for a trustworthy sampling typically ranges from 10 to 100.
- (ii) Care must be taken to ensure the test parameters (e.g.  $j$ ,  $T$ ) and measurement systems are accurate and stable over long test periods of typically 100–10,000 h.
- (iii) The devices must be maintained in a controlled environment for the duration of the test. These parameters include humidity, temperature and ambient light. It is common that the OLEDs are contained in packages that are epoxy sealed in ultrahigh purity nitrogen (<1 ppm  $O_2$  or  $H_2O$ ), along with a desiccant to scavenge residual  $H_2O$  incorporated in the organic films and package prior to encapsulation. A typical OLED package used in lifetime and in practical applications is illustrated in Fig. 6.169. The packages are sealed with a UV cured epoxy applied around the periphery of the lid and substrate. The lid is often either metal or a second thin glass sheet. A desiccant such as BaO is deposited on the inner surface of the lid.

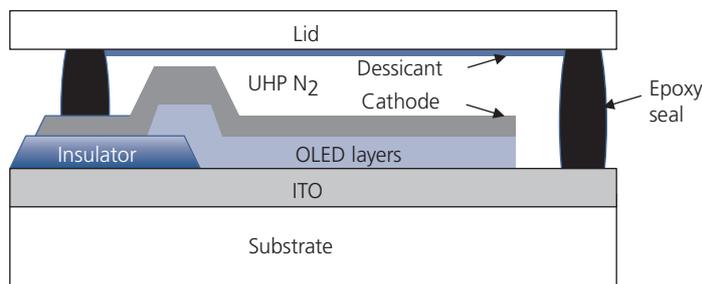

### 6.7.2 Degradation due to contacts and interfaces

The quality of the contacts and heterointerfaces within the device structure can have significant effects on the OLED lifetime. This failure mode can result from defects, impurities, charge, and excited state-induced chemical degradation of the layers. And when the interface presents a significant barrier to charge transport it can induce thermally-activated morphological and chemical changes. Many of these effects are of exogenous origin, and hence can be

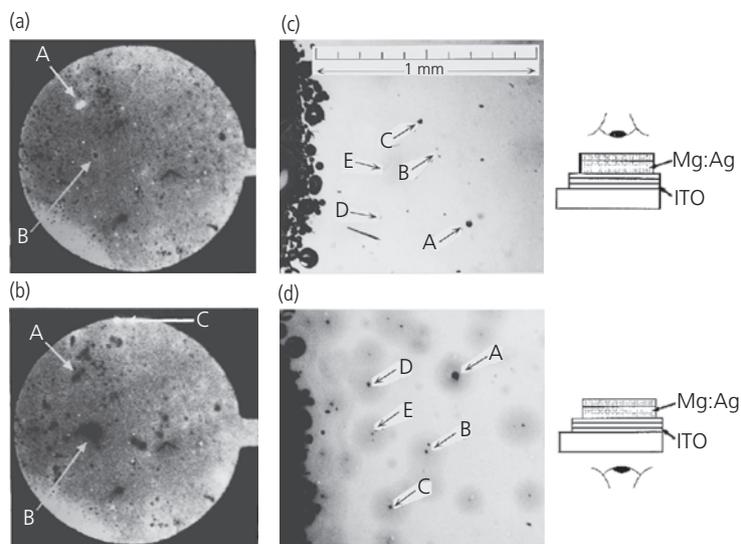

reduced or eliminated by using only stable materials, and the OLED fabrication processes are carefully controlled to prevent defects and impurities from entering the device active area.

Dark spot defects visible at the cathode contact have been identified as a significant source of failure (Burrows et al., 1994). The formation of dark spots was microscopically investigated in conventional Alq<sub>3</sub>/TPD devices. The devices exhibit considerable non-uniformities in EL intensity across their diameters (Fig. 6.170a and b). Several bright spots observed when the device is first turned on in air eventually transition to dark spots. Also, small dark spots grow, and even a few dark spots become intensely, albeit briefly luminescent with time. These changes are attributed to film non-uniformities, or to dust or other defects residing on the substrate that create pinholes. The electric field at the edges of the non-uniform region is higher than elsewhere, forming areas where the current (and hence the EL) is higher. These quickly carbonize, resulting in regions of relatively low emission intensity that continue to grow over time until the entire device area is consumed, rendering the OLED entirely non-emissive.

Packaged devices aged for several hundred hours show numerous pinholes apparent in the top electrode surface. When viewed from the bottom, the pinholes are still visible, which indicates that they penetrate the entire film. Furthermore, they are surrounded by discolored and non-emissive halos (Fig. 6.170c and d). These regions are possibly due to de-wetting (i.e. blistering) of the organic from the metal cathode. As in the EL images, the pinholes are likely due to defects in the film, electrode or ITO, creating regions of high electric field that burn out over time. It has been proposed that the discolored areas may be due to galvanic corrosion of Mg, resulting in the evolution of Mg(OH)<sub>2</sub> gas that forces the

**Figure 6.169** Example OLED packaging scheme. The insulator (often SiN<sub>x</sub> or SiO<sub>2</sub>) is used to prevent the metal cathode and ITO anode from shorting. The desiccant (e.g. BaO) is pre-deposited onto the glass or metal lid. Ultrahigh purity (UHP) N<sub>2</sub> or other inert gas fills the gap between lid and substrate. The package is sealed with UV curable epoxy applied around its periphery.

**Figure 6.170** (a) Relative EL intensity image of an as-grown unpackaged Alq<sub>3</sub>/TPD OLED as viewed via the ITO contact. (b) Image taken after operation for 4 min in air, showing that one defect (A) transitions from a high intensity spot to a dark spot, and another that begins as a small dark spot (B) has grown. An edge defect (C) transitions from dark to light. (c) Micrographs near the edge of the cathode contact of an encapsulated OLED after several hundred hours of operation as viewed from the top and (d) bottom surfaces of the device as shown in diagrams to the right (Burrows et al., 1994).

organic to delaminate from the electrode around the pinholes, subsequently admitting water into the active region (Aziz et al., 1998).

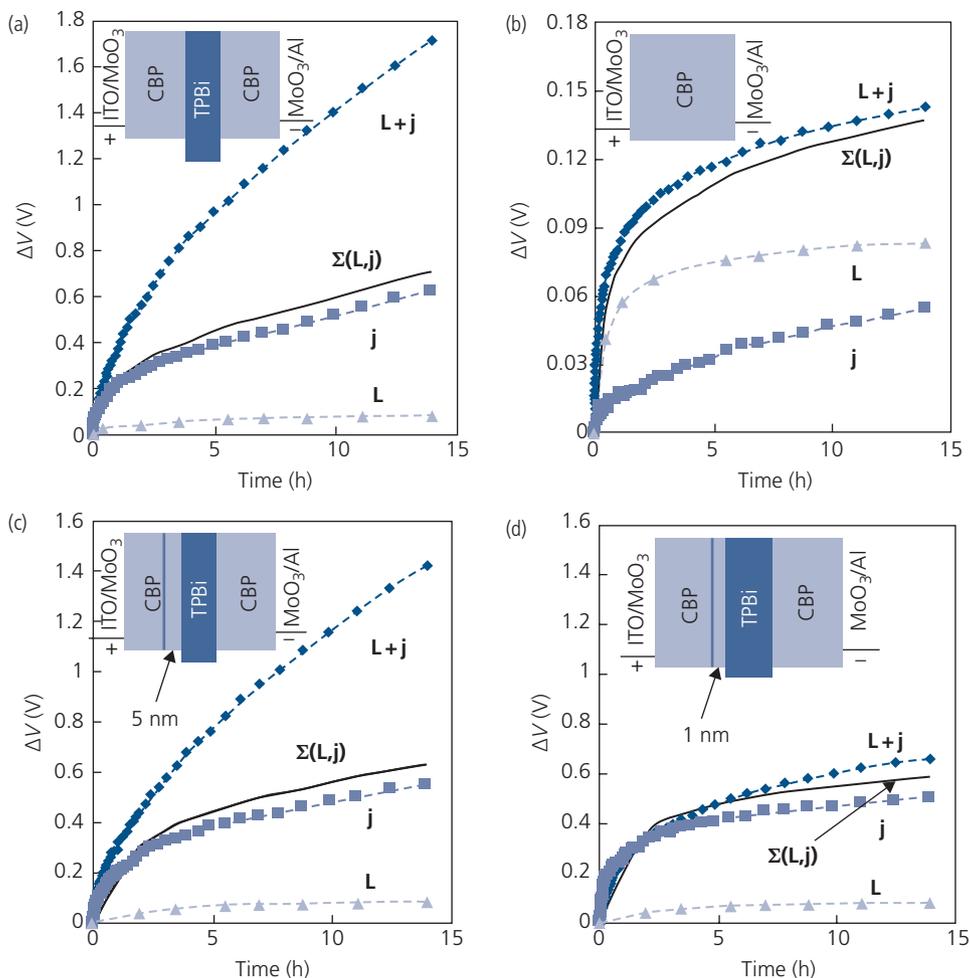

Metal cathodes other than Mg:Ag have shown similar effects of electrolysis with water. For example, Alq<sub>3</sub>/TPD OLEDs using Al contacts develop non-emissive, delaminated dome-like bubbles after operation in air. Mass spectrometry analysis indicates that these delaminated areas are filled with oxygen and hydrogen as products of electrolytic reactions between water and Al (Do et al., 1996). The ITO anode, too, can impact device lifetime. Plasma and other surface treatments clean the surface, and reduce the injection barrier to holes (and hence reduce the electric field across the anode/organic interface) leading to improved OLED operational lifetime (Wu et al., 1997b). Indeed, residual water in PEDOT:PSS anodes can lead to rapid degradation, similar to the effects found when cathodes are exposed to humid environments (Fehse et al., 2008).

Organic–organic interfaces have also been implicated in device degradation. Specifically, interactions between the high density of hole polarons and excitons at HTL/EML interfaces lead to a rise in operating voltage that accompanies a decrease in luminance. Following the method of Giebink et al. (2009) described in the following section, a hole-only conducting device was used to investigate changes in the interfaces of a 5 nm thick layer of a TPBi ETL sandwiched between two 20 nm thick CBP HTLs, as

shown in the inset of Fig. 6.171a. The voltage rise across devices ( $\Delta V$ ) operated in nitrogen was monitored as a function of time under 0.5 mW/cm<sup>2</sup> illumination at  $\lambda = 365$  nm (denoted by **L**), under a constant current density of 20 mA/cm<sup>2</sup> (**j**), and under their combination (**L+j**). Excitons are only generated in TPBi at this wavelength. Using these various conditions, the separate effects of current and illumination are determined.

In Fig. 6.171a, there is a minor increase in voltage over time for conditions **L**, a significantly higher increase with **j**, and a higher increase when both excitations are simultaneously applied, **L+j**. Notably, this combined excitation results in a significant increase in voltage rise compared to the sum of the voltage rises from separate application of these stimuli (solid line corresponding to  $\Sigma(\mathbf{L}, \mathbf{j})$ ). In contrast, in a device lacking the HTL/ETL interface, there is no enhanced degradation from the combination of current and illumination, as shown in Fig. 6.171b. From this we infer that excitons generated in CBP interact with holes in TPBi at their interface, inducing the voltage change.

The polaron/exciton induced degradation was further examined by placing a very thin red fluorescent DCJTb layer doped at 4% in CBP in the proximity of the interface. This layer decreases the exciton lifetime from  $\sim 1.3$  ns in CBP, to 0.5 ns in the doped zone. If excitons play a role in degradation, then decreasing their natural decay rate should result in a decreased impact on the operating voltage over

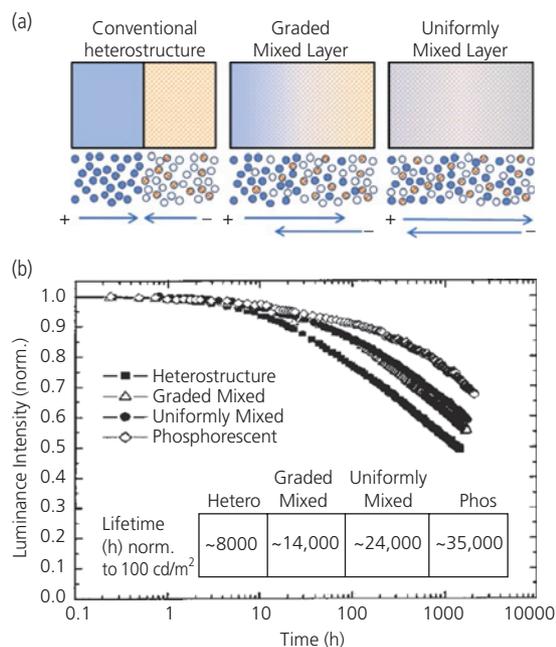

**Figure 6.171** Voltage rise ( $\Delta V$ ) vs operation time for hole only devices in the presence of current ( $j$ ), illumination at  $\lambda = 365$  nm ( $L$ ) and the presence of both ( $L+j$ ). The data are shown by points, and the solid line is the sum of the  $j$  and  $L$  data, denoted  $\Sigma(L,j)$ . In (c) and (d), a thin layer of the red emitting fluorophore, DCJTb is placed at (c) 5 nm and (d) 1 nm distance from the interface between CBP and TPBi. Insets: Device structures used in the corresponding tests. After Wang and Aziz (2013).

time. That is indeed the case in Fig. 6.171c and d, where placing the DCJTb layer within a Förster transfer radius of the interface results in a smaller increase in  $\Delta V$  than when it is placed farther away. When placed within 1 nm of the interface (Fig. 6.171d), the sum of the individual impacts of current and illumination,  $\Sigma(L,j)$ , is nearly the same as their combination,  $L+j$ .

The coexistence of a high density of excitons and polarons in OLEDs can result in interactions that lead to physical aggregation of the host (CBP) molecules (Wang et al., 2014b). Aggregates may introduce mid-energy gap interfacial defects that lead to increased voltage and decreased luminance. The formation of interface traps was identified by thermally stimulated current measurements of TADF-based OLEDs with

ultrathin ( $\sim 2\text{--}3$  nm) dipolar Liq layers located at the EML/HBL or HBL/ETL interface (Tsang et al., 2016). These morphological effects appear to be more prevalent in wider energy gap hosts (Zhang and Aziz, 2016). Attribution to morphological changes is based on an absence of new chemical species formed during aging, or to thermal effects that would introduce spectral changes for the  $j$  devices that are also found in the  $L+j$  devices. A long wavelength spectral feature due to aggregation (and thus excimer formation) in an OLED comprising these two materials was observed only in the  $L+j$  case (Wang et al., 2014b). Unfortunately, no explanation as to why excitons and polarons induce aggregation of host molecules has been proposed, nor is there direct morphological evidence for the existence of such aggregates.

An alternative explanation for these effects is that a decrease in energy barriers at the interfaces reduces the charge pile-up, thus reducing chemical reactions catalyzed by cationic or anionic species. The effectiveness of reducing energy barriers is tested by blending the electron and hole transporting materials in the EML. Schematic illustrations of three different compositionally graded HJ EMLs are shown in Fig. 6.172a. The conventional abrupt heterostructure consists of an ETL doped with the fluorophore adjacent to the HTL. Holes, electrons, and excitons pile up at the HJ between the layers, with the charge density depending exponentially on the size of the HOMO and LUMO energy offsets at the interface. In the graded mixed HJ, the dopant resides in an area where the HTL and ETL are mixed. This allows for considerable penetration of both electrons and holes in the exciton formation region, reducing the peak density of these species, but not the total number of excitons generated. The third device is a uniformly mixed HTL-ETL-chromophore device that spreads the polarons and excitons evenly throughout the blended EML.

**Figure 6.172** (a) Schematic of three types of HJ OLEDs: a conventional bilayer HJ, a graded-mixed HJ where the ETL and HTL are blended along with the dopant across the EML, and a uniformly mixed co-host device. The “range” of hole and electron injection is illustrated by the arrows beneath each junction. (b) Luminance as a function of aging time for packaged devices using C545T as the fluorescent dopant with the structures in (a), or an abrupt HJ Ir(ppy)<sub>3</sub> PHOLED. The  $LT_{50}$  normalized to  $L_0 = 100 \text{ cd/m}^2$  for each device is shown in the inset table. After Chwang et al. (2002).

The lifetimes of three green emitting HJ OLEDs in Fig. 6.172 based on C545T-doped fluorescent OLEDs employing NPD as the hole transporting, and Alq<sub>3</sub> as the electron transporting hosts were compared to an Ir(ppy)<sub>3</sub>:CBP abrupt HJ PHOLED. The most efficient fluorescent device had an abrupt HJ with an efficiency of 15.5 cd/A, followed by the graded mixed device at 9.5 cd/A, and finally the graded junction device at 8 cd/A. The lower efficiency of the graded devices results from reduced charge confinement, and hence a broader emission zone (Chwang et al., 2002).

The reduction of local densities of polarons and excitons leads to a considerable increase in operational lifetime (see Fig. 6.172b). Consistent with the hypothesis that charged and excited molecules lead to degradation, the abrupt junction device shows a lifetime of  $LT_{50} = 8000 \text{ h}$  (normalized to  $L_0 = 100 \text{ cd/m}^2$ ), compared with 14,000 h for the graded mixed structure, and 24,000 h for the uniformly graded device. Interestingly, the PHOLED has the longest lifetime with  $LT_{50} = 35,000 \text{ h}$ . This is due to its requiring a significantly lower current to achieve the same luminance as the fluorescent devices (cf. Eq. 6.127), along with the more rapid harvesting of triplet states that linger in fluorescent devices (Burrows et al., 2000). Reactive triplets either on the host or dopant in fluorescent devices have lifetimes of seconds or longer, during which time the molecules comprising the EML can undergo chemical dissociation. In PHOLEDs, the triplet is harvested by the dopant and radiatively recombines on timescales of a few hundred nanoseconds to a few microseconds, drastically reducing the time available for excited state reactions. Hence, it is reasonable to assume that the vastly shortened triplet lifetimes in PHOLEDs vs. that in fluorescent devices should also yield lifetime improvements. We will show in Section 6.7.4 that this is indeed true for all but blue emitting PHOLEDs where energy-driven aging mechanisms are active.

### 6.7.3 Degradation due to thermal effects and chemical decomposition

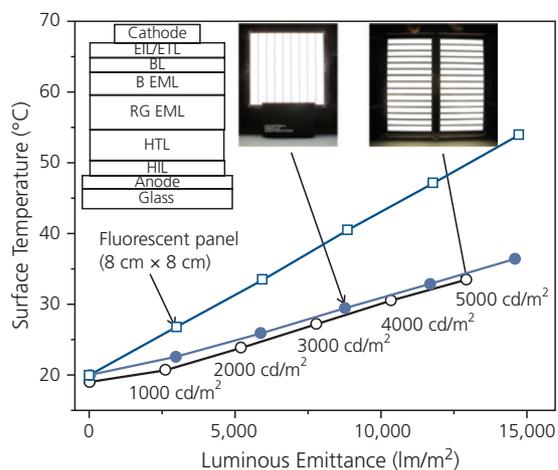

At this point it should be apparent that degradation is most likely due to a combination of effects. That is, assigning device aging simply to aggregation from a combination of polarons and excitons, or to layer delamination in the absence of thermal effects, environmental exposure, or energy-induced molecular decomposition generally provides a far from complete picture of all the mechanisms that shorten device operational lifetime.

In this context, we showed in Section 6.7.1 that the decrease in luminance is accelerated at elevated temperatures, with an activation energy,  $\Delta E_A$ . Thermal effects are an excellent example of how a single environmental variable can lead to numerous degradation pathways by accelerating morphological changes, degradation of molecular species, interdiffusion of constituents across interfaces, layer delamination, and so on. Primarily, elevated temperatures have two effects: disrupting the morphology of the as-deposited films that is particularly significant for low  $T_g$  materials, and decomposition of the constituent molecules.

Exceeding  $T_g$  of the materials comprising the OLED can lead to their crystallization on re-cooling. The crystallized areas disrupt the lamellar film structure, leading to shorts across the EML. For sufficiently low  $T_g$ , this process can occur even at room temperature, and can be accelerated by local Joule heating during device operation. For most devices, Joule heating (with dissipated power density of  $jV$ ) is small, although this does not avoid the problem of crystallization when the ambient temperature is increased. Hence, finding materials sets with high  $T_g$  is of great importance (O'Brien et al., 1998). While the device temperature rise may only be a few degrees above ambient, the local temperature at energy barriers between layers, or within a particular resistive layer itself, may be considerably higher.

The surface temperatures of several WOLED panels measured using a *forward looking infrared* (FLIR) *thermal imaging* camera are shown in Fig. 6.173. The two  $15 \times 15 \text{ cm}^2$  phosphorescent panels have efficacies at  $L_0 = 3000 \text{ cd/m}^2$  of 49 lm/W, whereas the  $8 \times 8 \text{ cm}^2$  fluorescent panel has an efficacy of 16 lm/W. The luminous emittance plotted in Fig. 6.173 is the efficacy times the area filled by the emitting surface. The latter is known as the *aperture ratio*. The surface temperatures of the PHOLED panels are considerably lower than the fluorescent panel. At  $L_0 = 3000 \text{ cd/m}^2$ , the surface temperatures are 29.4°C and 27.2°C for the panel in the center inset photo (panel 1) and the one on the right (panel 2), respectively. The difference is a result of the different aperture ratios for the two panels. In contrast, the lower efficiency fluorescent panel has a surface temperature of 40.5°C (Levermore et al., 2012).

The relationship between operating temperature and lifetime is shown in Fig. 6.174, with a thermal image of the surface of one half of panel 2 in the absence of heat sinking. Consistent with the discussion in Section 6.7.1, there is a pronounced

**Figure 6.173** Temperature of white light emitting panels vs. luminance emittance. The PHOLED panels are  $15 \times 15 \text{ cm}^2$ , and have the structure and layouts shown in the insets. The fluorescent panel is  $8 \times 8 \text{ cm}^2$  (Levermore et al., 2012).

dependence of panel lifetime on temperature. At  $3000 \text{ cd/m}^2$ , the activation energy of the lifetime is  $E_A = 0.40 \text{ eV}$ , leading to a 1.65-fold increase in lifetime per 10°C reduction in temperature. The cause of this degradation is not apparent from these data alone.

The relationship between device temperature and current is

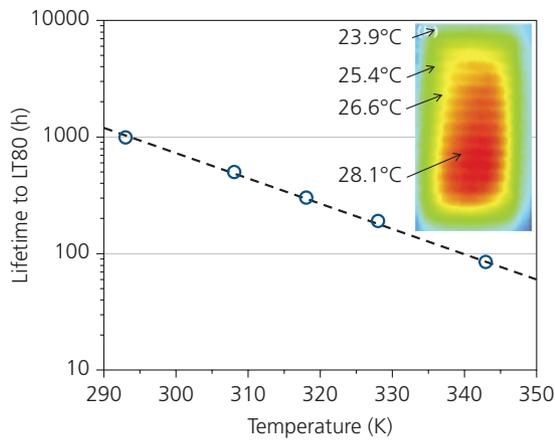

$$jV - P_{opt} = c_{sp}\rho L \frac{\partial T}{\partial t} - \kappa_T \nabla T, \quad (6.128)$$

where  $P_{opt}$  is the optical power emitted by the OLED,  $c_{sp}$  is the specific heat capacity (with units of [J/kg K]),  $\rho$  is the mass density of the solid,  $L$  is the layer thickness, and  $\kappa_T$  is the thermal conductivity ([W/m K]). The terms on the left hand side of Eq. 6.128 give the power dissipated via Joule heating, which is decreased by the fraction of power carried by out-coupled photons, the first term on the right is the transient temperature rise, and the last term is due to thermal conductivity via the substrate or convection. We assume that the temperature rise is sufficiently small that radiative losses (equal to  $\epsilon_{rad}\sigma_{SB}T^4$ , where  $\epsilon_{rad}$  is the emissivity and  $\sigma_{SB} = 5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$  is the Stefan-Boltzmann constant) are small. However, this is not always the case, with a more precise approach to calculating the temperature of multilayer OLEDs to be found elsewhere (Qi and Forrest, 2011, Bergemann et al., 2012).

Since the primary heat loss in steady state is via the substrate, the choice of substrate materials is of vital importance. Figure 6.175 shows thermal images as a function of time for top emitting devices with the structure: substrate/300 nm Ag/4 nm MoO<sub>3</sub>/54 nm

NPD/53 nm Alq<sub>3</sub>/1 nm Yb/20 nm Ag/45 nm Alq<sub>3</sub> driven at  $L_0 = 10,000$  cd/m<sup>2</sup>. The top Alq<sub>3</sub> layer serves as an antireflection coating to improve optical out-coupling (Chung et al., 2009). Three different substrates were used: glass (with  $\kappa_T = 1$  W/m K), polymer planarized SUS stainless steel (16 W/m K) and Si (150 mW/m K). The substrate conductivity plays a significant role in the steady state temperature (64.5, 40.5, and 21.4°C, respectively) as well as the lifetime. With  $L_0 = 10,000$  cd/m<sup>2</sup>, the  $LT_{80} = 31$  h for glass, 96 h for SUS stainless, and 198 h for Si, corresponding to  $\Delta E_A = 0.39$  eV.

The temperature can be further reduced through the use of pulsed rather than continuous current drive. The pulsed duty cycle should be sufficiently small to allow for thermal recovery with time

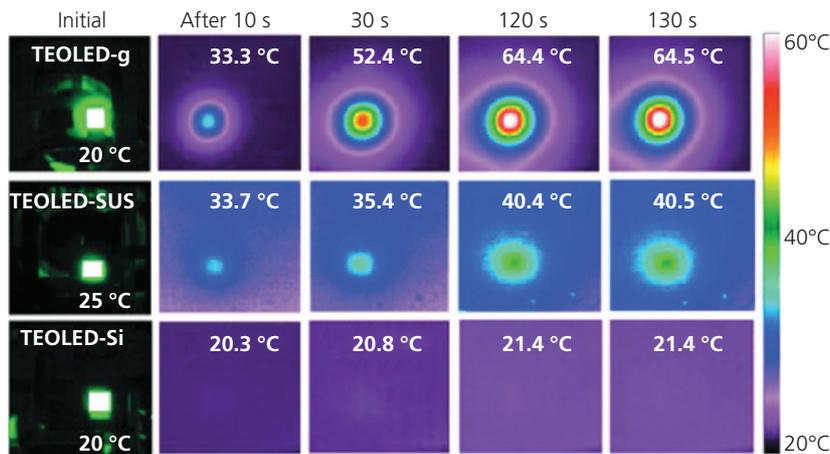

**Figure 6.174** Panel lifetime to  $LT_{80}$  vs operating temperature. Inset: FLIR surface image of the panel at 3000 cd/m<sup>2</sup> after 10 min of operation (Levermore et al., 2012).

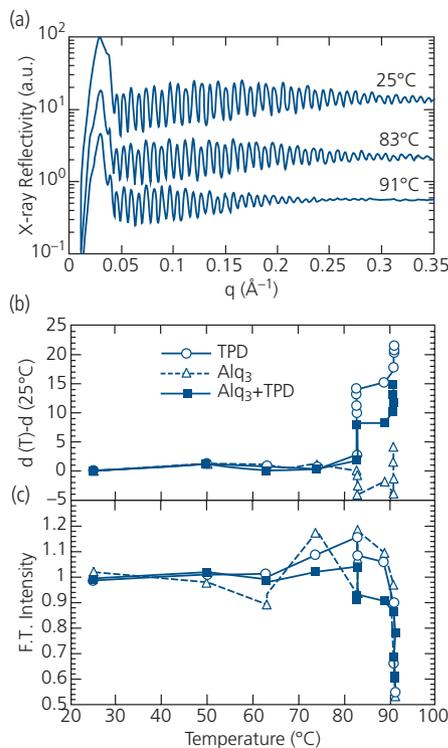

constant  $\tau_T = c_{sp}\rho L^2/\kappa_T$  between pulses (Cao et al., 2015). Temperature is also reduced by decreasing the contact (e.g. ITO/HTL) energy barriers or by employing doped transport layers to decrease series resistance, and thus Joule heating (Meerheim et al., 2006).

The morphological damage from heating can be manifested by local crystallization or film expansion. When the films are heated to  $T > T_g$ , the entire structure undergoes expansion, leading to strain between layers, and possibly delamination. A dramatic demonstration of the dependence of strain with temperature in Fig. 6.176a obtained via X-ray beam specular reflection from the surface of an initially planar TPD/Alq<sub>3</sub> heterostructure on a Si substrate. The initial molecularly flat surface results in an extended series of intensity oscillations due to Fabry-Pérot modes from X-ray reflection at each interface within in the structure. The film at  $T = 91^\circ\text{C}$  has fewer resolvable oscillations than at lower temperatures, indicating a reduction in flatness.

A Fourier transform of these oscillations yields the layer thicknesses (Fenter et al., 1997). The thermal expansion of the two layers plus that of the entire film is shown in Fig. 6.176b. The thickness is unchanged up to 83°C, at which point the Alq<sub>3</sub> thickness decreases by 5 Å while the TPD film increases by 11 Å, leading to a net film expansion of 6 Å. At 93°C, all three layers show a rapid increase in thickness, accompanied by a decrease in intensity of the Fourier transform peaks (Fig. 6.176c). This results from film roughening: as the film thickness varies across the sample, beam scattering increases, resulting in destructive interference of the reflected X-ray wavefront.

**Figure 6.175** Visible (left hand column) and FLIR images of top emitting fluorescent OLEDs (TE-OLEDs) as a function of time after turn-on for devices made (top to bottom) on glass, SUS, and Si substrates. The initial luminance is 10,000 cd/m<sup>2</sup> (Chung et al., 2009).

**Figure 6.176** (a) X-ray reflectivity data of a 29.6 nm TPD/51.8 nm Alq<sub>3</sub> heterojunction on a Si substrate at three different temperatures.  $q$  is the X-ray momentum transfer which is a function of scattering angle. (b) Thickness ( $d$ ) expansion (in Å) and (c) Fourier transform intensity of the oscillations for the heterostructure and layers vs. temperature. Here,  $d(T)$  is the layer thickness at temperature,  $T$  (Fenter et al., 1997).

This reduces the intensity and the regularity of the oscillations.

These data, along with the absence of X-ray evidence for crystallization, suggest that the TPD film undergoes expansion once its glass transition temperature of 60°C is exceeded. Expansion results in strain between the films that introduces blistering and other damage that propagates to the heterointerface. Thermal expansion induced strain is also likely to introduce defects that lead to non-radiative recombination of charges and excitons, and hence a reduced OLED luminance. While the effects revealed in Fig. 6.176 occur by uniform heating, similar effects can occur on a local level due to current “hot spots” arising from non-uniformities in growth, inhomogeneities in blends of more than one molecular species, contacts, substrate irregularities, etc.

Thermal effects can be minimized by using materials with a high  $T_g$ . Mixing low and high  $T_g$  components in a single layer increases  $T_g$  above that of the the lowest component. In effect, the

doping of the film by a high  $T_g$  species acts to “pin” the morphology in its as-grown state. This method for increasing  $T_g$  is useful when a low  $T_g$  material has a desired optoelectronic property (e.g. a large energy gap in a blocking layer) but has insufficient morphological stability needed for a long device lifetime. The glass transition temperature for the mixture is

$$\frac{1}{T_{gM}} = \frac{w_A}{T_{gA}} + \frac{w_B}{T_{gB}}, \quad (6.129)$$

where  $w_{A,B}$  is the weight percent of components A, B, respectively (Rudin and Choi, 2013). Component mixing has been used to significantly extend the operational lifetime of Ir(ppy)<sub>3</sub>:CBP PHOLEDs by blending the blocker BPhen ( $T_g = 62^\circ\text{C}$ ) with BALq ( $T_g = 92^\circ\text{C}$ ) (D’Andrade et al., 2003).

Simultaneous exposure to heat and current generates defects in the bulk due to molecular fragmentation. The fragments form exciton quenching as well as charge recombination sites (Scholz et al., 2007, Kondakov, 2008, Kondakov, 2015). Trap generation is inferred from an increase in operating voltage and a decrease in luminance efficiency. We can determine the relationship between the voltage rise and luminance loss over time by assuming that traps are formed at rate  $K_X$ . Then the density of fixed charge trapped at position  $x$ , is  $Q(x)$ . Following the treatment of Giebink et al. (2009), we can write Poisson’s equation as

$$-\frac{d^2V}{dx^2} = \frac{dF}{dx} = \frac{q}{\epsilon_r\epsilon_0} (n(x) + n_t(x) + \zeta Q(x)). \quad (6.130)$$

Here, the trapped electron density is  $n_t(x)$ , and the fixed charge due to defects is treated as a perturbation of strength,  $\zeta$ . A similar expression applies for hole densities  $p \gg n$ .

Following the treatment in Section 4.4.2 for an exponential trap distribution in the limit of  $n \ll n_t$ , we obtain a solution of the form:  $V \cong V_0 + \zeta V_1$ , where (Kao and Hwang, 1981)

$$V_0 = \frac{l}{2l+1} \left[ \frac{l+1}{l} d \right]^{2l+1/l+1} \left( \frac{qH_t}{\epsilon_r\epsilon_0 N_{LUMO}^{1/l}} \right)^{1/l+1} \left( \frac{j}{q\mu} \right)^{1/l+1}. \quad (6.131)$$

Here,  $d$  is the film thickness and  $\mu$  is the electron mobility. The characteristic trap temperature is  $T_c$ , where  $l = T_c/T$ , and  $N_{LUMO}$  and  $H_t$  are the densities of LUMO and trap states at the transport level, respectively. When an a.c. voltage is applied

whose modulation rate exceeds the characteristic trapping frequency, the small-signal capacitance is given by

$$C = \frac{dQ_{tot}}{dV} = \frac{1}{\mu} \frac{d}{dV} \left( \frac{j}{F} \right), \quad (6.132)$$

where  $Q_{tot}$  is the total mobile charge. Then from Eq. 6.131,

$$C_0 = q \frac{N_{LUMO}}{H_t^l} \left( \frac{l(2l+1)}{(l+1)^2} \frac{\epsilon_r \epsilon_0}{q} \right)^l \frac{l}{(2l-1)} \frac{V^{l-1}}{d^{2l-1}}. \quad (6.133)$$

Adding the area-specific geometric capacitance,  $C_{geom} = \epsilon/d$  to  $C_0$  gives the total device capacitance.

We start with the *ansatz* that defect formation requires the presence of a polaron on the molecule, forming an anionic or cationic state. Then the rate of change of the defect density is:

$$\frac{dQ}{dt} = K_X(n + n_t). \quad (6.134)$$

Defects can be formed on both the ground and excited states. Thus,  $K_X$  is written as

$$K_X = K_{X1} + K_{X2}G, \quad (6.135)$$

where  $K_{X1}$  is due to ground state degradation while  $K_{X2}$  describes degradation of the excited state, such as via exciton–polaron annihilation. Hence,  $K_{X2}$  is only present for molecules subject to an excitation at rate,  $G$ .

Equation 6.130 can be solved to first order in the perturbation  $\zeta$  under the assumption that  $n \ll n_t$ . Then, the voltage at constant  $j$  increases with time according to

$$V(t) \approx V_0 + \zeta V_1(t) = V_0 \left( 1 + \frac{\zeta t K_X}{t K_X + l + 1} \right). \quad (6.136)$$

Similarly, the capacitance decreases over time:

$$C(t) \approx C_0 \left( 1 + \frac{\zeta t K_X}{t K_X + l + 1} \right)^{-1}. \quad (6.137)$$

Temporal changes in voltage,  $\Delta V = V(t) - V_0$ , and capacitance,  $\Delta C = C(t) - C_0$ , are thus nonlinear at a constant  $j$  since polaron-induced defect states increase the voltage, which in turn increases the polaron density.

A schematic diagram of an experimental setup used to determine the role of defects in the OLED voltage and luminance over time is shown in Fig. 6.177a. In a demonstration of the method, four equivalent electron-only test structures (eTST) shown in Fig. 6.177b were simultaneously monitored to separately understand influences of polarons and excitons.

The test conditions for each of the devices are the same as in Fig. 6.171: constant intensity optical excitation (condition **L**), constant current (**j**), and the combination of the two (**L+j**). A device that is exposed to neither current nor illumination is used as a control (**C**). Each device is monitored over an extended time interval by periodically sampling both the voltage at constant  $j$ , and its capacitance-voltage characteristics. Optical excitation at  $\lambda = 442$  nm is only absorbed by Ir(ppy)<sub>3</sub>, thereby eliminating exciton generation on mCBP for the device in Fig. 6.177b (Holzer et al., 2005).

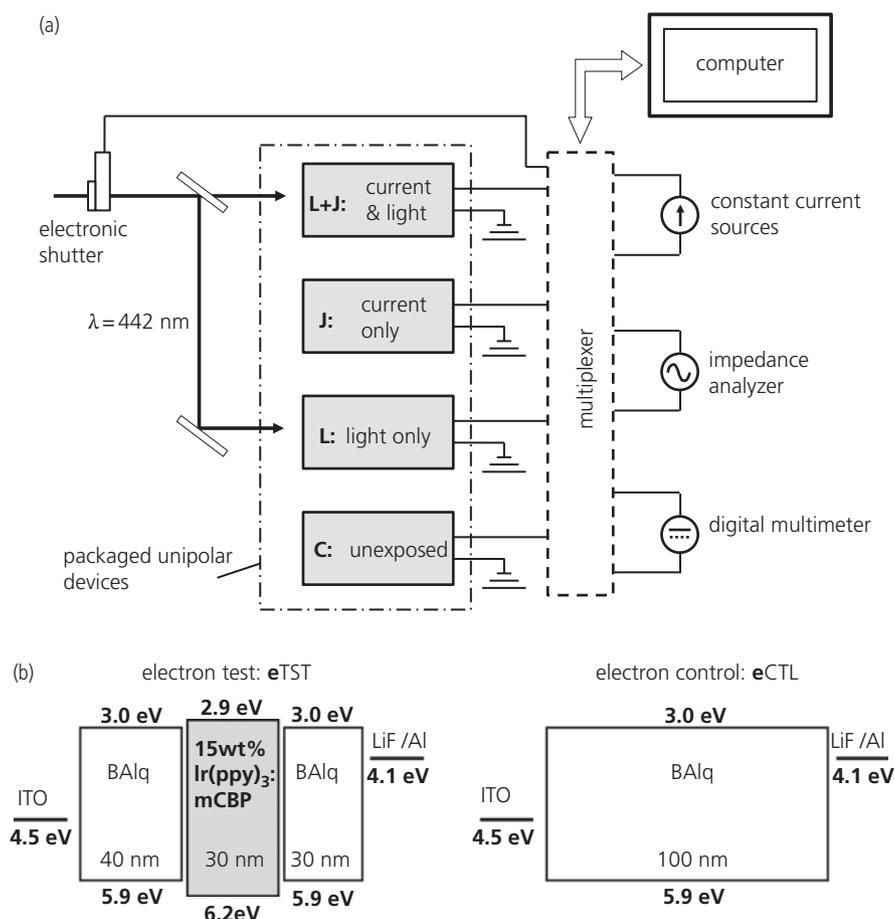

The eTST device consist of the 15 wt% Ir(ppy)<sub>3</sub>:mCBP EMLs sandwiched between electron conducting BALq layers. Analogous hole-only devices locate the EML between NPD layers. To isolate effects of degradation in the BALq buffer, a control device (eCTL) lacking the EML was fabricated, shown in Fig. 6.177b. Extrinsic factors such as degradation due to environmental exposure are identified using the control device, eCTL, and the **C** test condition.

Example  $\Delta C = C(t) - C(t = 0)$  data collected at 12 V for the electron-only devices in Fig. 6.177b at optical intensities of 1.1 and 19.5 mW/cm<sup>2</sup> are shown in Fig. 6.178. Electron current alone (condition **j**, open squares) reduces the capacitance of eTST in Fig. 6.178a. A further decrease in capacitance occurs for the combined condition, **L+j** (open circles), with negligible deviation from condition **j** at low pump intensities, to progressively larger shifts as intensity,  $I$ , is increased. No changes are observed in any of the eCTL devices (see Fig. 6.178b), or for eTST at any intensity, **L**, or **C** conditions. Fits to the data using Eq. 6.136 assuming,  $\mu = 2.2 \times 10^{-7}$  cm<sup>2</sup>/V s,  $l = 5.5$ ,  $H_t = 1.3 \times 10^{18}$  cm<sup>-3</sup> (obtained from the  $j$ - $V$  characteristics),  $N_{LUMO} = 10^{23}$  cm<sup>-3</sup>, and  $\zeta = 0.05$  are shown by the solid lines in Fig. 6.178a.

The data obtained in this study yield a rate of defect formation for eTST devices of  $K_X(\text{s}^{-1}) \approx 3.6 \times 10^{-5} + 5.2 \times 10^{-7} I(\text{mW}/\text{cm}^2)$ . This linear relationship with a non-zero intercept at  $I \rightarrow 0$  suggests degradation by polaron interactions (condition **j**). Since the LUMO of Ir(ppy)<sub>3</sub> is above that of mCBP, electron conduction through the Ir(ppy)<sub>3</sub>:mCBP matrix occurs via the host. Thus, mCBP anions appear to be unstable, and become more so upon optical excitation.

From Eq. 6.137, the linear relationship for eTST can be rewritten:

$$K_X = K_{X1} + K_{X2} \left[ \frac{I \tau_{ph} (1 - \exp(-2\alpha_{EML} x_{EML}))}{x_{EML} E_{ph}} \right], \quad (6.138)$$

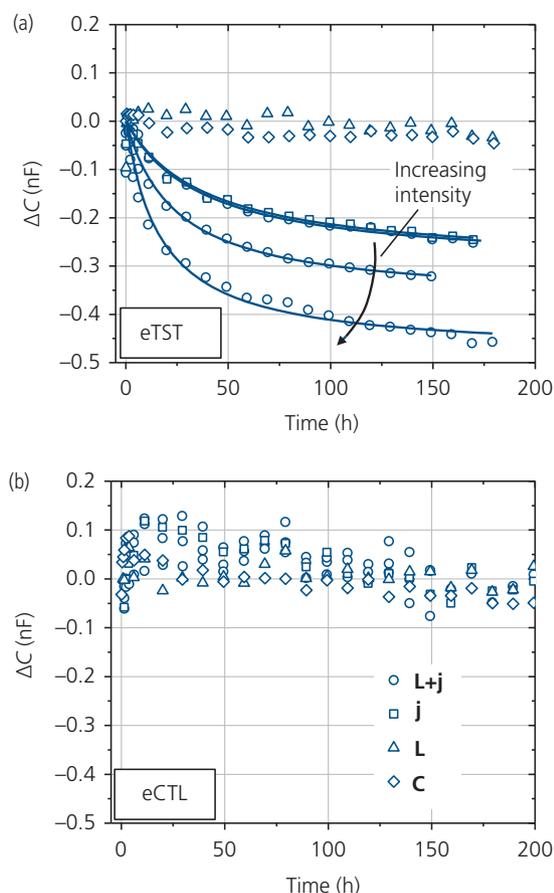

**Figure 6.177** (a) Test setup for measuring degradation mechanisms in OLEDs under different test conditions noted in text. (b) Example electron-only (eTST) PHOLED test structure along with its electron-only control (eCTL) (Giebink et al., 2009).

where the quantity in brackets is the density of Ir(ppy)<sub>3</sub> excitons generated at intensity,  $I$ . Thus,  $K_{X2}$  is the rate coefficient due to the combined probability of annihilation with Ir(ppy)<sub>3</sub> excitons followed by dissociation of the excited polaron state. Also,  $\tau_{ph}$  is the Ir(ppy)<sub>3</sub> phosphorescent lifetime,  $x_{EML}$  is the width of the Ir(ppy)<sub>3</sub>-doped layer,  $\alpha_{EML}$  is its absorption coefficient, and the photon energy is  $E_{ph}$ . Taking  $\alpha_{EML} = 4 \times 10^3 \text{ cm}^{-1}$  at  $\lambda = 442 \text{ nm}$  (Holzer et al., 2005), we obtain  $K_{X2} = (3 \pm 1) \times 10^{-20} \text{ cm}^3 \text{ s}^{-1}$ , which is consistent with the empirical relationship given above. These results indicate luminance loss in an Ir(ppy)<sub>3</sub>:mCBP OLED is predominantly due to non-radiative electron-hole recombination at defect sites formed by the interaction of an electron polaron on the host mCBP and an exciton on Ir(ppy)<sub>3</sub>. The defect sites are responsible for the increase in voltage and

decrease in capacitance and luminance with device operation (Giebink et al., 2009).

The preceding analysis indicates that generation of deep levels over time is one mechanism responsible for device aging. Yet it does not provide direct information about the *chemical origin* of those defects. One possible source is molecular fragmentation following reactions between radical and neutral species, perhaps resulting in spontaneous dimerization. Molecular fragments are identified using *laser desorption/ionization time-of-flight mass spectroscopy* (LDI-TOF-MS). A schematic diagram of the spectrometer is shown in Fig. 6.179. A high energy (UV) laser beam ionizes and desorbs molecules at the target. The ionized species are accelerated and selected by the ratio of mass-to-charge ( $m/z$ ) in the precursor selector. Unwanted ionic species are eliminated by collisions with non-reactive (e.g. He)

and/or reactive (e.g.  $H_2$ ) gases in the collision cell. The remaining molecules are accelerated once more, and subsequently selected in the mass spectrometer analyzer. The measurement provides the

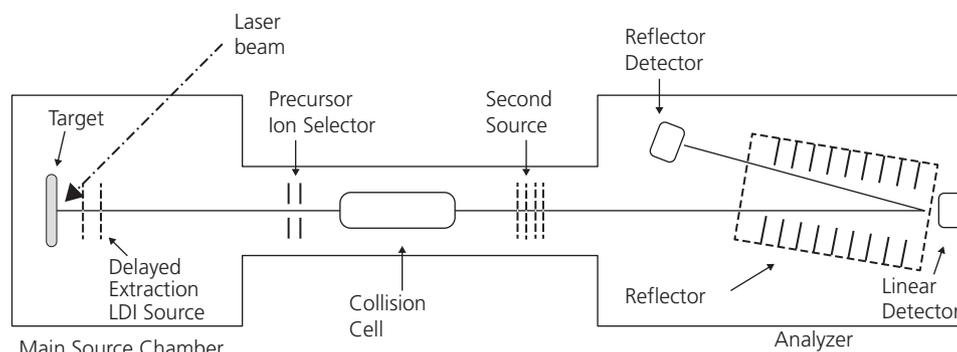

**Figure 6.178** (a) Change in capacitance for (a) eTST and (b) eCTL devices in Fig. 6.177b as a function of operating time. Solid lines are fits to the data following Eq. 6.137 (Giebink et al., 2009).

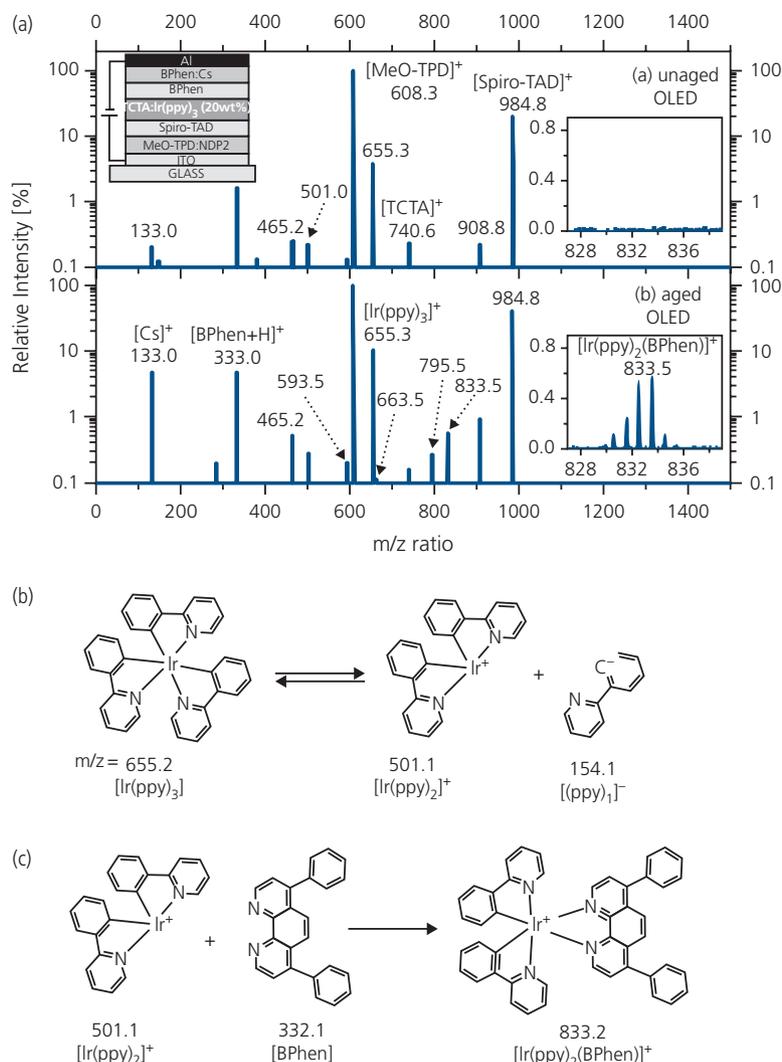

relationship between ionic species concentration vs. mass. Analyzing constituent materials before and after device aging can be used to identify molecular fragments and compounds produced under stress during OLED operation (Meerheim et al., 2008, Moraes et al., 2011). Given the high intensity and energy of the laser desorption beam, a high density of molecular excited states are generated during the measurement. This results in exciton annihilation whose impact on defect generation can also be studied (Sandanayaka et al., 2015, Lee et al., 2017).

Figure 6.180 shows the LDI-TOF-MS intensity spectra as a function of  $m/z$  for both a fresh and aged  $Ir(ppy)_3:TCTA$  PHOLED whose structure is shown in Fig. 6.180a, inset. Two identical devices were fabricated and encapsulated. The fresh device served as a control, whereas the aged device was driven at  $2.5 \text{ mA/cm}^2$  (corresponding to  $L_0 = 1012 \text{ cd/m}^2$ ), for 215 h, at which point it had lost 7% of its initial luminance. The packages were then opened, and the top contacts were peeled off to obtain the mass spectra.

The control device spectra exhibit signals from all of the components comprising the OLED. After aging, several new peaks emerge, notably those at or near  $m/z = 663, 795, \text{ and } 833$ . The larger mass species is assigned to a dissociative reaction of  $Ir(ppy)_3$  to form a reversible pair of fragments,  $[Ir(ppy)_2]^+ + [ppy]^-$ . The heavier fragment reacts with BPhen at the EML/HBL interface to form  $Ir(ppy)_2$  (BPhen) with  $m/z = 833.2$ . The sequence of proposed complexation reactions is shown in Fig. 6.186b and c. The features at  $m/z = 663$  and  $675$  are identified with BPhen dimers associated with a proton or  $Cs^+$  ion, respectively. Furthermore, it is proposed that the  $Ir(ppy)_2$ (BPhen) complex results in energy gap states at the interface that lead to recombination and accumulation of charge (Moraes et al., 2011). Hence, while

**Figure 6.179** An LDI-TOF-MS spectrometer used in identifying molecular species (Scholz et al., 2007).

**Figure 6.180** (a) Mass spectra of an unaged and aged PHOLED with the structure shown in the left-hand inset. The right insets show a detail of the mass to charge ratio ( $m/z$ ) between 828 and 838. (b) Proposed fragments of Ir(ppy)<sub>3</sub> and their masses generated on aging. (c) Proposed complexation between Ir(ppy)<sub>2</sub><sup>+</sup> and BPhen in the HBL (Moraes et al., 2011).

these investigations provide evidence for interface reactions as well as defects formed within the HBL, they do not rule out defects that occur within the bulk of the EML, nor do they associate a particular reaction product to a defect state that is responsible for the drop in luminescence.

A study of aged Ir(ppy)<sub>3</sub>-based PHOLEDs using a CBP host has also found numerous radical and ionic species that are fragmentation products from CBP. The species found after aging were isolated using high performance liquid chromatography (HPLC) and analyzed by nuclear magnetic resonance (NMR) spectroscopy. Calculations of the energy levels of the anions, cations and radicals led to two conclusions: several electronic states developed

within the CBP energy gap, but they had very low oscillator strengths and hence were non-radiative. It is reasonable, therefore, to assume that these degradation products may lead to the loss of luminance and increased voltage of the aged devices, yet no direct correlation was reported between a particular species and the changes in device performance (Kondakov et al., 2007).

The inferential connections between reactions at interfaces, as well as within the bulk layers themselves discussed in this section, and the resulting reduced performance is striking. We will show in the following section how molecular fragments can be associated with specific defect energy levels in aged OLEDs.

### 6.7.4 Lifetime of blue PHOLEDs: energy-driven degradation

While it is not possible to consistently compare the intrinsic lifetime of OLEDs comprising different materials systems and with different emission processes, it is clear that even the most optimized blue emitting devices have far shorter lifetimes than either red or green emitting OLEDs. Indeed, the blue emitter in OLED displays and lighting is the major limiting factor in the useable lifetime of such appliances. With this caveat, a comparison of lifetime of several OLEDs emitting at different wavelengths is provided in Table 6.14. Here, the lifetimes of PHOLEDs, fluorescent OLEDs, and TADF-based OLEDs taken from different laboratories are listed. Each of these devices comprises a different materials set and device architecture, so finding a consistent set of data is not possible. Nevertheless, there is a rough correlation between the energy of emission and device stability; the lower photon energy (red, green) emitting devices exhibit longer lifetimes than blue emitting devices. This is particularly pronounced for PHOLEDs and TADF emitters, with a weaker correspondence for fluorescent OLEDs. Furthermore, the development of TADF emitters lags far behind that

of phosphorescent and fluorescent molecular complexes. Anticipated advances in TADF molecular engineering will undoubtedly lead to significant improvements in these materials as well.

A compilation of blue PHOLED lifetimes is given in Table 6.15, roughly ordered by their CIE coordinates from deep blue to greenish-blue (i.e. cyan). The combination of longest lifetime and shortest wavelength emission is found for Ir(dmp)<sub>3</sub>; a material that will be discussed further below. However, even in this case the lifetime is insufficient to qualify for either lighting or display applications.

Since *deep* blue emitters are required in displays, it has been necessary to pair the less efficient but longer-lived fluorescent blue OLEDs with red and green phosphors to achieve a suitably long lifetime. In addition, red and green PHOLEDs have considerably longer lifetimes than their fluorescent counterparts. This leads to image “burn in” in displays that is a consequence of loss of blue intensity as the screen ages. As noted previously, phosphor dopants rapidly harvest both singlet and triplet excitons. Since material degradation is catalyzed by the combined presence of an excited state and a charge, rapid elimination of the exciton should increase device lifetime. In analogous fluorescent OLEDs, the triplets have no

quantum mechanically allowed transition path to the ground state, and hence they linger for many seconds or longer, possibly negatively impacting their lifetime.

The anomalously short lifetimes of blue OLEDs and PHOLEDs leads one to conclude that aging is intrinsically linked to the energy of the excited state. Indeed, it can be argued that extending the blue PHOLED lifetime to several tens of thousands of hours is the most important and difficult problem confronting the field of organic electronics today. Controlling intrinsic failure mechanisms in OLEDs should also deepen our understanding of failure mechanisms in organic electronic devices in general, ultimately leading to their acceptance in numerous other practical applications.

To understand the source of blue OLED failure, we first need to understand what is different for these vs. longer wavelength emitting devices:

- (i) Lack of a large palette of hosts, charge transport, and blocking layers. There are very few host materials whose triplet energies are higher than that of the dopant. Blue photon energies are typically >2.9 eV, which requires triplet energies at least

that high. Since the triplet energy is less than for the singlet by the exchange energy (ranging from 0.1 to 0.5 eV), the host singlet energy is pushed into the ultraviolet. To date, the most successfully employed hosts have a biphenyl carbazole structure such as mCBP. Similarly, electron and hole blocking layers must have very low LUMO energies (relative to vacuum). This results in materials sets that are easily oxidized and whose ability to balance charges within the EML is limited.

- (ii) The photon energy is sufficient to break many atomic bonds found in organic materials. In Table 6.16 we show a few bond energies (BE) found in common organic optoelectronic materials. Clearly, low energy bonds (e.g. O—O, N—O) must be avoided since energy dissipation on such bonds results in dissociation. However, almost all molecules such as CBP have at least one C—N bond, which is close to the photon energy from deep blue emitters. And as we show in the ensuing discussion, two particle collisions such as TTA or TPA momentarily promote the molecular excited state to double the photon energy, that is, as high as 5.5–6 eV. No bond can withstand such a high energy excitation, but this assumes that all

the excess energy from this reaction is dumped into a single bond, which is not always true. The deeper blue emitters have even higher energy photons than blue-green PHOLEDs, leading to ever shorter lifetimes. Doubling of green (2.3 eV) and red (2.0 eV) photon energies is far less destructive of the molecular structure.

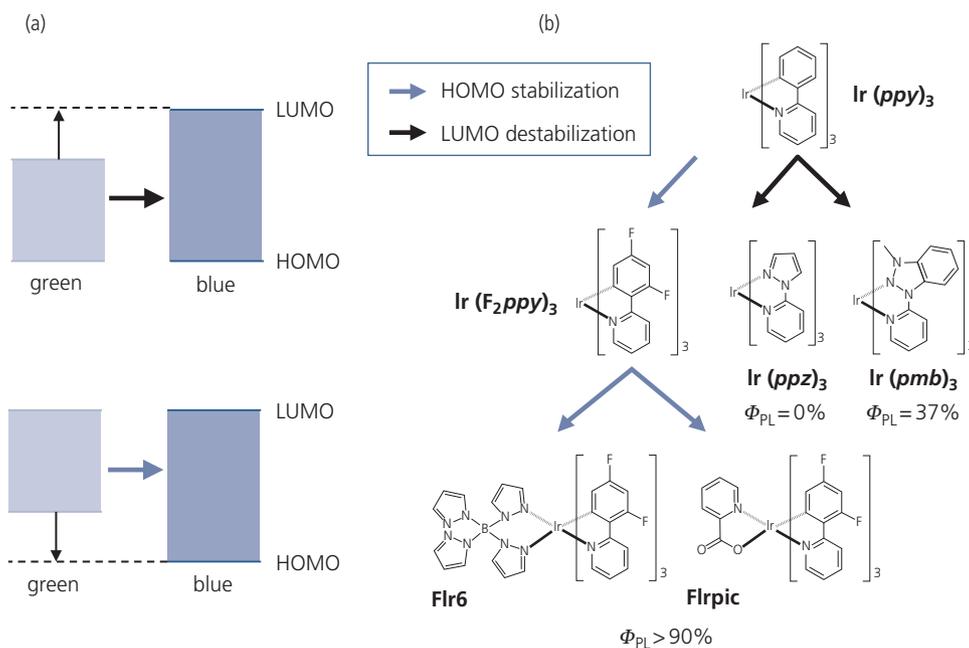

- (iii) The triplet radiative lifetime tends to be longer (2–5  $\mu\text{s}$ ) in blue emitting phosphors than in longer wavelength complexes ( $\leq 2 \mu\text{s}$ ) due to reduced  $^3\text{MLCT}$  or  $^3\text{LC}$  coupling. The longer lifetime leads to a higher probability for collision with another triplet or polaron to produce a “hot” excited state. This problem is exacerbated in TADF-based diodes due to their typically longer radiative lifetimes (2–20  $\mu\text{s}$ ). This is reflected in the data in Table 6.14. By the same argument, the short lifetime of the singlet state ( $\sim 1\text{--}10 \text{ ns}$ ) is responsible for the longer lifetimes of fluorescent blue OLEDs.

In Section 3.7.3, we discussed the energetic landscape of metalorganic phosphors. There, we found that the principal routes to high efficiency phosphorescence is via  $^3\text{MLCT}$  and  $^3\text{LC}$  transitions. In this context, blue emission can be accessed by chemical modifications that either destabilize the LUMO, or stabilize the HOMO, as shown in Fig. 6.181a. Destabilization of the LUMO implies moving the LUMO

closer to the vacuum level. This creates a vulnerability to oxidative dissociation of the molecules. As the  $T_1$  energy increases, the energy difference between  $T_1$  and the metal centered state,  $^3\text{MC}$  decreases. In Chapter 3, we showed that  $^3\text{MC}$  is an antibonding,  $\sigma^*$  orbital, and further, due to its  $t_{2g}$  symmetry, the  $t_{2g} \rightarrow e_g$  excited to ground state transitions are not allowed due to parity violations. Therefore,  $^3\text{MC}$  is a dark, or non-radiative state.

Examples of LUMO destabilization for tris-bidentate molecules starting from  $\text{Ir}(\text{ppy})_3$  are shown in Fig. 6.182. For  $\text{Ir}(\text{ppy})_3$ , the activation energy between the  $T_1$  and  $^3\text{MC}$  state is 0.5 eV. Hence, the latter state is thermally inaccessible and does not engage in molecular fragmentation. Assuming that TTA or TPA supplies the excess energy necessary for molecular dissociation, the hot (i.e. multiply excited) state will have at least twice the triplet energy, that is,  $2E_{T_1}$ . Now, the free energy from the ground state,  $G_0$ , to the dissociative state,  $G_{\text{diss}}$  is the energy of reaction, viz.  $\Delta G_{\text{react}} = G_{\text{diss}} - G_0$ . Thus, dissociation requires that  $\Delta G_{\text{react}} > 2E_{T_1}$ . From DFT calculations, it is found that  $\Delta G_{\text{react}} \approx 2E_{T_1} \approx 5.0 \text{ eV}$  (Jacquemin and Escudero, 2017). Since not all doubly excited states immediately localize all of their energy on a single bond, it is unlikely that  $\text{Ir}(\text{ppy})_3$  dissociates either by hot excited states or by thermal activation to the  $^3\text{MC}$  state.

The circumstances are considerably different for the larger energy gap  $\text{Ir}(\text{ppz})_3$ . In this case, the  $^3\text{MC}$  state

**Figure 6.181** Pathways to stable blue phosphor complexes. (a) (top) LUMO destabilization and (bottom) HOMO stabilization. (b) Example blue emitting Ir-complexes, starting with the archetype green emitting  $\text{Ir}(\text{ppy})_3$ .

is thermally accessible to  $T_1$ , with an activation energy of only 0.2 eV. Due to the ease of access to  ${}^3\text{MC}$ , the molecule is non-radiative, that is, the PLQY is  $\Phi_{\text{PL}} = 0$ . Furthermore,  $\Delta G_{\text{react}} = 4.18\text{eV}$ , which is considerably smaller than  $2E_{T1} = 6.0\text{eV}$ . This can result in the rupture of the  $\text{N}_1\text{—C}$  bond, forming the five coordinated trigonal bipyramidal (TBP) structure in Fig. 6.182, center. The energy difference between TBP and  ${}^3\text{MC}$  of 0.4 eV is also too large for the molecule to recover by healing of the bond rupture. For all of these reasons, LUMO destabilization by this chemical route is not a viable approach to achieve long-lived blue phosphor.

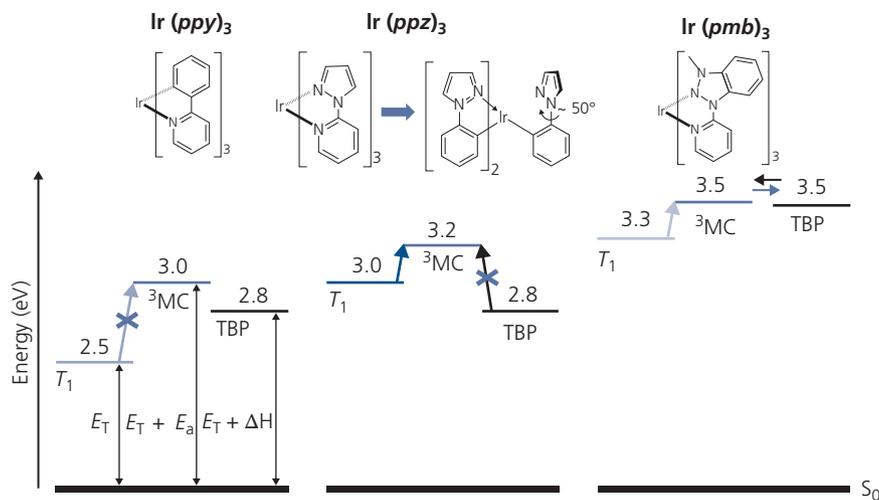

The third molecule to consider is  $\text{Ir}(\text{pmb})_3$ , shown in Figs. 6.181b and 6.182. Like  $\text{Ir}(\text{ppz})_3$ ,  $T_1$  and  ${}^3\text{MC}$  are separated by 0.2 eV. This leads to  $\Phi_{\text{PL}}$  of only 37%. However, since  ${}^3\text{MC}$  and TBP are degenerate, bond rupture can result in reversibility of the dissociation reaction and hence a longer operational lifetime of PHOLEDs employing this species. Furthermore, it has been suggested that tris-bidentate N-heterocyclic carbene (NHC) molecules such as  $\text{Ir}(\text{pmb})_3$  can have a longer lifetime as well as a high  $\Phi_{\text{PL}}$  since  $\Delta G_{\text{react}} = 5.77\text{eV}$  compared to  $2E_{T1} = 6.0\text{eV}$  for the dissociative reaction  $\text{Ir}(\text{pmb})_3 \rightarrow [\text{Ir}(\text{pmb})_2]^+ + [\text{pmb}]^-$ . Unfortunately, this competes unfavorably with  $\text{Ir}(\text{pmb})_3 \rightarrow \text{Ir}(\text{pmb})_2 (\text{C}_6\text{H}_5)^+ (\text{C}_8\text{N}_2\text{H}_7)^-$  where  $\Delta G_{\text{react}} = 4.60\text{eV}$  (Jacquemin and Escudero, 2017). Hence, this particular NHC still results in unstable PHOLEDs, although NHCs with different energetic manifolds may be found that do not undergo this type of low energy ligand fragmentation.

The second approach to achieving blue is via HOMO stabilization. This is accomplished by replacing the luminescent moiety with an ancillary ligand such as acetylacetonate (acac), picolinate (pic), or pyrazolyl (ppz). This raises the  ${}^1\text{MLCT}$  state without affecting the  ${}^3\text{LC}$ . From Eq. 3.185 we see that the triplet is stabilized by the singlet via

$$E'({}^3\text{LC}) = E({}^3\text{LC}) + \frac{|{}^1\text{MLCT}|H_{\text{SO}}|{}^3\text{LC}|^2}{E({}^3\text{LC}) - E({}^1\text{MLCT})}. \quad (6.139)$$

The increase in  ${}^1\text{MLCT}$  thus results in an increase in  ${}^3\text{LC}$ , thereby shifting the emission toward the blue. The attachment of ancillary, non-radiative ligands has proven to be a viable approach to achieving greenish-blue (cyan) emission, illustrated by the two examples of  $\text{Flr6}$  and  $\text{Flrpic}$  in Fig. 6.181. However, this entails an Ir-N double bond, or even the weaker Ir—O bond for pic-complexes. Furthermore, the addition of an electron-withdrawing F-atom can also lead to molecular instabilities. Hence, HOMO stabilization has, to this point, been unsuccessful in leading to stable, deep blue emission.

The energetics of molecular dissociation in blue TADF and metal complexes are shown in Fig. 6.183. The excited state in one molecule (which for the purposes of this discussion will be assumed to be a long-lived triplet) can collide with an excited state in a second molecule (Fig. 6.183a) or a polaron (Fig. 6.183b). The collision results in the non-radiative transition of the exciton on the first molecule to its ground state, along with promotion of the second excited state or polaron to a very high, hot energy state. Although this highly

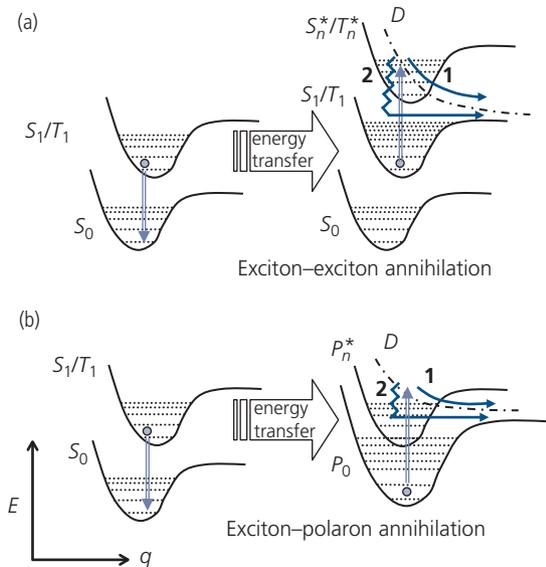

**Figure 6.182** Energy level diagrams for three different phosphors: green emitting  $\text{Ir}(\text{ppy})_3$ , non-emissive, LUMO-stabilized  $\text{Ir}(\text{ppz})_3$ , and emissive LUMO-stabilized  $\text{Ir}(\text{pmb})_3$ . TBP = trigonal bipyramidal structure illustrated by the bond-cleavage of  $\text{Ir}(\text{ppz})_3$ .

excited state is expected to be very short lived due to coupling to numerous lower energy states, occasionally a dissociative reaction (to state  $D$ ) will occur that results in the destruction of the excited molecule. This is analogous to non-radiative *Auger* processes in inorganic semiconductor lasers and LEDs (Coldren and Corzine, 1995).

The rich energy landscape of phosphors and hosts is exemplified by the excited state energy manifolds in Fig. 6.184 for two phosphors, Ir(pmp)<sub>3</sub> and Ir(dmp)<sub>3</sub>, and the host mCBP. Although the energies shown are only a sampling of the entire manifold, it is readily apparent that there are numerous hot excited states accessible to Auger recombination in Fig. 6.183. Interestingly, while the host mCBP has a high triplet state suitable for blue PHOLEDs, its singlet is inherently unstable with a dissociative state energy,  $D_1 = 3.6$  eV  $< S_1 = 3.7$  eV (Lee et al., 2017).

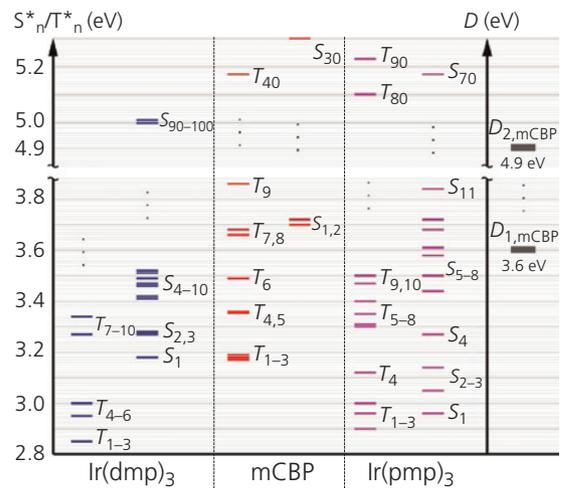

Defects formed by triplet annihilation result in both a decrease in luminance and an increase in operating voltage. Hence, it is reasonable to assume that the annihilation reactions result in defect states in the host and/or the dopant. The states may be mid-energy gap traps that quench excitons in the EML. The number of defects formed increases with time, thereby decreasing luminance and increasing voltage over time. This situation is shown

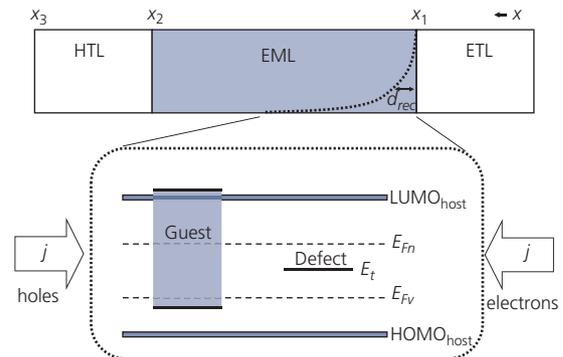

**Figure 6.183** Configuration space diagrams showing how two particle collisions result in molecular dissociation reactions ( $D =$  predissociative state). (a) Annihilation between excitons on adjacent molecules results in the non-radiative transition to the ground state of the first molecule, and promotion of the lowest excited state of the adjacent molecule to a higher manifold (denoted  $S_n^*/T_n^*$ ). (b) As (a) except for exciton-polaron (denoted  $P_0, P_n^*$ ) collisions (Giebink et al., 2008).

schematically in Fig. 6.185 for a single, discrete, deep defect state at energy,  $E_t$ , that lies within the energy gap of the host. Luminescence quenching by defects occurs when energy is transferred to the trap state by a Förster or Dexter transition from the guest or host molecule.

To quantify the effects of trap states on device operation over time, we assume that only hole traps with  $E_t$  are formed. In practice, however, defects may have either or both their HOMO and LUMO levels, or singly occupied molecular orbitals within the host energy gap, and hence can act as traps to either electrons or holes (Kondakov et al., 2007). The defect state itself may not lead directly to a quenching transition,

**Figure 6.184** Singlet and triplet excited state energies calculated via density functional theory for two blue emitting Ir-complexes and the host molecule, mCBP. The energies of the lowest dissociative states ( $D_n$ ) for mCBP are shown at the right (Lee et al., 2017).

**Figure 6.185** Schematic energy level scheme of a PHOLED. A detail of the guest blue phosphor/host EML recombination zone of width  $d_{rec}$  shows the guest (emitter) and host energy levels, along with the approximately mid-energy gap defect at energy  $E_t$ .

but becomes active once it is occupied with a trapped polaron.

The evolution of the energy-driven formation of midgap defects in the EML is determined by assuming that radiative decay decreases exponentially with characteristic length  $d_{rec}$  from the edge of the EML where excitons are formed, as in Fig. 6.185 (Tutis et al., 2003). For simplicity, we further assume that equal numbers of electrons and holes enter the recombination zone, that is, the charge balance efficiency is unity. Excitons either form directly on guest molecules, or they rapidly transfer from the host due to their high doping concentration.

Following the treatment of Giebink et al. (2008), these assumptions lead to rate equations for hole ( $p$ ), electron ( $n$ ), and exciton ( $N$ ) densities in the recombination zone of

$$\begin{aligned} \frac{dp(x, t, t')}{dt} = & \frac{j}{qd_{rec} \left( 1 - \exp \left( -\frac{(x_2 - x_1)}{d_{rec}} \right) \right)} \\ & \times \exp \left( -\frac{(x - x_1)}{d_{rec}} \right) \\ & - \gamma n(x, t, t') p(x, t, t') \\ & - \sigma v_{th} [f_D(E_t)] Q(x, t') p(x, t, t'), \end{aligned} \quad (6.140)$$

$$\begin{aligned} \frac{dn(x, t, t')}{dt} = & \frac{j}{qd_{rec} \left( 1 - \exp \left( -\frac{(x_2 - x_1)}{d_{rec}} \right) \right)} \\ & \times \exp \left( -\frac{(x - x_1)}{d_{rec}} \right) \\ & - \gamma n(x, t, t') p(x, t, t') - \tilde{\gamma} [1 - f_D(E_t)] Q(x, t') n(x, t, t'), \end{aligned} \quad (6.141)$$

$$\begin{aligned} \frac{dN(x, t, t')}{dt} = & \gamma n(x, t, t') p(x, t, t') \\ & - \left( \frac{1}{\tau_{Ph}} + k_{DR} Q(x, t') \right) N(x, t, t'). \end{aligned} \quad (6.142)$$

The electron, hole, and exciton densities (Eqs. 6.140, 6.141, and 6.142, respectively) depend on the timescale of transport and energy level transitions,  $t$  (on the order of microseconds), as well as on that of degradation,  $t'$  (hours), due to formation of defects of density  $Q(x, t')$ . The electron and hole densities are also functions of the current density,  $j$ . Excitons are formed at the Langevin rate of  $\gamma = q(\mu_n + \mu_p)/(\epsilon_r \epsilon_0)$  (see Section 4.5.4) and decay with natural lifetime,  $\tau_{Ph}$ .

The hole and electron mobilities in the doped emissive layer are  $\mu_p$  and  $\mu_n$ , respectively.

In Eq. 6.140, holes with thermal velocity,  $v_{th} \sim 10^7$  cm/s, trap at defect sites of energy,  $E_t$ , and capture cross-section,  $\sigma$ . The Fermi factor,  $f_D(E_t) = [\exp(E_t - E_{Fv}) + 1]^{-1}$ , gives the probability that the hole trap is empty, where  $E_{Fv}$  is the hole quasi-Fermi energy. Electrons in Eq. 6.141 non-radiatively recombine at a rate proportional to the trapped hole density,  $Q(x, t') [1 - f_D(E_t)]$ , and the reduced Langevin coefficient,  $\tilde{\gamma} = q\mu_n/(\epsilon_r \epsilon_0)$ , since trapped holes are assumed to be immobile. Quenching of excitons by defects occurs at the bimolecular rate given by  $k_{DR}$  in Eq. 6.142.

There are four possible routes leading to defect generation expressed by the following:

$$\frac{dQ(x, t')}{dt'} = \begin{cases} K_X n(x, t'), K_X p(x, t') & (6.143a) \\ K_X N(x, t') & (6.143b) \\ K_X N^2(x, t') & (6.143c) \\ K_X N(x, t') n(x, t'), K_X N(x, t') p(x, t') & (6.143d) \end{cases}$$

Here, the defect formation rate is  $K_X$ , whose dimensions are consistent with the order of the reaction (i.e.  $[s^{-1}]$  for first order, and  $[cm^3 s^{-1}]$  for second order processes). In Eq. 6.143a, only the presence of an electron or hole (i.e. a polaron) leads to molecular degradation, while in Eq. 6.143b excitons are responsible. More likely, the higher energy second-order processes of exciton-exciton annihilation in Eq. 6.143c and exciton-polaron annihilation in Eq. 6.143d will lead to luminance loss and increased voltage. Note that this theory is similar to the defect generation model used to describe the voltage rise in devices exposed to current and illumination in Section 6.7.3. The principal difference is that here we consider only those processes where excess energy dissipation leads to bond breaking reactions specifically within the EML.

On the short timescale,  $t$ , Eqs. 6.140–6.143 are at steady state and can be solved to yield  $N(x, t')$ . The resulting coupled differential equations containing  $N(x, t')$  and  $Q(x, t')$  are solved numerically to arrive at the normalized luminescence:

$$L_{norm}(t') = \frac{\int_{x_1}^{x_2} N(x, t') dx}{\int_{x_1}^{x_2} N(x, 0) dx}, \quad (6.144)$$

and the defect formation rate per exciton, averaged over the recombination zone:

$$F_X(t') = \frac{1}{d_{rec}} \int_{x_1}^{x_2} \frac{1}{N(x, t')} \frac{dQ(x, t')}{dt'} dx. \quad (6.145)$$

Here, the integration limits,  $x_1$  and  $x_2$ , are defined in Fig. 6.185.

The density of trapped charge increases with defect density following  $\rho_t(x, t') = qQ(x, t') [1 - f_D(E_t)]$ . Assuming that the increase in  $\rho_t$  is offset by an equal density of opposing charge at the cathode, and that the free charge distribution under steady-state operation is unperturbed, then the voltage rise is

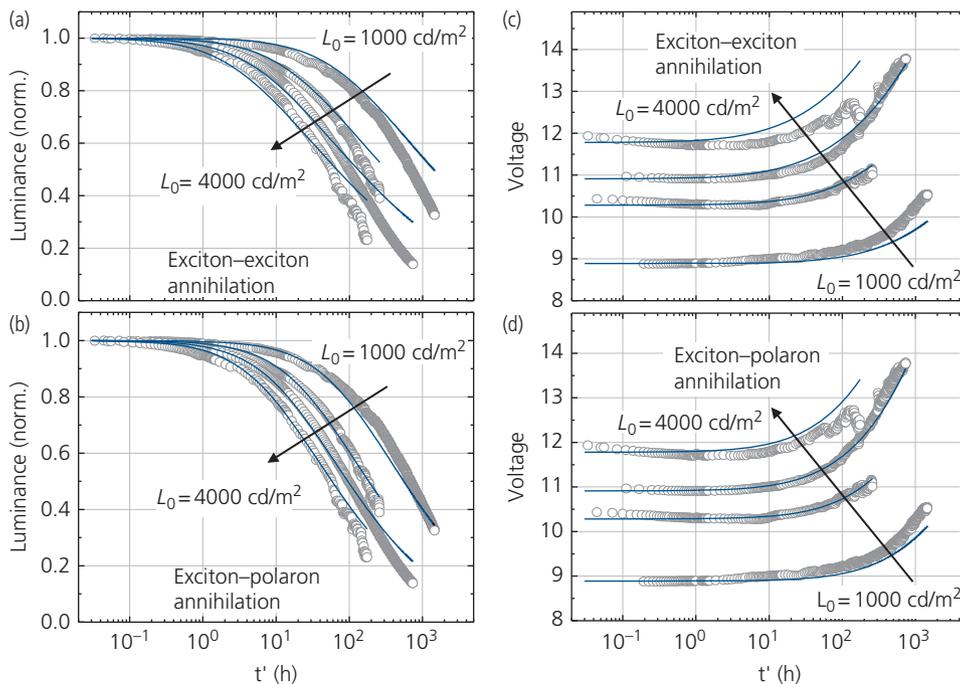

$$\Delta V(t') \approx \int_0^{x_3} x \rho_t(x, t') dx. \quad (6.146)$$

Non-radiative recombination via defects should also decrease the radiative lifetime of the phosphor via:  $1/\tau_{ph} = 1/\tau_{ph0} + 1/\tau_{nr}$ , where  $\tau_{ph0}$  is the natural lifetime for phosphorescent emission. Hence, changes in the PL decay rate vs.  $t'$  are also due to trap formation.

To determine which of the intrinsic processes in Eq. 6.143 dominate, the long-term changes in luminance and voltage can be measured for a population of OLEDs whose fabrication process is stable, and the materials are as free from impurities as possible. The most active aging mechanism represented in Eq. 6.143 is the one that yields the best fit to the  $L_{norm}(t')$  and  $\Delta V(t')$  data.

Figure 6.186 shows the application of this procedure to a population of packaged PHOLEDs whose 30 nm thick EML comprises 9 wt% Ir(dmp)<sub>3</sub> doped into mCBP. The full device structure is: ITO/30 nm  $\alpha$ -NPD/EML/5 nm mCBP/40 nm Alq<sub>3</sub>/0.8 nm LiF/100 nm Al (Giebink et al., 2008). The solid lines show the fits to TTA- and TPA-induced degradation, corresponding to Eqs. 6.143c and d, respectively. The fits use the following model-dependent parameters:  $d_{rec} = 10$  nm and 8 nm,  $k_{DR} = 4 \times 10^{-12}$  cm<sup>3</sup>/s and  $5 \times 10^{-12}$  cm<sup>3</sup>/s, and  $K_X = 1.7 \times 10^{-22}$  cm<sup>3</sup>/s and  $7 \times 10^{-24}$  cm<sup>3</sup>/s for TTA and TPA, respectively. Similar fits attempted for the various other monomolecular processes in Eq. 6.143 did not provide reasonable matches to the data. The fits, therefore, suggest that the most likely contribution to both the luminance and voltage changes over time is TPA, although contributions from TTA cannot be ruled out.

The relative contributions to luminance loss from exciton quenching and non-radiative recombination inferred from the PL transients vs. time are estimated to be about 70% and 30% respectively. The rate of exciton decay through quenching is  $-k_{DR}QN$  (see Eq. 6.142), whereas the loss of

**Figure 6.186** Luminance vs. time measured (points) for the blue PHOLED described in text, and fit to (a) TTA and (b) TPA models. These same processes are used to fit the voltage rise vs. time data in (c) and (d). The various curves correspond to initial luminances of 1000, 2000, 3000, and 4000 cd/m<sup>2</sup> (Giebink et al., 2008).

Intrinsic luminance loss in phosphorescent small-molecule organic light emitting devices due to bimolecular annihilation reactions. *J. Appl. Phys.*, 103, 044509 with the permission of AIP Publishing

excitons to trapped charge from Eq. 6.141 is given by  $-\tilde{\gamma}[1-f_D]Qn$ . The 70/30 split is then the ratio of these two rates.

Now, the average defect density is given by

$$Q_{AVG}(t') = \frac{1}{d_{rec}} \int Q(x, t') dx. \quad (6.147)$$

From the fits to the exciton–polaron model in Fig. 6.186, it is found that a defect density of  $10^{18} \text{ cm}^{-3}$ , which is  $\sim 0.1\%$  of the molecular density, leads to  $>50\%$  loss in luminescence. Furthermore, the rate of defect formation across the EML at  $1000 \text{ cd/m}^2$  is  $F_X \approx 0.04 \text{ h}^{-1}$ , which is equivalent to a defect formation rate of  $\sim 6 \times 10^{11} \text{ cm}^{-3} \text{ s}^{-1}$ .

The probability that an exciton–polaron encounter leads to formation of a defect can now be estimated. Assuming that if a polaron comes within the exciton encounter radius,  $r$ , then the number of encounters per unit volume is  $Nn(\frac{4}{3}\pi r^3)$ , each of which has probability,  $P$ , for resulting in a defect. The number of defects produced during  $\tau_{ph}$  is  $\Delta Q = K_X Nn\tau_{ph} = PNn(\frac{4}{3}\pi r^3)$ . Thus, the probability that an encounter leads to the formation of a defect is

$$P_{TPA} = \frac{3K_X\tau_{ph}}{4\pi r^3}. \quad (6.148)$$

Using  $K_X = 7 \times 10^{-24} \text{ cm}^{-3} \text{ s}^{-1}$  and  $\tau = 1.1 \mu\text{s}$  for  $\text{Ir}(\text{dmp})_3$ , and assuming nearest molecular neighbor interactions (corresponding to  $r \sim 1 \text{ nm}$ ), then  $P \approx 2 \times 10^{-9}$ , or roughly 1 in  $5 \times 10^8$  encounters result in molecular dissociation. Note that in a cavity with a Purcell factor,  $PF > 1$ , the probability of defect formation is decreased by this same amount since the lifetime is reduced according to  $\tau'_{ph} \rightarrow \tau_{ph}/PF$  (cf. Eq. 6.110ff). Similarly, if TTA is the primary source of degradation, two excitons are required, and the probability for a destructive event is reduced by  $P_{TTA} \rightarrow \tau_{ph}^2 \sim \tau_{ph}^2/PF^2$ .

The exceptionally low rate of defect formation suggests that numerous pathways exist for the hot polaron to non-destructively relax back to  $T_1$ . In Fig. 6.184, we showed a near continuum of accessible hot excited states. Transitions among these states leads to extremely fast rates of internal conversion ( $\sim$ picoseconds) that compete with dissociation. Even with this remarkably low dissociation rate, the device has an  $LT50 = 700 \text{ h}$  with  $L_0 = 1000 \text{ cd/m}^2$  due to the very high exciton and polaron densities required to achieve this luminance.

From the foregoing, we conclude that strategies for extending blue PHOLED lifetime must involve lowering the densities of excitons and polarons. From the fits in Fig. 6.186, the device lifetime can more than double as the EML thickness becomes large ( $d_{rec} \rightarrow \infty$ ). However, there is little improvement in

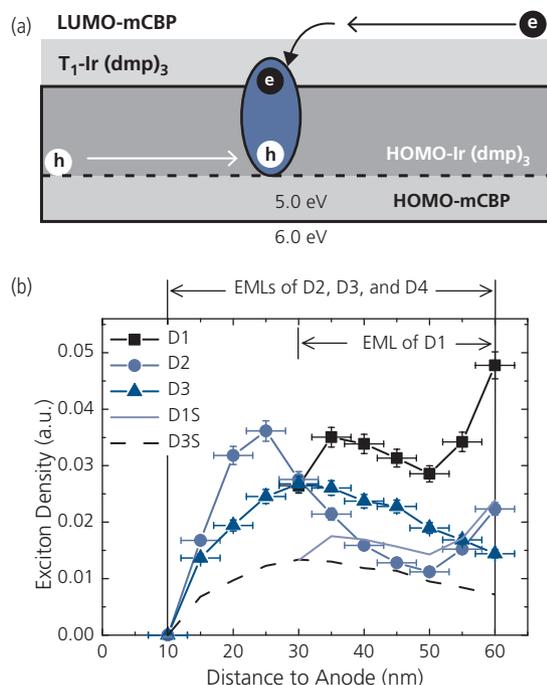

$LT80$  for  $d_{rec} > 30 \text{ nm}$ . Since voltage increases rapidly with EML thickness,  $30 \text{ nm}$  is near the upper limit for power efficient OLEDs. Alternatively, control of electron and hole mobilities in the EML, as well as the strategic placement of energy barriers in the device can lead to a more uniform distribution of excited states within the recombination zone.

Engineering host and guest molecules to lower the annihilation probability also leads to increased operating lifetime, as well as improved efficiency at high brightness (Reineke et al., 2007). Since the probability for defect formation is proportional to  $\tau_{ph}$  (Eq. 6.148), one of the most effective methods for decreasing the probability of defect production is to decrease  $\tau_{ph}$ . However, as seen in Section 3.7.3, the natural lifetime is intrinsically limited by the magnitude of zero-field splitting to  $\sim 500 \text{ ns}$  for metalorganic complexes. Furthermore, blue emitting complexes typically have reduced metal–ligand interactions, leading to  $\tau_{ph} > 2 \mu\text{s}$ , setting a limit on the leverage that changes in this parameter can have on improving the lifetime of blue PHOLEDs.

Note that the foregoing analysis is independent of the source of the luminescence. Hence, it is equally applicable to TADF emitters. Indeed, the exceptionally long radiative lifetimes of  $2\text{--}20 \mu\text{s}$  of non-metalorganic TADF molecules can account for the relatively poor reliabilities observed in OLEDs employing these materials (see Table 6.14).

The prediction that reducing the exciton density within the EML results in a concomitant reduction in the defect formation rate has been directly tested by grading the dopant concentration in the EMLs of blue PHOLEDs (Zhang et al., 2014b). In  $\text{Ir}(\text{dmp})_3$ :mCBP devices such as in Fig. 6.186, the  $\text{Ir}(\text{dmp})_3$  preferentially conducts holes and mCBP conducts electrons in the EML, as shown in Fig. 6.187a. Once the carriers encounter each other on adjacent molecules, an exciplex is briefly formed, which then transfers to a triplet exciton on  $\text{Ir}(\text{dmp})_3$ , resulting in blue emission. Since the hole mobility on the Ir-complex is higher than electrons on mCBP, the electron-polarons and excitons in a uniformly doped emission region pile up near the ETL/HBL interface. This high density of charge encourages TPA and TTA, accelerating aging.

The exciton formation zone was uniformly spread across the entire EML by linearly grading the hole-conducting dopant from 18% at the EML/HTL interface to 8% at the EML/HBL interface. The reduction in  $\text{Ir}(\text{dmp})_3$  concentration leads to a reduced hole polaron hopping efficiency (and hence mobility), shifting the exciton formation zone away from the HBL toward the center of the EML.

**Figure 6.187** (a) Schematic of the energetics and charge conduction levels in the  $\text{Ir}(\text{dmp})_3$ :mCBP EML. Holes are conducted on the  $\text{Ir}(\text{dmp})_3$  HOMO, and electrons on the mCBP LUMO. (b) Exciton profiles in 5 different devices described in text (Zhang et al., 2014b).

To determine the spatial distribution of excitons in the EML in both graded and ungraded PHOLEDs, thin (1.5 nm), red emitting 2 vol.% PQIr “sensing” layers were doped in the EMLs of several otherwise identical devices, but spaced at 5 nm intervals in each PHOLED. The relative intensity of red emission from each of the positions within the EML gives the relative exciton density at that position, thus mapping the exciton spatial distributions. Since the thickness of the sensing layer is much less than that of the EML, its presence does not significantly perturb the voltage or exciton distribution in the EML from that in the absence of the sensor layers. This procedure is used to map the exciton distribution in three different device architectures. (i) D1—a uniformly doped PHOLED with a conventional structure that includes an HTL. The EML is uniformly doped comprising 13 vol.%  $\text{Ir}(\text{dmp})_3$ :mCBP. (ii) D2—same as D1 except the HTL (in this case, NPD) is omitted and the EML thickness is increased to 50 nm to ensure that the  $\text{Ir}(\text{dmp})_3$  is an efficient hole conductor, and (iii) D3—same as D2 except the  $\text{Ir}(\text{dmp})_3$  concentration is also linearly graded from 18 vol.% to 8 vol.%. Two stacked devices were included in the study. D1S, which is a double stack of D1 with 70 nm thick 2 vol.% Li-doped

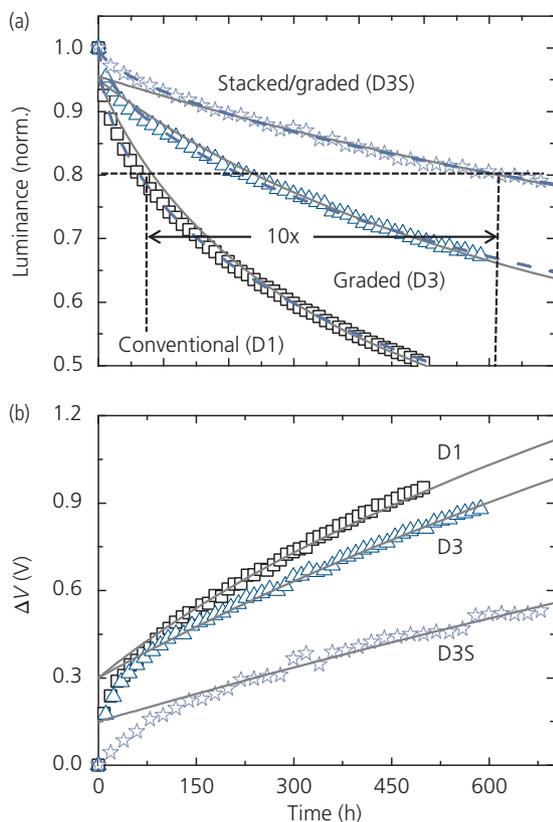

$\text{Alq}_3$  interconnecting charge generation layer between stacked elements, and D3S which is a double stack of D3 elements with the same interconnecting layer as in D1S. Stacked devices have an exciton concentration that is reduced by the number of stacked elements compared to single element devices (Adamovich et al., 2012).

The measured exciton distributions are shown in Fig. 6.187b. In D1, significant exciton accumulation occurs at the EML/HBL interface. In D2 that lacks an HTL, the exciton formation zone is broadened due to the increase in the EML thickness. As a result, the exciton density at the HIL/EML interface is reduced due to a correspondingly low concentration of holes. The reduced hole transport efficiency of these devices leads to electron penetration deep into the EML, resulting in a peak exciton density near the HIL/EML interface. In contrast, efficient hole transport near the HIL/EML interface and the gradual hole blocking in the EML in D3 lead to a more uniform exciton distribution (and hence higher  $\eta_{\text{ext}}$  at high current due to reduced TTA) compared to both D1 and D2. Figure 6.187b also shows the inferred exciton density profiles of D1S and D3S, estimated at 50% of the exciton density in D1 and D3.

The lifetime data of D1, D3, and D3S are shown in Fig. 6.188, along with fits to the TPA model and empirical model of Eq. 6.121. Consistent with the TPA analysis, the lifetime of D3 is approximately three times longer than D1 due to the extended exciton recombination zone, and is ten times longer when two D3 elements are stacked.

The results from this series of devices along with the lifetime fitting parameters of  $k_{\text{DR}} \approx 1 \times 10^{-11} \text{cm}^3 \text{s}^{-1}$  and  $K_X \approx 7 \times 10^{-24} \text{cm}^3 \text{s}^{-1}$  from the TPA model are summarized in Table 6.17 (Zhang et al., 2014b). The values from the fits are consistent with those in Fig. 6.186 using this same materials system. Furthermore, the efficiency of D3 is higher than that of D1 and D2. This is also expected for devices in which bimolecular annihilation is reduced in EMLs that have a lower local exciton density. Finally, the voltage at  $L_0 = 1000 \text{cd/m}^2$  is higher for D3 (7.7 V) than for D1 (6.9 V) which is the result of the larger EML thickness of the former device.

Reducing the exciton density via grading confirms the TPA mechanism, however, it is unclear that this strategy alone can result in blue PHOLEDs with sufficiently long lifetimes to be practical. To achieve this latter objective, hot excited states must be entirely eliminated before they can damage the emitting molecules. This can be partially accomplished by including a third molecular species; a *hot excited state manager molecule* into the phosphor-doped EML. The

**Figure 6.188** (a) Blue PHOLED luminance vs. aging time for three different devices described in text, and (b) the voltage rise vs. time for these same devices. The solid lines are fits to the TPA degradation model using values listed in Table 6.17, and the dashed lines are fits to the stretched exponential in Eq. 6.121 (Zhang et al., 2014b).

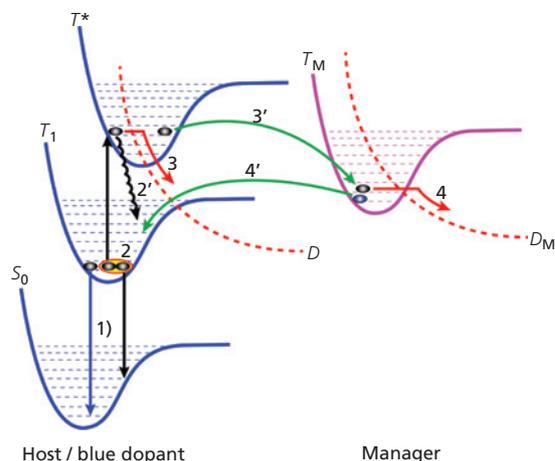

**Table 6.17** Characteristics at  $L_0 = 1000 \text{ cd/m}^2$  for blue emitting PHOLEDs

<sup>a</sup> Estimated extrapolations from the TPA model.

manager dissipates the excess energy generated in TTA and TPA reactions prior to localization on a single molecular bond.

The Jablonski diagram in Fig. 6.189 illustrates the process of hot excited state management. By introducing a manager whose excited state energies  $S_M/T_M$  are greater than that of the dopant, excitons formed on, or transferred to the manager can be returned to

**Figure 6.189** Jablonski diagram of an EML containing the manager. Here,  $S_0$  is the ground state,  $T_1$  is the lowest energy triplet state, and  $T^*$  is a hot triplet manifold of the dopant or host.  $D$  represents the dissociative state accessed via the predissociative potential in the EML.  $T_M$  is the lowest triplet state of the manager. Possible energy-transfer pathways are numbered as follows: (1) radiative recombination, (2) TTA resulting in excitation to  $T$ , (2') internal conversion and vibrational relaxation, (3) and (4) dissociative reactions leading to molecular dissociation, (3') exothermic energy transfer for transitions to the manager, and (4') back transfer from the manager to  $T_1$  (Lee et al., 2017).

the dopant for emission. Exothermic transfer from  $S_n^*/T_n^*$  to  $S_M/T_M$  is also allowed, and damage to these molecules via dissociative reactions (process 3) is reduced provided that the rate for  $S_n^*/T_n^* \rightarrow S_M/T_M$  is comparable or higher than  $S_n^*/T_n^* \rightarrow D$ , where  $D$  is the predissociative state, via process 3'. A transferred singlet undergoes vibrational relaxation and subsequently transfers back to the lowest dopant singlet state. Alternatively, the thermalized singlet state intersystem crosses to the triplet state via  $S_M \rightarrow T_M$ , which subsequently transfers back to the dopant or host ( $T_M \rightarrow T_1$ ) via process 4'. This leads to radiative recombination (process 1), or is recycled back to  $S_n^*/T_n^*$ . It is also possible that the high energy  $T_M$  state can result in dissociation of the manager itself via  $T_M \rightarrow D_M$  (process 4), that is, where the manager serves as a sacrificial additive to the EML. Process 4 is not optimal since the number of effective managers decreases over time, providing less protection for the host and dopant. Even in this case, however, the manager can still increase device stability.

From the foregoing, three primary criteria must be met for effective design of the manager. (i) The exciton energy of the manager should be higher than lowest exciton states ( $S_1/T_1$ ) of the dopant; (ii) the rate of transfer to the manager (process 3') must be comparable to or higher than that for dissociation

(process 3); and (iii) the manager should be sufficiently stable such that it does not degrade on a timescale short compared to that of the unmanaged device (process 4).

The principle of hot excited state management in Ir(dmp)<sub>3</sub>:mCBP based PHOLEDs was investigated by including the manager, *mer*-Ir(pmp)<sub>3</sub>, in the EML. The manager triplet energy is at  $E_{T1} = 3.1$  eV compared with the dopant at  $E_{T1} = 2.8$  eV. Hence, at least criterion (i) is satisfied (Lee et al., 2017). The devices tested consisted of a 50 nm thick EML that was graded from 15 vol.% Ir(dmp)<sub>3</sub>:mCBP at the HTL/EML interface, to 5 vol.% Ir(dmp)<sub>3</sub>:mCBP at the EML/HBL interface. Six different structures were compared: M0 has 3 vol.% of the manager molecule doped uniformly across the EML, whereas M1–M5 have a 10 nm zone of the EML doped with 3 vol.% *mer*-Ir(pmp)<sub>3</sub> doped in 10 nm wide zones starting at the HTL/EML interface (M1), and ending in the last 10 nm wide zone at the EML/HBL interface (M5). The PHOLEDs were otherwise analogous to D1 in Fig. 6.187, except that the HTL comprised CPD.

No emission was observed from the high energy manager, indicating that there was complete energy transfer from *mer*-Ir(pmp)<sub>3</sub> to Ir(dmp)<sub>3</sub>. The luminance and voltage changes with operating time are fit using a TTA model modified from that in Eq. 6.140–6.142 (lines, Fig. 6.190a) that includes voltage increases due to deep traps formed in both the EML and the HTL, and luminance loss only due to a trap within the EML itself.

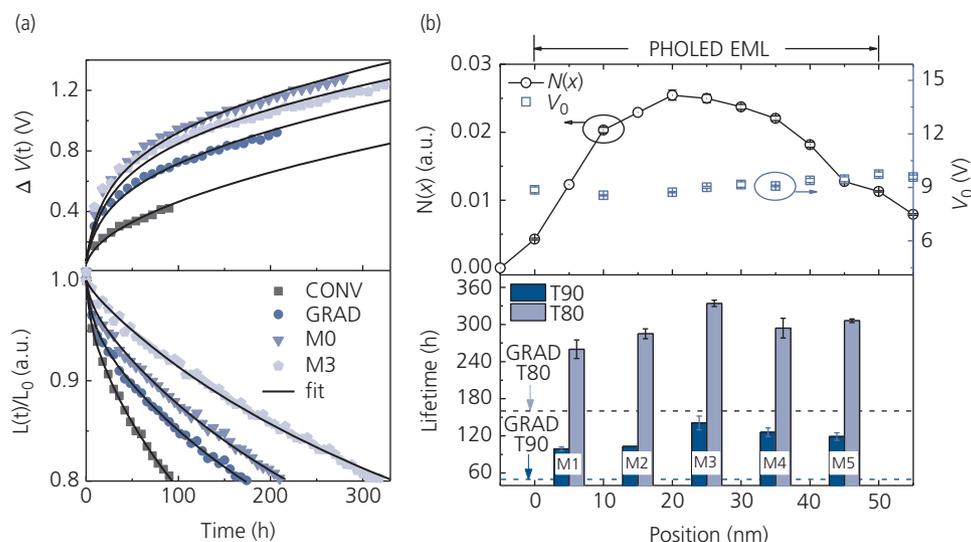

The exciton distribution is determined by doping 1.5 Å thick red phosphor slabs at successively distant positions from the HTL/EML interface, and then measuring the relative red emission intensities from these layers. Grading results in a reasonably uniform exciton distribution, see Fig. 6.180b. Interestingly, the *LT90* and *LT80* lifetimes of the devices M1–M5 qualitatively match the exciton density profile in Fig. 6.190b, that is, the lifetime is longest when the manager is placed in the zone with highest exciton density (M3). This is expected if the manager is in fact eliminating excitations from the dopant and host prior to their damaging the active molecules in the emitting zone.

The performance of all devices is summarized in Table 6.18 and Fig. 6.190c. The improvement in lifetime at *LT90* is 5.2-fold compared to that of a conventional, ungraded EML device (CONV), falling to 3.5-fold at *LT80*. A similar decrease is seen for the graded (GRAD) device whose structure is similar to that in Fig. 6.187. This is attributed to depletion of the manager due to dissociative reactions, corresponding to process 4 in Fig. 6.189. While the improvements are

insufficient for displays, hot excited state management appears to provide a strategy for extending the lifetime of blue PHOLEDs provided stable manager molecules can be developed that promote extremely rapid energy transfer from the dopant and host. Notably, the drive voltages of the managed devices are higher than for GRAD and CONV. This is due to the lower hole conductivity of *mer*-Ir(pmp)<sub>3</sub> compared with Ir(dmp)<sub>3</sub>. Increased voltage leads to increased Joule heating, and hence a relative reduction in lifetime. Local doping of the manager in M3, therefore provides an improved lifetime compared with uniformly doped M0.

Since the fits in Fig. 6.190a suggest that traps in the HTL are partially responsible for the voltage rise, it is reasonable to assume that degradation of the blocking and transport layers in PHOLEDs may also occur over time. We have already noted that LUMO energies of layers used in blue PHOLED lie close to the vacuum level, and thus are more easily oxidized than materials used in longer wavelength emitting devices. Hence, loss of charge balance may also contribute to the loss of luminance in blue PHOLEDs. The contributions from the transport and blocking layers have been independently measured by placing thin red phosphorescent and fluorescent sensing layers in the ETL and HTL in the CONV devices in Fig. 6.190. The emission from these sensing layers as a function of time is used to determine whether the charge balance or exciton leakage from the EML is also changing. The phosphor dopant, PtOEP in the ETL and HTL is sensitive to triplet leakage, and the DCM2 fluorophore placed in the ETL is sensitive to loss of charge balance, since electrons and holes in the Alq<sub>3</sub> ETL transfer to the DCM2 and result in red emission. The 0.5 Å thick sensor layers were placed within 5 nm of the EML or HBL, as shown in Fig. 6.191a (Coburn and Forrest, 2017).

The blue spectral intensities in Fig. 6.191b and c decrease with operating time as the device ages. However, there are only very small changes to the PtOEP emission on the HTL and ETL sides of the device, indicating a minor increase in triplet exciton leakage from the EML. In contrast, there is no change in DCM2 emission since the HBL does not undergo significant changes in its ability to block holes during the timescale of the experiments. These experiments find that no more than 3% of the luminance loss and voltage rise is due to changes in charge or exciton confinement within the EML. Hence, the degradation of the PHOLEDs is indeed almost entirely due to energy-induced degradation of the molecular constituents in the EML.

**Figure 6.190** (a) Lifetime characteristics of the conventional (CONV), linearly graded (GRAD), and managed PHOLEDs M0 and M3. Top and bottom plots show the time evolution of the operating voltage change,  $\Delta V(t) = V(t) - V_0$ , and the normalized luminance degradation,  $L(t)/L_0$ , respectively. Solid lines are fits based on the TTA/TPA model. (b) (Top) Exciton density profile,  $N(x)$ , at  $L_0 = 1000 \text{ cd/m}^2$  of the EML vs. position,  $x$ , from the HTL/EML interface, and operating voltages obtained using sensing layers. (Bottom) Lifetimes ( $LT_{90}$  and  $LT_{80}$ ) of managed devices (M1–M5) as functions of the position of the manager in the EML.  $LT_{90}$  and  $LT_{80}$  of the managed devices are compared with those of GRAD (dotted lines). The variation in lifetimes qualitatively follows the exciton density profile (Lee et al., 2017).

<sup>a</sup> Parameters are measured at  $L_0 = 1000 \text{ cd/m}^2$ .

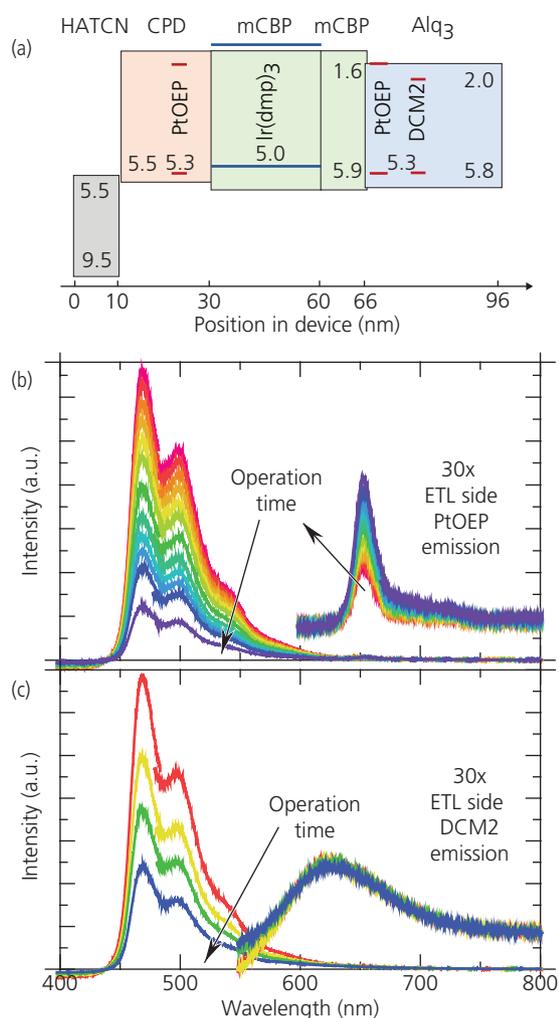

<sup>b</sup> Increase in lifetime compared to the conventional, ungraded device (CONV) lifetime.

<sup>c</sup> Increase in lifetime compared to the graded device (GRAD) lifetime.

The TTA/TPA model is based solely on the assumption that deep levels are generated by destructive, high-energy reactions with the emitting and host molecules, but it does not identify the chemical source of the defects. These chemical origins have been studied for the graded device, D3, in Figs. 6.187 and 6.188 using LDI-TOF-MS (see Section 6.7.3). The mass spectra for fresh (unaged) devices, and for packaged devices aged to  $LT_{40}$  starting at  $L_0 = 3000 \text{ cd/m}^2$  are shown in Fig. 6.192a. The aged device spectra exhibit

peaks from the undamaged dopant,  $\text{Ir}(\text{dmp})_3$ , the host, mCBP, and the  $\text{Alq}_3$  ETL molecules. But after aging, several additional peaks appear. These are associated with fragments of the dopant (DX), host (HX) and ETL (EX) molecules, where X identifies a particular fragment species.

The proposed fragmentation products of  $\text{Ir}(\text{dmp})_3$  and mCBP are shown in Fig. 6.192b. The bond rupture sites on the parent molecules are indicated by wiggly lines. D1 is the most massive fragment resulting from

**Figure 6.191** (a) Energy level diagram of a blue PHOLED showing materials used in each layer, along with the placement of the DCM2 and PtOEP sensing layers in the Alq<sub>3</sub> ETL, and PtOEP layer within the CPD HTL. (b) Spectra of the blue PHOLED as a function of operating time along with the increasing ETL-side emission spectrum from PtOEP. The spectral evolutions are shown periodically along the directions of the arrows between 0 and 214 h of operation at  $j_0 = 30 \text{ mA/cm}^2$  ( $L_0 \sim 5000 \text{ cd/m}^2$ ). (c) As in (b) but showing the DCM2 singlet emission from 0 to 109 h (Coburn and Forrest, 2017).

cleavage of an entire ligand, which is labelled D4 with  $m/z = 334$ . Other products include a 2-coordinated Ir atom containing only a single ligand (D2) and a pair of ligands (D3) with twice the mass of D1. Several other products, D4–D7 are due to loss of only a few low mass groups from one or more of the ligands themselves. Similarly, mCBP, which we have already shown is unstable when excited to its S1 state, dissociates into several smaller species, labeled H1–H3.

While a large number of fragments are identified, the question remains as to whether, or what fragments actually produce traps that can affect the luminance and voltage of the PHOLED over time. For this purpose, the energy levels of the various decay products have been calculated using TD-DFT, with results provided in Fig. 6.193. The calculations suggest that the D6, H1, H3, and H4 radicals have deeper LUMOs than mCBP. These energy levels are available to trap electrons, and thus form recombination centers that lead to a drop in luminescence and an increase in voltage. The D7 radical can quench excitons since it has lower triplet energy than Ir(dmp)<sub>3</sub>. This fragment species, however, does not have an impact on charge trapping due its wide energy gap. Further, mCBP forms neutral fragments (i.e. carbazole, phenyl-carbazole, etc.) upon proton abstraction. These have wider energy gaps and higher  $E_T$  than Ir(dmp)<sub>3</sub>, and hence they, too, are inactive in affecting voltage and luminescence over time.

Figure 6.193 shows that the D2, D4, and H1–H4 cations have deeper LUMO energies than the HOMO of the dopant. These positively charged fragments can attract electrons to become neutral species as shown, and hence do not persist as electronically active states. This leaves the anion series of D1 and H1–H4. Electron transfer from these states will also be rapid, converting them to neutral species. Thus, only the neutral fragments, D6, H1, H3, and H4, appear to be responsible for device aging. The calculations also show that these species have lower  $E_T$  than Ir(dmp)<sub>3</sub>, suggesting that they are likely sources of exciton quenching that is absent from the triplet annihilation model.

While deep blue emitters are required for displays, only cyan emission is needed in an illumination source to achieve an acceptable CCT and CRI. Coupled to the relaxed criterion of  $LT70$  (compared to  $LT90$ – $LT95$  for display pixels) the lifetime of WOLEDs nearly meets many of the requirements demanded for interior lighting. An example structure of a high brightness, long-lived all-phosphorescent stacked WOLED consisting of a single blue emitting element and one, two, or three red-green (R-G) elements (devices D3–D5, respectively) is shown in Fig. 6.194a. Since only  $\sim 25\%$  of the light emitted by an illumination source is blue, only a single blue element is required to achieve a high total brightness. The WOLED employs a blue element whose graded, Ir(dmp):mCBP EML center section is doped at 3 vol.% with an Ir(pmp)<sub>3</sub> manager molecule, along with a R-G bilayer comprising 25 nm thick and 10 nm thick 10% PQIr:8% Ir(5-ph-ppy)<sub>3</sub> in mCBP (R-G) layer that is separated by a 3 nm thick BAq spacer from a pure red emitting 5 nm thick 10% PQIr:BAq layer. The composition of each of the

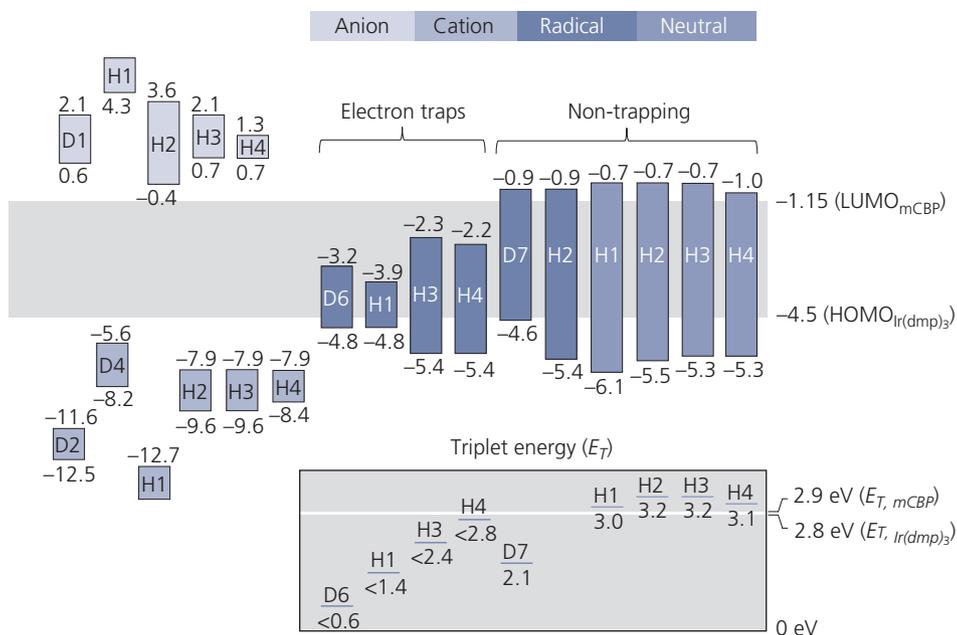

**Figure 6.192** (a) LDI-TOF-MS spectra for aged and unaged graded EML PHOLEDs with the D3 structure. Here, H = host, D = dopant, and E = ETL fragments. The unaged molecular features are also labelled. (b) Proposed molecular fragmentation routes for dopant and host molecules corresponding to the  $m/z$  peaks in (a). The wiggly lines indicate possible bond rupture sites (Jeong et al., 2019).

Reprinted from *Organic Electronics*, 64, Jeong, C., Coburn, C., Idris, M., Li, Y., Djurovich, P. I., Thompson, M. E. & Forrest, S. R., Understanding molecular fragmentation in blue phosphorescent organic light-emitting devices, 15-21, Copyright 2019 with permission from Elsevier.

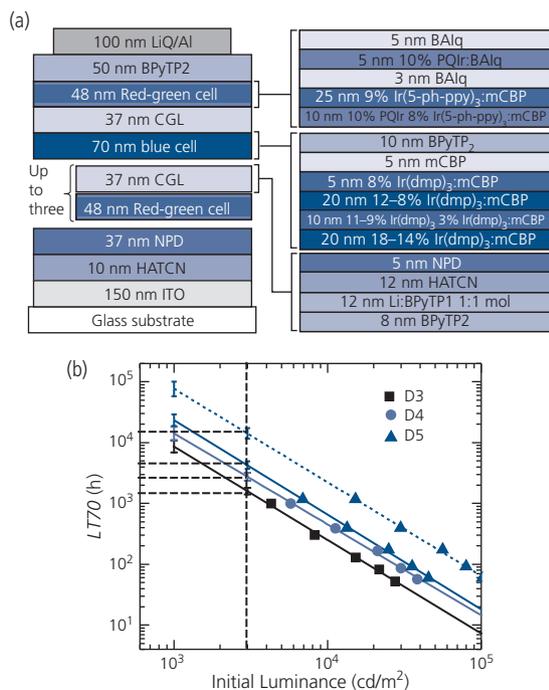

elements is provided for this 48-layer phosphorescent diode in Fig. 6.194a. The layers are optimized to achieve the desired color coordinates and brightness demanded of high quality lighting sources. The 3-R-G element device, D5, exhibits a maximum brightness of  $\sim 200,000$   $\text{cd}/\text{m}^2$ ,  $\eta_{\text{ext}} = 170\%$ , a luminous power efficiency at  $L_0 = 1000$   $\text{cd}/\text{m}^2$  of 50  $\text{lm}/\text{W}$  using substrate outcoupling index matching fluid, a  $\text{CCT} = 3000$  K and  $\text{CRI} = 89$ .

The  $LT_{70}$  of devices D3–D5 as a function of initial luminance is shown in Fig. 6.194b. The vertical dashed line corresponds to  $L_0 = 3000$   $\text{cd}/\text{m}^2$ , which is the nominal operating point of an illumination source. The  $LT_{70}$  of D5 using IMF outcoupling is

approximately 14,000 h, which increases to 80,000 h at  $L_0 = 1000$   $\text{cd}/\text{m}^2$ . Using fewer R-G elements results in a small decrease in lifetime since these layers must deliver a large fraction of the emission brightness, and thus undergo the highest stress. The color shifts during aging are criteria that are as important as luminance loss in setting the failure criteria of an illumination source. The device in Fig. 6.194 in fact redshifts with age, due to the more rapid differential aging of the blue emitting element, as expected. At  $LT_{70}$ , the color coordinates of D5 change as follows:  $\Delta\text{CCT} = -360$  K,  $\Delta\text{CRI} = -0.8$ , and  $\Delta u, \Delta v = 0.03, 0$ . While all of these performance characteristics indicate that all-phosphorescent stacked PHOLEDs can meet

**Figure 6.193** Energy level diagram of the fragments produced on PHOLED aging. The broad gray shaded region shows the LUMO energy of mCBP and the HOMO energy of Ir(dmp)<sub>3</sub>. Anion, cation, radical, and neutral species are displayed as shown in the legend at top. Triplet energies of the parent as well as neutral and radical fragment molecules are given at the bottom right (Jeong et al., 2019).

**Figure 6.194** (a) Stacked, all-phosphorescent WOLEDs. SWOLEDs D3, D4, and D5 have one, two, and three CGL/red-green element pairs below the blue emitting element, respectively. The total number of layers in D5 is 48. (b) Extrapolation of  $LT70$  vs. initial brightness. Error bars represent one standard deviation from a fit to the data using the relation:  $LT70 \times L_0^n = \text{const}$ , with  $n = 1.50-1.54$ . The diagonal dashed line corresponds to the initial luminance obtained using index matching fluid for substrate mode outcoupling. The vertical dashed line corresponds to an initial luminance of 3000 nits (Coburn et al., 2017).

many of the criteria required of efficient and bright white illumination sources, energy-driven degradation of the blue element still presents the limiting factor in their lifetime.

To summarize this discussion, a combination of TTA and TPA initiated reactions is the source of intrinsic losses in luminance and operating voltage of blue light emitting devices. The energies produced are at least double that of the molecular bond energies. Hence, energy-driven aging becomes increasingly important as the emission wavelength is reduced. To mitigate these effects, decreasing the exciton and polaron densities in the EML can significantly increase blue PHOLED lifetime by decreasing the probability for annihilation events. An alternative route to an extending the PHOLED lifetime is to incorporate hot excited state managers in the EML to siphon off the excess energy induced by TPA and TTA.

There is one other important route to increasing the blue PHOLED lifetime, and that is by decreasing the exciton recombination lifetime itself (see Eq. 6.148). Shorter exciton lifetimes reduce the opportunity for annihilation reactions, since this also reduces the exciton concentration in the EML. This is the primary reason that blue fluorescent OLEDs have significantly longer operational lifetimes than PHOLEDs—the lifetime of the singlet state is often  $< 10^{-2}$  times that of triplets. As a result, fluorescent blue OLEDs have lifetimes at least 10 times greater than phosphorescent blue devices, see Table 6.14.

We have seen in Section 3.7.3 that improved  $^3\text{MLCT}$  results in a decreased  $\tau_{\text{ph}}$ , but a few hundred nanoseconds appears to be a minimum attainable value in transition metal complexes (Yersin et al., 2011). Due to the ligand structure of blue PHOLEDs with their strongly electron withdrawing nature, the spin-orbit coupling, and hence the degree of  $^3\text{MLCT}$  is reduced, leading to  $\tau_{\text{ph}} > 2 \mu\text{s}$ . Cavity effects (i.e. via the Purcell effect), or rapid extraction of energy via surface plasmons or other “external” approaches to decreasing the exciton lifetime offer possibilities to reducing exciton recombination times, and hence increasing device stability.

It is worth reiterating that the problem, and the solution for extended blue lifetime is equally relevant for both transition metal phosphor complexes and TADF molecules. In both cases, the emission is driven by triplets, and it is their high densities and long lifetimes that lead to energy-enhanced aging. Notably, TADF molecules, with their reduced spin-orbit coupling, typically have significantly longer exciton recombination times than metal-based phosphor complexes. Hence, it is not surprising that TADF-based OLEDs have shorter lifetimes than those based on  $\text{Ir}(\text{dmp})_3$  and Pt-based blue complexes (see Tables 6.14 and 6.15) (Nakanotani et al., 2013). Thus, while TADF molecules are still in the early stages of development, it seems unlikely that their lifetimes will exceed those of the metal-organic complexes. Nevertheless, managers, EML grading, reducing the excited state lifetime, and other such strategies that have proven beneficial to blue PHOLEDs should serve equally well for TADF-based blue emitting OLEDs.

Finally, efficient blue emission can also be accessed via phosphor- or TADF-sensitized fluorescence (Baldo et al., 2000b, Nakanotani et al., 2014). At first glance, this would appear to be a promising route to achieving the efficiency of triplet emission and the lifetime of fluorescent OLEDs. Since the energy transfer process to the blue fluorophore from the initiating phosphor or TADF molecule is exothermic, this requires that the initial state be at a higher energy. That is, the initiating molecule must emit in the UV to excite a deep blue emitting fluorophore. Furthermore, the recombination time in sensitized systems is determined by the initiating molecule, not the fluorophore (Baldo et al., 2000b). We have seen that the operating lifetime decreases very rapidly with increased energy, and that even accessing the deep blue with long lived OLEDs has not yet been possible. Hence, it has proven to be more difficult to achieve a long-lived blue sensitized

fluorescent device than one that directly emits from the phosphor or TADF complex itself.

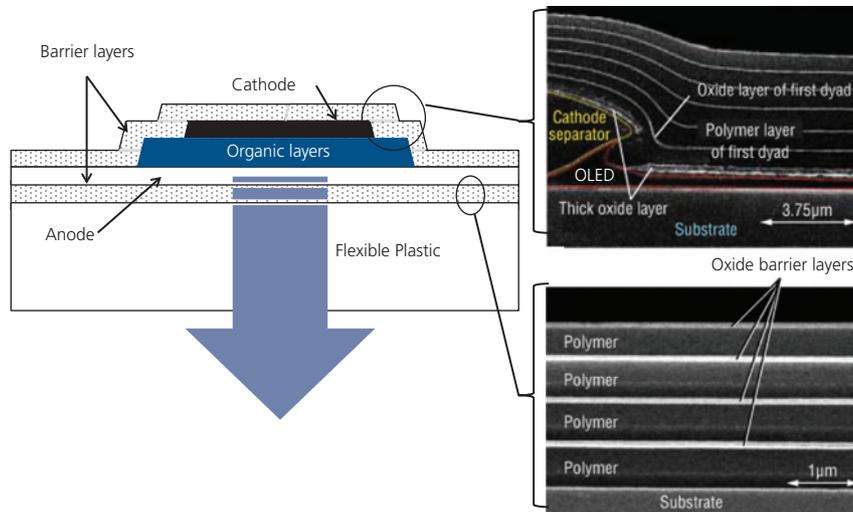

We end this section where we began. Achieving deep blue PHOLEDs with both a high efficiency and stability is arguably the most challenging high value problem confronting organic electronics today, with far-reaching consequences for all organic devices if it can be adequately solved for display applications. Whichever strategy is employed to increase lifetime, it must not compromise other device operating characteristics of high efficiency, low operating voltage and color purity.

### 6.7.5 OLED lifetime on flexible plastic substrates

Up to this point, we have been concerned primarily with intrinsic luminance loss due to chemical degradation that leads to morphological changes from Joule heating, exciton-polaron interactions in the bulk and at interfaces, and so on. However, there is one case where special attention needs to be paid to extrinsic loss when the OLEDs are deposited onto flexible plastic substrates. A significant advantage of OLEDs is their flexibility, opening the door to numerous exciting applications such as wearable or rollable displays and lighting appliances. The earliest example of an OLED on a plastic substrate employed polymer OLEDs (Gustafsson et al., 1992), soon followed by small molecule devices (Gu et al., 1997a). These demonstrations showed the advantages and also several of the problems encountered when fabricating OLEDs on plastic foils, although neither considered environmental exposure as a potential source of device lifetime.

More recently, the Samsung Galaxy Edge series smart phones employ flexible displays mounted behind the front glass panel. Furthermore, flexible substrates allow for rapid, low cost and high volume production of OLED appliances. As we found in Section 5.7, plastic foils such as PET, PEN, PES, PC, and PI have been used as substrates, but they have oxygen with *water vapor transmission rates* of  $\text{WVTR} \sim 1\text{--}0.1 \text{ g/m}^2/\text{day}$ . However,  $\text{WVTR} < 10^{-5} \text{ g/m}^2/\text{day}$  is required for long term, stable OLED operation (see Section 5.8). Alternative flexible substrates can be employed, such as metal (Wu et al., 1997a, Cheon et al., 2006) or very thin glass foils, but these materials bring their own challenges such as unacceptable levels of surface roughness, fragility and cost (Bhandari and Gaspar, 2015).

In Section 5.8, we discussed processes for depositing encapsulating layers on plastic films using multiple polymer/inorganic layer coatings (Moro et al.,

**Figure 6.195** Schematic of an OLED encapsulated with barrier layer films on the top of a plastic substrate, as well as conformally onto the OLED surface. To the right (*top*) is a scanning electron micrograph of a conformal multilayer coating on the OLED surface, and (*bottom*) on the substrate. Multilayer coatings can be deposited by CVD or ALD. Images from Suen and Chu (2008).

2004), or more precise and conformal *atomic layer deposition* (ALD). For flexible OLED applications, the barrier coating needs to cover both the bottom and top device surfaces, as shown in Fig. 6.195.

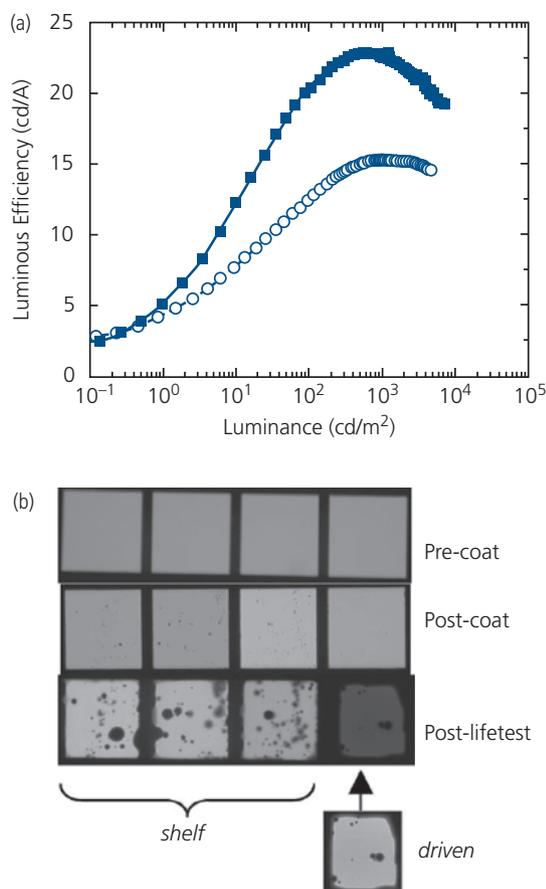

Effective encapsulating layers must have the following properties:

- (i) *Low moisture and oxygen permeation rates:* A  $WVTR < 10^{-6}$  g/m<sup>2</sup>/day is preferred, with  $10^{-5}$  g/m<sup>2</sup>/day considered to be the minimum acceptable rate (see Fig. 5.90).
- (ii) *Flexibility:* They must survive repetitive bends over radii of typically a few centimeters during the projected lifetime of the devices. Depending on the application, this can be many thousands to hundreds of thousands of flexes.
- (iii) *Conformability:* The coatings should be capable of conforming to surface features, and be tolerant to morphological defects such as dust. This is shown by the ALD multilayer film deposited onto the surface of an OLED in Fig. 6.195 (top right image) where a smooth transition covers the 100 nm thick cathode and the organic layers without a break in the multilayer barrier structure.
- (iv) *Throughput and low cost:* Low cost demands high product throughput and yield. However, ALD growth is slow, resulting in a long takt time in fabricating the substrates. Low cost also implies that low energy processes are combined with low cost materials. To date, barrier-coated plastic substrates are more costly to produce than metal foils,

but they also have compelling advantages such as smoothness and transparency that may ultimately be more important than cost alone.

- (v) *Non-destructive processing:* The deposition of the encapsulation directly onto the OLED surface must be achieved at sufficiently low temperature, and cannot use materials or chemistries that lead to deterioration of the underlying active device layers.
- (vi) *Small coefficient of thermal expansion:* The expansion coefficient should be sufficiently small such that stress from the substrate or coating does not degrade device performance as the temperature is varied over the full range needed in device fabrication and operation.
- (vii) *Transparency:* For bottom emitting devices, the substrate must be >90% transparent across the visible spectrum. Metal foils and other opaque substrates require top emitting architectures.
- (viii) *High Young's modulus:* In roll-to-roll manufacturing, the substrate (often called the *web*) should be resistant to stretching or other geometric distortion as it is translated from the feed to the take-up reel. Distortions result in misalignment with masks, uneven pixel spacing, etc.

The permeability of plastic to moisture can promote the formation of dark spot defects, and hence a loss of emissive area over time. In Fig. 6.196a we show that the efficiency of fresh and aged Ir(ppy)<sub>3</sub>:CBP PHOLEDs with  $L_0 = 600$  cd/m<sup>2</sup> results in  $LT50 = 2500$  h.

**Figure 6.196** (a) The efficiency before (squares) and after (circles) life test of an Ir(ppy)<sub>3</sub>:CBP PHOLED encapsulated in an organic/inorganic barrier layer film. (b) Images of an array of 5 mm<sup>2</sup> PHOLEDs before coating by the top barrier layer encapsulation (top row), after coating (middle row), and post life test (bottom row). The pixel on the far right was aged at  $L_0 = 600$  cd/m<sup>2</sup> until  $LT50 = 2500$  h (Chwang et al., 2003).

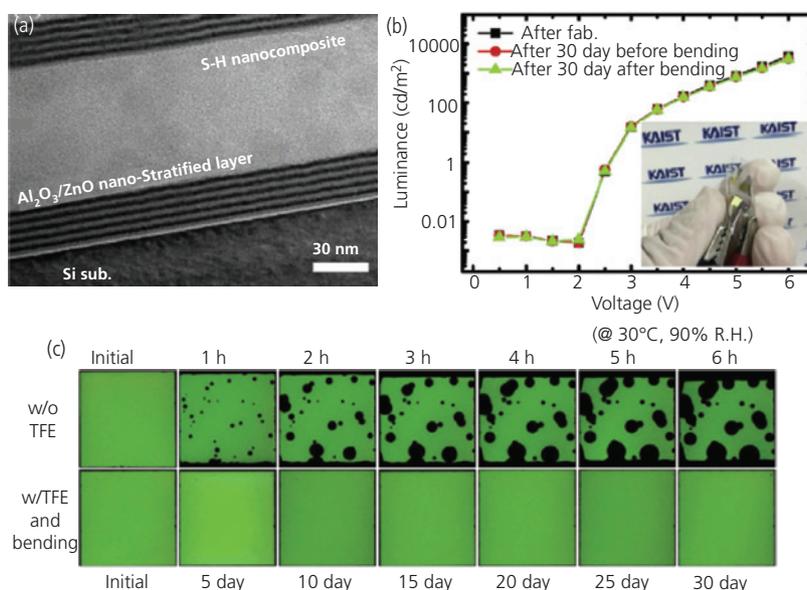

These devices were deposited on a PET substrate, with a barrier coating comprising four *dyads* (or layer pairs) comprising 5–7  $\mu\text{m}$  thick pairs of reactively sputtered, 10–30 nm thick Al<sub>2</sub>O<sub>3</sub> and polyacrylate films (Weaver et al., 2002). The polyacrylate itself was deposited by flash evaporation of the acrylate monomer followed by cross-linking via exposure to ultraviolet light. A similar multilayer structure was deposited onto the top surface of the PHOLED, completing the encapsulation. These barrier layer structures delay, but do not halt the ingress of environmental contaminants. The laminate presents a long circuitous path that water and oxygen molecules must take along the polyacrylate layer before finding a defect that allows the contaminant to penetrate the inorganic barrier. After sufficient time has elapsed, these contaminants find such a path, and arrive at the PHOLED active layers (Graff et al., 2004). It is

estimated that multilayer film stacks have  $WVTR = 4 \times 10^{-6}$  g/m<sup>2</sup>/day (Weaver et al., 2002).

Using multilayer coatings, the encapsulated device has  $LT50 = 2500$  h, compared to 9000 h for glass encapsulation that included a desiccant within the package (Chwang et al., 2003). The source of the luminance loss is apparent from the pixel images in Fig. 6.196b. The dark spots appear over a large fraction of the emitting surface after many hours of storage (denoted “shelf” in the image), or operation (“driven”). Interestingly, the same dark spots are visible in the stored devices as after operation. In both cases, they grow considerably after aging. The dark spots are likely due to particulates that are present during PHOLED film deposition, thus having an origin similar to the dark spots in devices on glass in Fig. 6.170.

Highly conformal coatings of precise thickness can be applied by ALD. The conformality is useful in protecting the OLEDs from penetration by dust particulates or rough surfaces. Figure 6.197a is a micrograph of a top OLED surface encapsulation comprising five pairs of 3 nm Al<sub>2</sub>O<sub>3</sub>/3 nm ZnO ALD layers separated by 120 nm layer of silica nanoparticles embedded in an organic–inorganic, sol-gel nanocomposite (Jeong et al., 2016). The ALD process is at 70°C using trimethylaluminum and H<sub>2</sub>O as precursors for Al<sub>2</sub>O<sub>3</sub>, and diethylzinc and H<sub>2</sub>O for ZnO. The deposition time of each layer is 0.2 s, followed by a 10 s purge. The nanocomposite was spin-coated to achieve the desired thickness. The bottom emitting Alq<sub>3</sub>-based OLEDs were deposited onto PET substrates pre-coated with 2.5 dyads of the ALD/nanocomposite stacks. While the deposition was slow, the devices themselves were robust with  $WTVR = 1.91 \times 10^{-5}$  g/m<sup>2</sup>/day as a result of the lack of defects in the ALD layers. After 1000 bends over a 3 cm radius, the devices showed no degradation of their current-voltage or luminance-voltage characteristics (Fig. 6.197b). Furthermore, this nanostratified/nanocomposite structure was exposed for 30 days at 30°C and 90% relative humidity without the OLEDs developing significant dark spot defects (Fig. 6.197c).

Due to their many unique features, flexible OLEDs on plastic substrates remain a subject of intense investigation. While their properties are inferior to analogous devices on glass, they already have operational lifetimes that are acceptable for many applications. It is anticipated that flexible OLED technology will continue to improve, and that their characteristics will eventually equal those of devices on conventional substrates, albeit possibly at a higher cost.

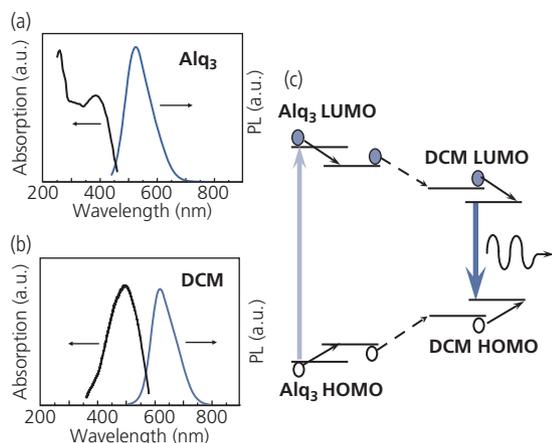

**Figure 6.197** (a) High resolution transmission electron micrograph of a nanostratified barrier layer used as thin film encapsulation for a fluorescent OLED. (b) Luminance–voltage characteristics immediately after fabrication, after 30 days exposure to 30°C and 90% relative humidity, and an aged device after 1000 bends over a radius of 3 cm. Inset: Photograph of the FOLED. (c) Luminescence images taken at  $L_0 = 400$  cd/m<sup>2</sup> for an unencapsulated and an encapsulated device vs. aging time under the conditions in (b). No aging results under continuous operation are available (Jeong et al., 2016).

## 6.8 Organic semiconductor lasers

Organic semiconductor lasers (OSLs) have been pursued since their first demonstrations in the mid-1990s in the hopes that they would eventually lead to a new generation of intense optical sources that could be tailored to emit at desired wavelengths by drawing on the same enormous palette of materials developed for OLEDs. And while organic lasers do indeed have many remarkable properties such as emission over a wide range of wavelengths spanning the visible to the NIR, nearly temperature-independent operating characteristics, ability for growth on any smooth substrate (including flexible plastic foils) without materials constraints set by lattice matching, etc., to date only optically pumped lasing using organic semiconductors have been convincingly achieved. In this section we will discuss the principles of organic lasers, some of their unique operating characteristics, and the prospects for electrically pumped lasing. Indeed, optically pumped lasers in themselves hold great interest due to the insights they provide into the properties of organics under intense optical or electrical excitation. The scientific rewards for their study, coupled to the ease with which they can be fabricated and tested, makes the investigation of organic lasers an ongoing source of fascination for scientists and engineers alike.

A laser is an *optical resonator* that comprises three components: a *gain medium*, a low loss optical cavity, and a pump source (electrical or optical). The pump intensity must be sufficient to drive the gain medium into an excited state population inversion, leading to stimulated emission. Organic materials are particularly suited as gain media since they can have very high fluorescent yields, and their Franck–Condon shifts between the absorption and emission spectra lead to exceptionally low material absorption losses. Energy transfer from the pump-absorbing host to an emitting guest molecule results in a further bathochromic shift that reduces absorption losses to near zero. The four-level energy scheme for a laser based on Förster energy transfer from an optically pumped Alq<sub>3</sub> host to a DCM guest is shown in Fig. 6.198. Many such guest–host schemes have been developed for optically pumped lasing based on both small molecule and polymer active media (Hide et al., 1996, Kozlov et al., 1997a, 1998, Vasdekis et al., 2006).

Lasing, along with *amplified spontaneous emission* (ASE) that is easily confused with lasing, has also been observed in single component systems, where the molecular species used to absorb the pump radiation also serves as the laser gain medium (Tessler et al., 1996). However, such single component gain media are not as efficient, and have higher thresholds than four level guest–host systems.

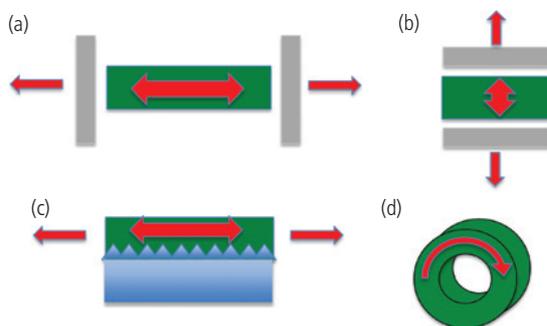

**Figure 6.198** The absorption and emission spectra of (a) Alq<sub>3</sub> and (b) DCM. The overlap of the Alq<sub>3</sub> emission and DCM absorption spectra lead to efficient Förster energy transfer from the host to guest. The almost complete separation of the red DCM emission spectrum from the absorption of the two species results in very low optical losses. (c) Energy scheme of the Alq<sub>3</sub>:DCM system leading to red laser emission (Kozlov et al., 1998).

The second element of the laser is the resonant cavity that provides optical feedback via the use of high reflectivity mirrors bounding the gain medium. The resonator extends the photon lifetime within the cavity, thereby building up the photon density to create a population inversion (i.e. a non-equilibrium concentration of lasing molecules in their excited states). Numerous resonator geometries have been demonstrated, with a few such designs illustrated in Fig. 6.199.

- (i) The most common and simplest form of resonator is the Fabry–Pérot resonator, or longitudinal cavity, in Fig. 6.199a, where the gain medium is sandwiched between two high reflectivity mirrors (Kozlov et al., 1997a). A high mirror reflectivity decreases the pump threshold required for population inversion. Leakage of a fraction of the light through the mirrors results in the observed laser emission. The advantage of this structure is that the overlap between the optical modes and the gain medium is large, leading to high gain and hence high brightness and low threshold. Often, the mirrors are simply cleaved facets of the gain medium whose reflectance is determined by the difference in index of refraction between the semiconductor and air. The reflectivity at normal incidence is given by (cf. Eq. 6.114)

$$R_{ga} = \left| \frac{n_g - n_a}{n_g + n_a} \right|^2, \quad (6.149)$$

**Figure 6.199** Resonators used in lasers. Green regions are the gain media, gray are the mirrors, blue is the substrate, and the optical mode propagation directions are shown in red. (a) Fabry–Pérot or longitudinal laser, (b) vertical cavity surface emitting laser, (c) distributed feedback laser, and (d) ring resonator laser.

where  $n_g$  and  $n_a$  are the refractive indexes of the gain medium and air, respectively. The two mirrors may have different reflectivities, in which case most of the light is emitted from the lowest reflectivity mirror.

- (ii) A *vertical cavity surface emitting laser* (VCSEL) is shown in Fig. 6.199b. This too is a Fabry–Pérot resonator, where the propagation is transverse to the thin film sandwiched between mirrors. At least one mirror must be semitransparent (Hide et al., 1996, Bulovic et al., 1998b). Due to the limited overlap between the optical mode and the gain medium, VCSELs require exceptionally high mirror reflectivity and high gain. An advantage of the VCSEL is its compactness (it is only as thick as the gain medium film), and its cylindrical symmetry. This can result in a symmetric, conical output beam that is easily coupled to external optical systems such as fibers, lenses, etc. that commonly also have cylindrical symmetry. If the mirrors are multilayer dielectric stacks whose reflectance stop band is at the same wavelength as the peak of the gain spectrum (approximately coincident with the PL spectral peak of the emitting species), the external mirrors are known as *distributed Bragg reflectors* (DBRs). Thus, VCSEL is a DBR laser with a single optical mode whose wavelength is determined by the periodicity ( $\Lambda$ ) of the dielectric layers comprising the mirror stack:

$$\Lambda = \frac{m\lambda_0}{4} \left( \frac{1}{\bar{n}_1} + \frac{1}{\bar{n}_2} \right) \approx \frac{m\lambda_0}{2\bar{n}}, \quad (6.150)$$

where  $\bar{n}_1$  and  $\bar{n}_2$  are the effective refractive indexes of the two media in the reflectors,  $\bar{n} = (\bar{n}_1 + \bar{n}_2)/2$ , and  $\lambda_0$  is the emission wavelength. Also,  $m = \pm 1$ ,

$\pm 2, \dots$  is the grating order ( $m = 1$  is a first order grating, 2 is a second order grating, and so on).

- (iii) When the reflective grating is placed either within or in close proximity to the gain medium as in Fig. 6.199c, the structure is known as a *distributed feedback (DFB) laser* (McGehee et al., 1998, Kozlov et al., 2000, Karnutsch et al., 2006). This is distinct from a DBR laser where the grating is located outside of the cavity as discussed in the context of VCSELs. External gratings can also be used in longitudinal geometries (Vasdekis et al., 2006). The DFB grating condition is similar to Eq. 6.150.

The symmetrical, counter-propagating optical fields within the gain medium create a degeneracy resulting in two output modes, separated by the cavity *free spectral range*:

$$\Delta\lambda = \frac{\lambda_0^2}{2nL}, \quad (6.151)$$

where  $L$  is the cavity length. The cavity symmetry can be lifted to create only a single mode output by “breaking” the grating into two sections of unequal length. This can also be done by inserting a spacer of length,  $\lambda/4$  within the grating. The spacer creates a phase delay for the counter-propagating modes that favors one over the other. DFB resonators are a common means for providing high reflectivity, and hence a low lasing threshold.

- (iv) An approach that differs from these one dimensional architectures is the *ring resonator* in Fig. 6.199d. The resonator can be formed by depositing the organic gain medium around a cylindrical core such as an optical fiber (Frolov et al., 1997, Schülzgen et al., 1998). The mode is trapped by circulation within the ring by TIR due to the higher index of the gain medium compared to the surrounding air. Only modes whose wavelengths that are integer multiples of the ring circumference constructively interfere, and hence have the possibility for lasing. That is, the modes must satisfy the following condition:

$$\lambda_0 = \frac{2\pi r n}{m}, \quad (6.152)$$

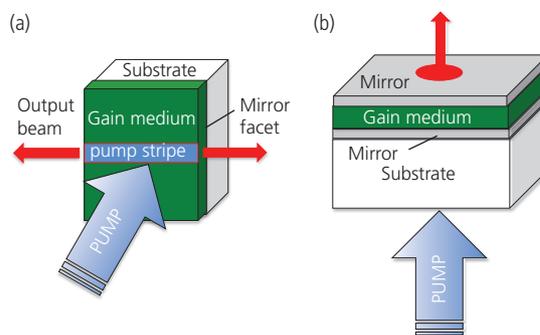

where  $r$  is the ring radius. The light is outcoupled from the ring due to scattering from imperfections around its periphery. However, this does not result in a usable output that is efficiently coupled into an external optical system. A method for more focused outcoupling is to bring a waveguide into close proximity, and within the plane of the ring. The evanescent optical field from the mode

trapped within the ring evanescently couples into the waveguide at the point of closest approach. The advantage of the ring resonator is that it provides for a maximal overlap between the optical mode and the gain medium as the mode circulates around the ring periphery, and can have an extremely large quality, or *Q-factor* ( $\sim 10^9$ ) compared with other cavities described, where  $Q$  ranges from 10 to  $10^4$ . For an emission line of width  $\Delta\lambda$ , the  $Q$ -factor is:

$$Q = \frac{\Delta\lambda}{\lambda_0}. \quad (6.153)$$

The final element comprising the laser is the excitation source. To date, all OSLs have been excited by a short wavelength optical pump, such as a  $N_2$ , He-Cd laser, or InGaN diode laser. The pump beam is typically projected onto the laser cavity as a stripe that establishes a well-defined region of high optical gain, forming a so-called *gain-guided laser*, that is, the lasing mode is also confined to the region being pumped where there is a population inversion of excited states. In longitudinal (e.g. Fabry-Pérot or DFB) lasers, the optical pump beam illuminates a stripe along the length of the active medium defining the gain region shown in Fig. 6.200a. The intensity is sufficient to induce a population inversion, and hence this is the region where the stimulated emission intensity is higher than the losses, resulting in mode propagation along the stripe. The mode is said to be gain-guided within the stripe since the high excited state population induces transparency. Hence, both the optical mode and the inverted excited state population coexist within the stripe, maximizing the gain.

Reflective mirrors, cleaved facets, or gratings at both ends of the stripe provide the surfaces that define the oscillator dimensions. Surface emitting lasers are

**Figure 6.200** Optical pumping schemes for (a) longitudinal and (b) surface emitting lasers.

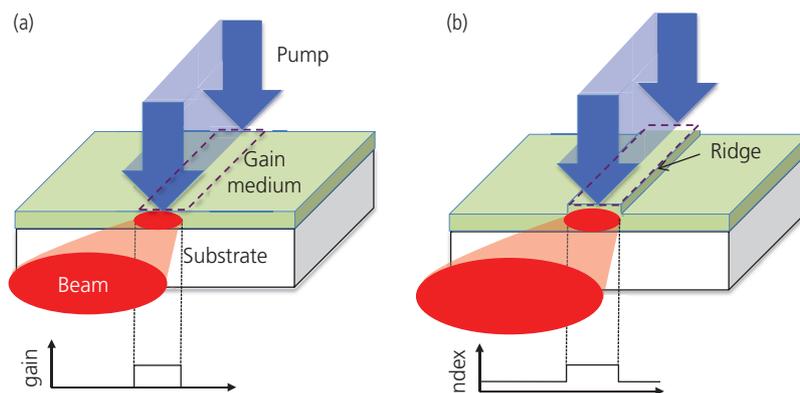

pumped either from the bottom or top surfaces to create a high gain region within the active medium; see Fig. 6.200b. Depending on whether or not the two surface mirrors have the same reflectivity, the output beam can be preferentially emitted from the top or bottom surface. Ring resonator lasers are typically pumped by directing the exciting laser beam at the gain medium along the ring axis.

In a slab laser, a waveguide is formed transverse to the laser cavity by the pump itself (Fig. 6.201a). As gain continues to increase to the point of transparency of the laser medium, the index of refraction decreases. This causes a break-up (*mode repulsion*) of the single transverse mode, thus reducing the overlap between the optical field and the gain region. Mode repulsion is prevented by employing the *index-guided ridge waveguide* structure in Fig. 6.201b. A shallow ridge in the gain medium is optically pumped. Because the gain medium has a higher index than the surrounding air, the effective index sampled by the mode is higher in this region than elsewhere. The ridge, therefore, provides additional confinement that stabilizes the transverse mode even at high pump powers. Since high efficiency, low threshold lasing requires confinement of the optical mode in the direction perpendicular to the waveguide plane, the gain medium must have a higher index of refraction than either the substrate or the air.

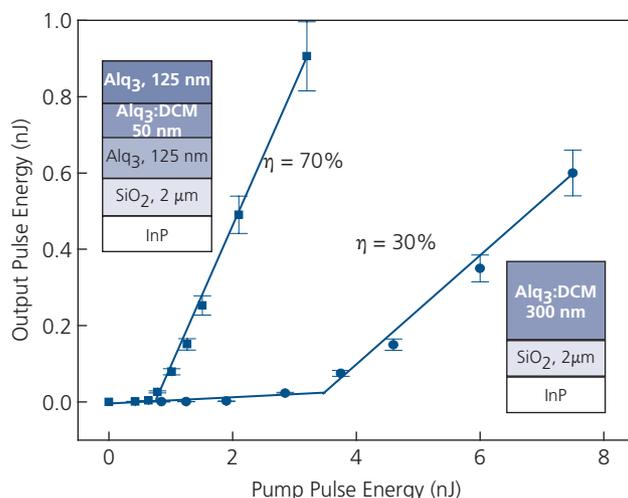

There has been considerable confusion in the literature in identifying a true laser source. Often *superluminescence* or ASE are mistaken for laser emission (Denton et al., 1997). Here, ASE refers to the presence of gain in a medium in the absence of a resonant cavity that produces stimulated emission via photon recycling. Hence it is useful to enumerate those

properties of the emitted light that should be observed before the device can be unambiguously identified as a laser oscillator.

- (i) *Lasers exhibit a clear threshold delineating regions of spontaneous and stimulated emission.* The threshold is identified by an abrupt increase in slope efficiency, which is the ratio of the output intensity to the pump energy (or in the case of an electrically pumped device, the drive current). Examples of the threshold and high slope efficiency above threshold are illustrated for Alq<sub>3</sub>:DCM (2.5%) double and single heterostructure, Fabry-Pérot lasers on InP substrates in Fig. 6.202. Below threshold, the spontaneous emission efficiency is only ~1%, whereas it rises abruptly once lasing is reached. The higher refractive index of the DCM doped layer (with  $n = 1.78$ ) compared to the Alq<sub>3</sub> cladding layer ( $n = 1.72$ ) in the double heterostructure in the upper left of Fig. 6.202 provides optical confinement within the doped layer (Kozlov et al., 1998). The lasing mode is trapped in the thin, high refractive index active region resulting in a significant decrease in threshold and increase in slope efficiency compared with the single heterostructure in the lower right of the figure. Note that it is customary to display the light output vs. excitation intensity on a linear plot where the threshold can be accurately determined from the point of intersection between the spontaneous and stimulated emission regimes. Displaying these data on semi-log or log-log plots can result in an S-shaped curve that can lead one to conclude there is a lasing threshold, yet a straight line with an intercept at the origin

**Figure 6.201** (a) Gain-guided and (b) index-guided Fabry-Pérot laser structures. Qualitative plots of the gain and index of refraction along the transverse axis are shown below each structure. The dashed line is the approximate zone being pumped. To achieve optical confinement in the vertical direction, the gain medium must have a higher index than either the air or the substrate.

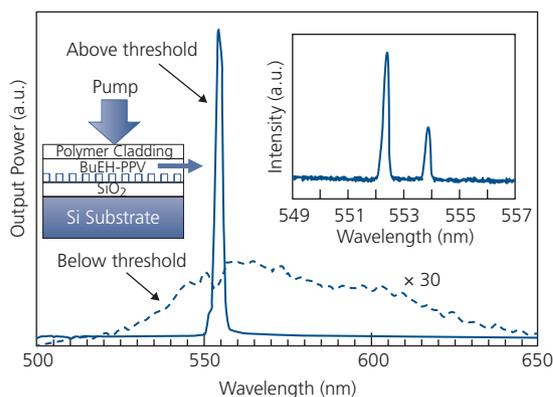

**Figure 6.202** Light output vs. input pump energy for two Alq<sub>3</sub>:DCM Fabry–Pérot lasers. Upper left: Double heterostructure laser with a slope efficiency of  $\eta = 70\%$  and a threshold energy of 1 nJ. Lower right: Single heterostructure with a slope efficiency of 30% and a threshold of 3.5 nJ. The pump is a N<sub>2</sub> laser with a wavelength of 337 nm and a pulse length of 500 ps (Kozlov et al., 1997a).

will also show an S-shaped dependence if the abscissa is a logarithmic scale.

- (ii) *Laser linewidths are substantially narrower than spontaneous emission sources.* A transition from a broad spontaneous PL spectrum to a single or multimode spectrum at threshold is an essential feature of lasing. Narrowing above threshold is shown in Fig. 6.203 for an optically pumped polymer-based DFB laser. The active lasing region consists of the semiconducting polymer, BeEH-PPV. The 0.15–0.35  $\mu\text{m}$  thick polymer was deposited onto the surface of a 1  $\mu\text{m}$  thick SiO<sub>2</sub> layer on whose surface was etched a grating with  $\Lambda = 170$  to 185 nm (see inset) (McGehee et al., 1998). The spontaneous emission spectrum below threshold is characteristically broad (dashed line), but once the pump energy exceeds threshold there is a dramatic narrowing (solid line). Examination of the emission in the inset shows two modes offset by approximately  $\Delta\lambda = 2$  nm arising from the pair of resonances from counter-propagating waves supported by the grating. The differences in mode intensities arises since the short wavelength mode is better aligned to the gain peak of the medium, which is located at the peak of the spontaneous (PL) emission spectrum.

Caution must be used in associating spectral narrowing with gain, however, Microcavity effects, and propagation in waveguides near their modal cutoff can also result in narrow spectra even when only spontaneous emission is present (Yokoyama et al., 2008). Modal narrowing in the absence of gain is easily identified, however, since

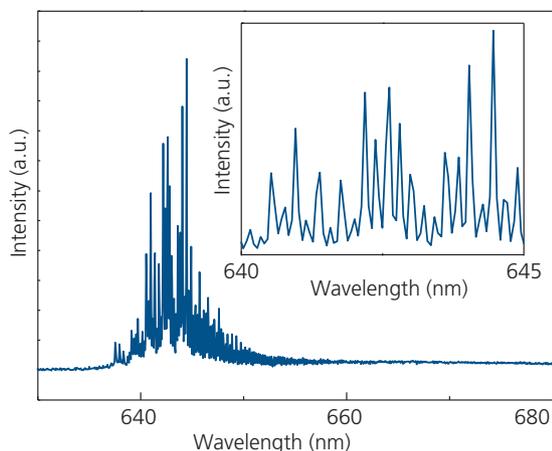

**Figure 6.203** Optical output spectrum from the optically pumped DFB OSL both below and above the lasing threshold. Right inset: Detail of the optical modes above threshold. The mode pair is expected for a DFB laser as discussed in text. Left inset: OSL structure. After McGehee et al. (1998).

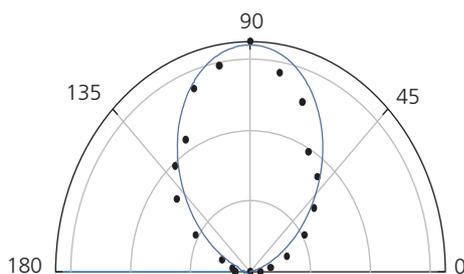

the narrow spectra are present even as the pump fluence is decreased to zero.

Lacking a wavelength-selective element such as a grating, numerous modes are supported within the gain envelope. This is shown by the multimode spectrum of the Fabry–Pérot laser in Fig. 6.204. The cavity is bounded by organic facets cleaved at both ends of a  $L = 500$   $\mu\text{m}$  long slab of Alq<sub>3</sub>:DCM (2.5%). The modes are evenly spaced at 2  $\text{\AA}$ , with a mode width of 0.6  $\text{\AA}$ . The free spectral range given by Eq. 6.151 determines the mode spacing.

- (iii) *Lasers are spatially coherent light sources.* This is identified by a diffraction-limited emission

**Figure 6.204** Multimode spectrum of a 500  $\mu\text{m}$  long  $\text{Alq}_3\text{:DCM}$  (2.5%) single heterostructure OSL in Fig. 6.202. The modes entirely fill the gain spectrum of DCM defined by its broad PL spectrum, with the highest intensity modes at the gain peak (Kozlov et al., 1998).

**Figure 6.205** Intensity of polarized light emission as a function of the angle,  $\alpha$ , of a linear polarizer relative to the normal to the substrate plane of the single heterostructure OSL in Fig. 6.202. The line follows  $\sin^2\alpha$ , as expected for TE-polarized emission (Kozlov et al., 1997a).

beam, or in the case of a multimode laser, a speckle pattern in the laser output. Coherence can also be identified by polarization of the output beam as shown in Fig. 6.205 for the single heterostructure OSL in Fig. 6.202. The beam is polarized in the plane of the active medium, which is expected for TE emission. The line in Fig. 6.205 is a fit to the TE polarized beam intensity that follows  $I(\alpha) = I(\pi/2) \sin^2\alpha$ , where  $\alpha$  is the angle between the polarizer axis and the normal to the substrate plane, and  $I(\alpha)$  is the intensity at  $\alpha$ . The existence of a well-defined beam is clear evidence for lasing. While spontaneous emission can result in a spectrally broad, Lambertian pattern, lasers are characterized by narrow and directional transverse mode emission.

- (iv) *Lasers are temporally coherent sources.* Temporal coherence is the property that two wave sources have the same period, frequency and waveform. Thus, a purely monochromatic source is temporally coherent and can interfere with itself. If a

source emits a range of frequencies of width  $\Delta f$ , then the coherence time,  $\tau_C$ , is

$$\tau_C \Delta f \leq 1. \quad (6.154)$$

Thus, the coherence time decreases as the source becomes increasingly polychromatic: lasers have a long temporal coherence, whereas white light sources are incoherent. The temporal coherence is typically measured using a Michelson or Mach–Zehnder interferometer.

### 6.8.1 Theory of lasing in optically pumped OSLs

Since laser emission is due to inversion of the singlet exciton population, all sources of singlet generation and losses must be included in the rate equations that describe laser action. Previously (Section 6.3.5) we have shown that singlets are primarily lost to SSA and STA in the absence of an electric current. The slow buildup of triplets during optical pumping due to the presence of weak spin–orbit coupling even in fluorescent materials has been found to turn off laser emission after only a few tens or hundreds of nanoseconds following the onset of the optical pump. Furthermore, triplet-induced absorption in the cavity can reduce the net optical gain (Kozlov et al., 2000, Baldo et al., 2002, Giebink and Forrest, 2009, Lehnhardt et al., 2010). Including all significant cavity losses, the coupled rate equations that describe laser transient behavior under optical pumping are as follows (Zhang and Forrest, 2011):

$$\frac{dS}{dt} = \frac{\eta_p I_p}{h\nu_p d} - k_S S - k_{ISC} S - k_{ST} S T_G - \gamma \frac{c}{n} P, \quad (6.155)$$

$$\frac{dT_H}{dt} = k_{ISC} S - k_{HG} \exp\left(-\frac{2}{R_0} \sqrt{\frac{1}{N_0 - T_G}}\right) T_H, \quad (6.156)$$

$$\frac{dT_G}{dt} = k_{HG} \exp\left(-\frac{2}{R_0} \sqrt{\frac{1}{N_0 - T_G}}\right) T_H, \quad (6.157)$$

$$\frac{dP}{dt} = \left(\Gamma\gamma - \alpha_{CAV} - \frac{1}{L} \ln(R)\right) c\bar{n}P + \Gamma\beta k_S S, \quad (6.158)$$

where  $S$ ,  $T_H$ ,  $T_G$ , and  $P$  are guest singlet, host triplet, guest triplet, and lasing mode photon densities, respectively,  $\eta_p$  is the fraction of the pump emission absorbed by the organic film,  $I_p$  is the pump intensity,  $h\nu_p$  is the pump photon energy,  $k_S$  is the guest singlet natural decay rate,  $k_{ISC}$  is the host ISC rate,  $k_{ST}$  is the

guest STA rate,  $\gamma = \sigma_{stim}S$  is the gain, is  $\sigma_{stim}$  the stimulated emission cross-section, and  $\bar{n}$  is the effective refractive index of the dielectric cladding layer and gain medium waveguide (Chuang, 2009). The optical confinement factor,  $\Gamma$ , is the ratio of the optical mode intensity confined within the gain region of thickness,  $d$ , to the total intensity of the propagating mode. Also,  $k_{HG}$  is the host-guest Dexter transfer coefficient where we assume that triplets are transferred by exchange interactions,  $R_0$  is the guest-host van der Waals radius ( $\sim 1$  nm),  $N_0 > T_G$  is the guest triplet saturation population (i.e. the point at which the triplet loss rate equals its generation rate as determined from the saturation of PL quenching, as we have observed for OLEDs in Section 6.3.5),  $\alpha_{CAV}$  is the cavity loss without contributions from triplet absorption given by  $\alpha_{TT}$ , and  $\sigma_{TT}$  is the guest triplet absorption cross-section. The losses from the optical cavity with mirrors with reflectivities of  $r_1$  and  $r_2$  gives a total reflectivity of  $R = r_1 r_2$ . The mirror loss is given by the logarithmic term in Eq. 6.158 for a cavity of length,  $L$ . That is, the mirror losses decrease with increasing cavity length. Finally,  $\beta$  is the spontaneous emission factor, which is equal to the inverse of the total number of modes within the PL (i.e. the gain) spectrum of the active medium (Coldren and Corzine, 1995). For spontaneous emission,  $P = 0$ , and the intensity is proportional to  $S$ .

The exponential functions in Eqs. 6.156 and 6.157 are due to Dexter transfer that decays exponentially with molecular distance,  $R_0$ . The simultaneous solutions of this system of coupled equations provide the transient response of an OSL both below and above the lasing threshold.

Lasing is achieved when the net gain,  $g(t)$ , is equal to the loss. This is the point when the laser medium

has reached *transparency*. Thus, from Eq. 6.161, the lasing condition is given by

$$g(t) = \Gamma\sigma_{stim}S(t) - \alpha_{CAV} - \frac{1}{L}\ln(R) - \Gamma\sigma_{TT}T_G(t) = 0. \quad (6.159)$$

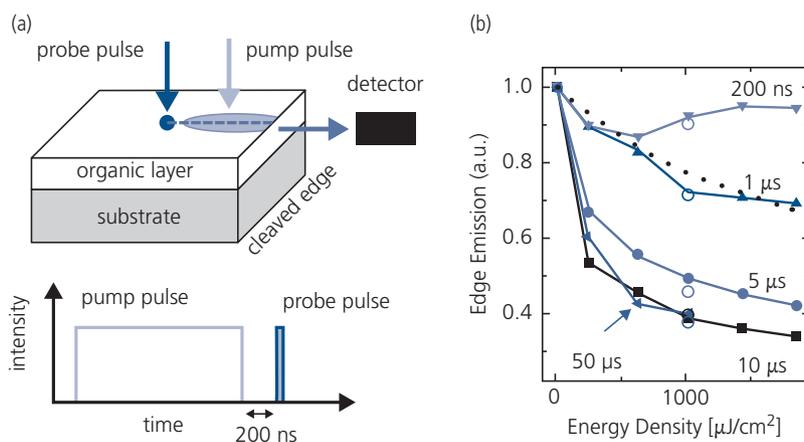

This equation can be solved to determine the threshold singlet population,  $S_{TH}(t)$ . Surprisingly, OSLs exhibit two distinct threshold singlet populations. The CW threshold population ( $S_{CW}$ ) must be high enough to overcome triplet losses as  $T_G(t)$  increases with time. In contrast, the lasing population under pulsed excitation is  $S_{PS} < S_{CW}$ , since for short pumping durations the triplet population is too small to affect the cavity gain. Then, ignoring mirror losses, as  $t \rightarrow 0$ , the triplet loss  $\Gamma\sigma_{TT}T_G \ll \alpha_{CAV}$ , and thus Eq. 6.159 yields  $S_{PS} = \alpha_{CAV}/(\Gamma\sigma_{stim})$ . With time,  $T_G$  increases, which increases the associated loss until  $\Gamma\sigma_{TT}T_G > \alpha_{CAV}$ . Finally,  $T_G$  reaches its saturation density,  $N_0$ , at which point the triplet loss can no longer increase, and  $S_{CW} = (\alpha_{CAV} + \Gamma\sigma_{TT}N_0)/(\Gamma\sigma_{stim})$ .

The CW threshold is approximately

$$I_{CW}(N_0) = h\nu_p d(k_S + k_{ISC} + k_{ST}N_0) \times (\alpha_{CAV} - \frac{1}{L}\ln(R) + \Gamma\sigma_{TT}N_0)/(\eta\Gamma\sigma_{stim}), \quad (6.160)$$

compared to the pulse threshold  $I_{PS} = I_{CW}(N_0 \approx 0)$ . Thus,  $I_{CW}$  is a *quadratic* function of guest triplet saturation population. That is,  $k_{ST}N_0$  is due to STA that reduces the gain; and  $\Gamma\sigma_{TT}N_0$  is due to triplet absorption that leads to loss.

The presence of two thresholds appears to be a unique feature of OSLs, and explains why CW lasing was not observed for 15 years after the first demonstrations of laser action in an organic semiconductor (Zhang and Forrest, 2011).

**Figure 6.206** (a) Pump-probe measurement of triplet absorption in a slab of F8BT/MEH-PPV on a silica substrate. The UV probe beam is delayed by 200 nm from the end of the pump beam, and the waveguided PL induced from the probe is measured by a photodetector at the edge of the slab. (b) Edge emission intensity vs. pump energy density and duration (Lehnhardt et al., 2010).

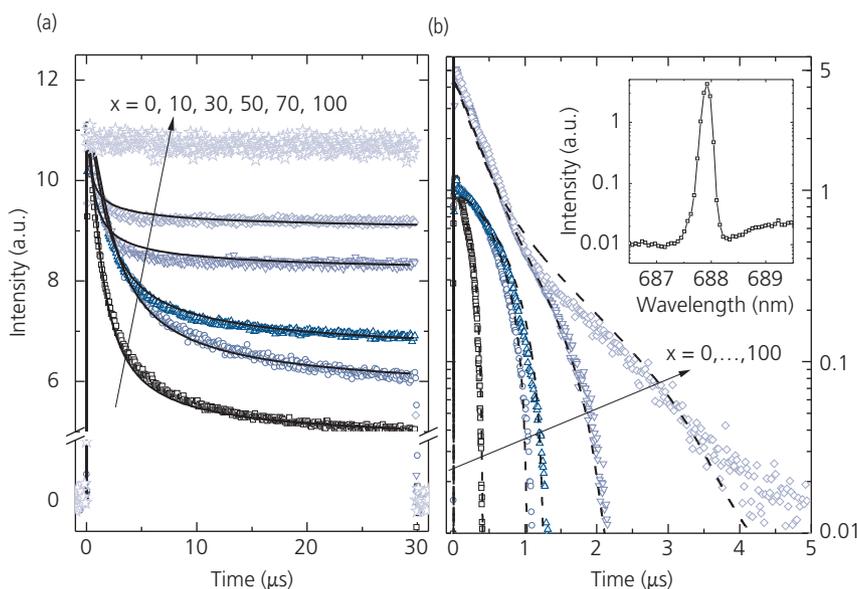

The importance of triplet absorption has been measured in the polymer blend F8BT/MEH-PPV (16 wt%) using the pump-probe arrangement in Fig. 6.206a. A waveguide comprising a slab of active material is pumped in the UV to create a large density of singlets along with a much smaller density of triplets formed via weak ISC. After a delay of 200 ns during which time the singlets completely recombine, a second UV probe pulse creates a second population of singlets whose radiation propagates through the now triplet-rich, previously pumped region. By measuring the intensity of the emission as a function of distance from the waveguide edge, the triplet absorption coefficient is determined. The long interaction length between the waveguided fluorescence and the residual triplet population minimizes measurement inaccuracies (Lehnhardt et al., 2010).

The edge emission intensity vs. pump energy density and duration is shown in Fig. 6.206b. The intensity falls to an asymptotic value once the saturation triplet density,  $N_0$ , is reached. Furthermore, as the pump duration and energy density increase, the triplet density also increases, as apparent from the larger decrease in edge emission intensity. A fit to the data (dashed line, Fig. 6.206b) using a theory similar to that in Eqs. 6.155–6.158 yields a spectrally broad triplet absorption loss of  $\alpha_{TA} \sim 30 \text{ cm}^{-1}$ .

The laser rate equations have been used to analyze a gain-guided DFB laser that included a triplet

manager analogous to managed OLEDs with reduced TTA discussed in Section 6.3.5. The OSL comprised a 200 nm thick gain layer containing the manager, ADN, co-deposited into the guest–host gain medium consisting of 2 vol.% DCM2 in Alq<sub>3</sub>. The manager is included to remove triplets generated by the pump, thereby reducing  $N_0$  and extending the lasing duration. As noted in Section 6.3.5 (cf. Fig. 6.76), ADN has lower triplet ( $E_T = 1.69 \text{ eV}$ ) and higher singlet energy ( $E_S = 2.83 \text{ eV}$ ) than Alq<sub>3</sub> ( $E_T = 1.99 \text{ eV}$  and  $E_S = 2.38 \text{ eV}$ ). Furthermore,  $E_S = 2.03 \text{ eV}$  and  $E_T = 1.74 \text{ eV}$  for DCM2. The manager concentration in Alq<sub>3</sub>(98 –  $x$  vol.%):DCM2(2 vol.%):ADN( $x$  vol.%) is  $x$  vol.% ADN ( $x = 0, 10, 30, 50, 70, 100$ ). The same films were deposited on gratings with a period of  $\Lambda = 430 \text{ nm}$  and a 50 nm depth on the SiO<sub>2</sub>-on-Si substrate to form the DFB OSLs. Output from a 0.6 W pump laser diode at wavelength  $\lambda = 405 \text{ nm}$  was focused to a  $150 \mu\text{m} \times 250 \mu\text{m}$  spot on the thin film.

Results from pumping OSLs with different concentrations of managers along with fits to Eqs. 6.155–6.158 are shown in Fig. 6.207. The theory and measurement agree well for both the unmanaged laser ( $x = 0$ ), as well as lasers with increasing amounts of the manager, ADN (Fig. 6.207a). As in the case of the managed OLED, the initial drop in PL intensity is considerably reduced with increasing concentrations of the manager until there is no apparent loss from TTA at  $x = 100$ . The fits to the lasing transients in

**Figure 6.207** (a) Photoluminescence and (b) lasing transients measured at a pump intensity of  $1.6 \text{ kW/cm}^2$  for different host blends. The PL transients of the triplet-managed Alq<sub>3</sub>(98 –  $x$  vol.%)DCM2(2 vol.%)ADN( $x$  vol.%) OSLs are normalized to the peak intensities, and lasing transients are normalized to unity for  $x = 0, 10, 30$ , and to 5 for  $x = 50$  and 70. The fits (lines) are obtained by the lasing model that includes triplet annihilation and absorption, using parameters summarized in Table 6.19. Inset: Single mode lasing spectrum of an  $x = 70$  OSL (Zhang and Forrest, 2011).

<sup>a</sup> Parameters from measurement.<sup>b</sup> Parameters from fits to data.**Figure 6.208** (a) Streak camera image of laser emission for the triplet-managed OSL in Fig. 6.207 measured at a pump intensity 2.4 kW/cm<sup>2</sup>. This shows a CW lasing duration of >18 μs lasing duration. (b) Simulated lasing duration evolution with increasing pump power for a triplet managed OSL (Zhang and Forrest, 2011).

Fig. 6.207b are more revealing. In the absence of the manager, triplets rapidly build up, resulting in a lasing duration of only 400 ns. However, as the manager is increased to 70%, the duration is increased by a factor of ten, to 4.5 μs. At all concentrations, the data are accurately fit to the model described above, using parameters listed in Table 6.19.

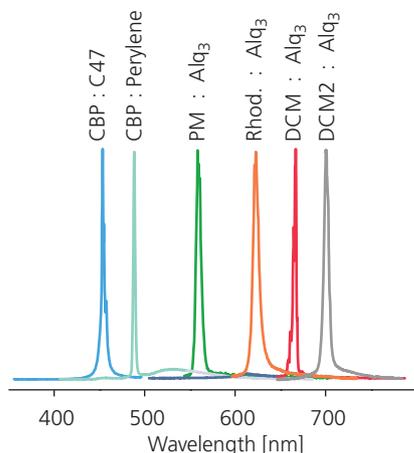

From the fits, we see that in unmanaged devices, the pulsed threshold pump fluence is more than 30 times less than its CW value. Indeed,  $I_{CW} = 32$  kW/cm<sup>2</sup> is well above the damage threshold of this (and most) organic semiconductor systems. However, at  $x = 70$ , the CW threshold drops to only 2.2 kW/cm<sup>2</sup>, which should not induce immediate damage to the organics. Figure 6.208a shows a streak camera image of CW lasing achieved at  $I_{CW} = 2.4$  kW/cm<sup>2</sup>. The lasing lasts as long as the pump beam is applied, and in fact only ceases after 100 μs once the high excitation density damages the gain region. Thus, CW lasing is achieved once the triplet population is sufficiently reduced. The lasing duration vs. pump power is calculated for this same  $x = 70$  managed laser, indicating that the lasing duration becomes infinite once  $I_{CW}$  is exceeded.

### 6.8.2 Distinguishing characteristics of OSLs

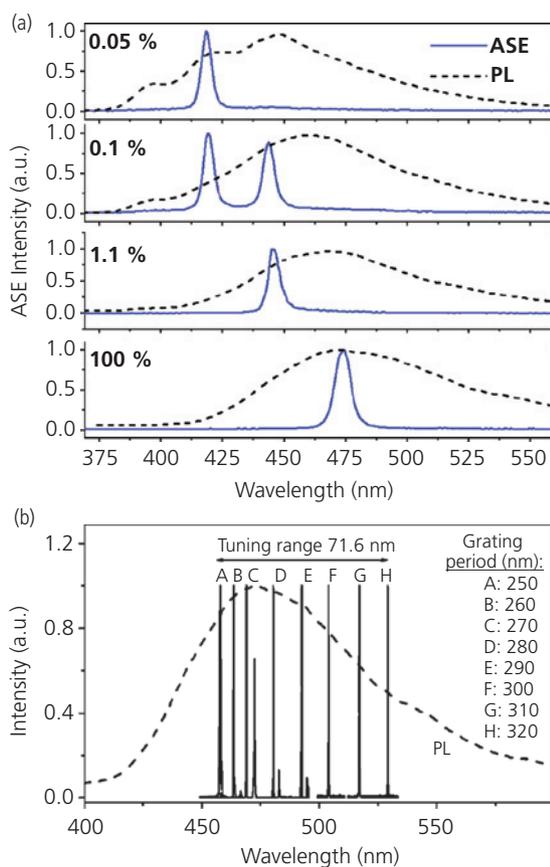

We noted at the beginning of our discussion that OSLs are interesting due to many characteristics that distinguish them from conventional, inorganic laser diodes. In the following, we discuss a few of these unique characteristics that have provided motivation to seek means for electrical pumping, and in some cases provide sufficient cause for using OSLs in optically pumped applications as well.

(i) *Access to a broad and tunable range of emission wavelengths across the visible and NIR.* The appeal of organic materials is their versatility. By simple modifications of chemical structure, a nearly unlimited range of properties can be accessed. From the earliest demonstrations of both polymer and small molecule-based lasers, researchers demonstrated OSLs with emission from the deep blue to the NIR (Hide et al., 1996, Kozlov et al., 1998), with example lasing spectra in Fig. 6.209 for six different small molecule dopants and two hosts.

Another feature of organics is their broad gain spectrum, as determined by the width of the PL

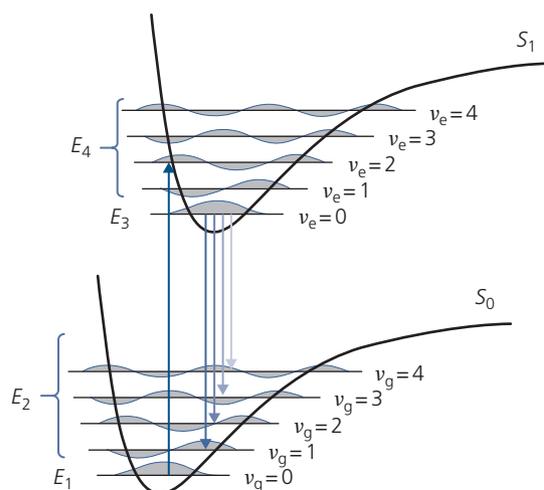

**Figure 6.209** Lasing wavelengths of several host-guest systems. The host materials are CBP and Alq<sub>3</sub>. Dopants are Rhod = Rhodamine 6G, PM = pyromethane, C47 = coumarin 47. After Kozlov et al. (1998).

**Figure 6.210** Extraordinary tuning range of a small molecule guest-host system. (a) Amplified spontaneous emission spectra of the guest, Spiro-DPVBi with concentration (wt.%) in Spiro-BTBi. (b) Lasing spectra for a neat guest using second order DFB gratings of different periods to tune the wavelength. The total tuning range is 71.6 nm (Schneider et al., 2004).

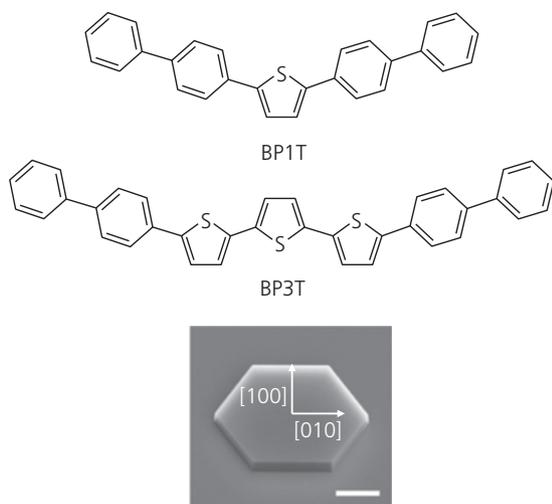

emission peak. This allows for an exceptionally broad selection of lasing wavelengths in even a single molecular system. An example of this tuning range is shown in Fig. 6.210. The optically pumped ASE spectra of the guest, Spiro-DPVBi, in the host, Spiro-BTBi, red shifts with guest concentration, from 415 nm at 0.05% to 475 nm at 100% (Fig. 6.210a). The red shift is likely due to dielectric polarization, via the SSSE discussed in Section 3.6.7 (Bulovic et al., 1999). The accessible wavelength range is determined by the broad PL spectrum shown by the dashed line. Indeed, SSSE red shifts in the lasing spectrum itself have been observed over a remarkable range of 35 nm by varying the DCM concentration from 0.05–10% in Alq<sub>3</sub>:DCM Fabry-Pérot lasers (Kozlov et al., 1997b). The DFB lasing spectrum of a neat film of Spiro-DPVBi can be tuned over 71.6 nm by varying the second order grating period on a Si/SiO<sub>2</sub> substrate (Fig. 6.210b).

The broad gain spectrum of OSLs can also be exploited to select the lasing wavelength from among the several vibronic modes of a single molecular species. This can be understood from the electronic state diagram in Fig. 6.211. In this example, optical pumping results in the transition:  $S_1(v_e = 2) \leftarrow S_0(v_g = 0)$ . Emission occurs from the  $S_1(0)$  state to any one of the ground state vibronics, with the strength of a given transition dependent on the ground state wavefunction overlap with  $S_1(0)$ . The transitions between energies:  $E_1 \rightarrow E_4 \rightarrow E_3 \rightarrow E_2$  defines the four-level lasing system, with the gain envelope extending across the

**Figure 6.211** Ground and first excited states of a laser. The pump excites the molecule into its  $S_1$  state (gray arrow), and following Kasha's rule, emission occurs from  $S_1(v_e = 0)$  to any one of several vibronic states ( $v_g = 0-4$ ) within the  $S_0$  manifold (green arrows). Due to lack of orbital overlap between  $S_1(0)$  and  $S_0(0)$ , the oscillator strength is very small (Dong et al., 2018).

accessible ground state vibronics for which the oscillator strength for a particular transition is significant (in this case, from  $v_g = 1$  to 4). Ordinarily, lasing occurs between  $S_1(0)$  and  $S_0(1)$ . However, the other ground state vibronics can be selected by increasing their

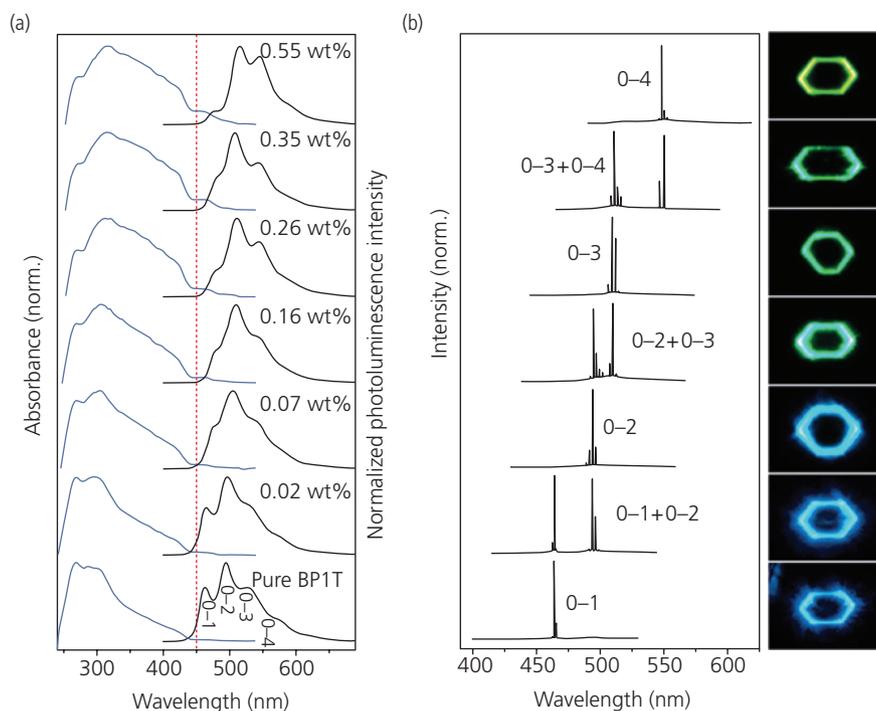

**Figure 6.212** Molecular structural formulae of the luminescent BP1T, and the UV–green absorber, BP3T. The electron micrograph shows a single BP1T nanocrystal along with two crystalline axes indicated. The scale bar is 5  $\mu\text{m}$  (Dong et al., 2018).

oscillator strength relative to the  $S_1(0) \rightarrow S_0(1)$  transition. The selection of a given transition can thus be used to “digitally tune” the lasing wavelength.

Selection of a particular vibronic transition has been demonstrated for nanocrystals of the green emitting thiophene, BP1T, by doping with low concentrations of the absorber BP3T. The molecular structures of these complexes are shown in Fig. 6.212. The doped, 20  $\mu\text{m}$  hexagonal crystallites were grown by OVPD in an Ar carrier gas on quartz substrates. Since the excited state dipole moments are oriented perpendicular to the (001) crystal plane that lies parallel to the substrate surface, emission is preferentially within the plane, and is incident to the facets. The crystallites thus form ring (or *whispering gallery*) lasers, with cavity length  $L$  equal to the sum of the lengths of the 6 facets.

The BP1T emission and BP3T absorption spectra are shown in Fig. 6.213a. The low concentrations of the dopant are easily controlled by OVPD by placing both the dopant and host in a temperature gradient along the length of a horizontal tube furnace. Each species is located at the optimal point to control its individual evaporation rate. From the figure, we see that the long wavelength absorption tail of BP3T extends into the high energy limb of the BP1T emission spectrum. As the dopant concentration is increased,

**Figure 6.213** (a) Absorption and PL spectra of BP3T and BP1T, respectively, as functions of BP3T concentration. The transitions of the BP1T vibronic progression are shown for the pure BP1T crystal. (b) Lasing spectrum vs. BP3T concentration shown in (a). The various transitions are indicated. Left: Micrographs of the laser emission from a BP1T crystal, varying from blue (bottom) to green (top) (Dong et al., 2018).

the higher energy BP1T emission is reduced, effectively reducing the strength of the 0–1 transition, moving to the 0–4 transition at a BP3T concentration of 0.55 wt%. This, in turn selects the lasing mode, as shown in Fig. 6.213b. The pure crystal emits only from the 0–1 transition in the blue, at a wavelength of  $\lambda = 464$  nm. The emission pattern is shown to the right, indicating that the crystal facets indeed form mirrors that confine the optical mode within the hexagonal resonant cavity. As the dopant concentration increases to 0.07 wt%, lasing “digitally” shifts to the 0–2 transition at 495 nm, at 0.26 wt% to the 0–3 mode, and finally at 0.55 wt%, emission is solely from the 0–4 transition in the green, at 550 nm. Interestingly, at intermediate concentrations of BP3T, laser emission from two modes are simultaneously observed. These lasers exhibit multi-mode emission, indicating that there may be more than one optical path that circulates within the hexagonal cavity at one time.

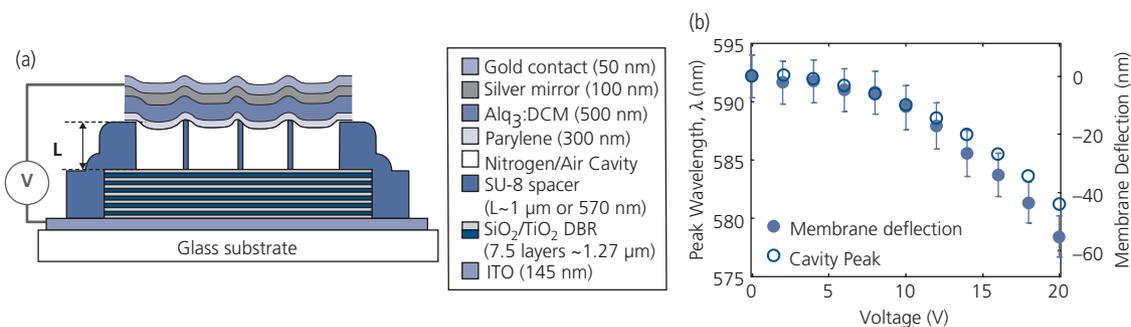

Selecting the lasing wavelength by absorption has the adverse effect of increasing the threshold pump power, which increases by approximately 20% from the undoped to the 0.55 wt% sample. This roughly corresponds to the increased absorption of BP3T (Dong et al., 2018). The ability to select the lasing wavelength from the transitions from within the vibronic progression of a single molecular species is due to the very broad gain spectrum of organic molecules.

One further exploitation of the broad gain spectrum is an electrically tunable organic VCSEL (OVCSEL) in Fig. 6.214a. The DCM (2.5%):Alq<sub>3</sub> gain medium is separated from a dielectric DBR stack by a 1  $\mu\text{m}$  thick air gap. The top reflector of this bottom emitting device is a 100 nm thick layer of Ag deposited onto the gain medium surface. By applying a voltage between the Au top contact and the ITO layer that underlies the dielectric mirror stack, the cavity length is reduced via electrostatic attraction. This results in a shift in resonant wavelength of  $\Delta\lambda > 10$  nm at 20 V, as shown in Fig. 6.214b.

From these few examples, we see that the exceptionally broad gain spectrum of OSLs can lead to wavelength versatility over a large range.

(ii) *Temperature independent gain characteristics.* Inorganic semiconductor laser characteristics such as the threshold current, slope efficiency and emission wavelength show significant temperature dependencies. This arises from the broad densities of states of electrons and holes. As temperature increases, the Fermi energy moves toward the band edge due to the increase in free charge density. This, in turn, increases the threshold current needed to reach transparency. The threshold current (or excitation density) in inorganic laser diodes follows the empirical relationship:  $j_{th} = j_0 \exp(T/T_0)$  where  $T_0$  is the characteristic temperature of the lasing medium and cavity architecture. For group III–V semiconductor lasers such as those based on InP or GaAs,  $T_0 \sim 100$ –150 K (Coldren and Corzine, 1995). To reduce the effects of temperature, the confinement of the density of states in engineered quantum well and QD structures are widely employed (Arakawa and Sakaki, 1982). We have shown in Part I that the energetics of organic semiconductors are inherently different from their inorganic analogues. Disorder leads to a lack of well-developed bands except in only a handful of molecular systems. Thus, a strong energy gap dependence on temperature in inorganic semiconductors is absent in organics. Indeed, in organic host–guest systems, excitations are localized on the guest molecule after Förster transfer from the host. Thus, we can think of such excited, widely dispersed fluorescent molecules as natural quantum dots. These molecular systems thus have very weak threshold power dependence on temperature.

The temperature dependent characteristics for an Alq<sub>3</sub>:DCM (5%) Fabry–Pérot laser are shown in Fig. 6.215, and are compared with expectations for a

**Figure 6.214** (a) Schematic diagram of a mechanically tunable OVCSEL. (b) Optically pumped OVCSEL wavelength and mirror deflection distance as functions of applied voltage between the Au and ITO contacts in (a) (Chang et al., 2014).

conventional GaAs-based semiconductor laser diode (dashed lines). As expected for a quantum-confined state, there is only a small increase in threshold pump energy with temperature from 0°C to 150°C for the organic laser. Its characteristic temperature of  $T_0 = 1000$  K is nearly an order of magnitude higher than for the inorganic device. The slope efficiency of the organic laser does not change over this same temperature range, whereas many inorganic laser diodes do not even reach threshold at the highest temperatures used in this experiment (Kozlov et al., 1997b). Moreover, the wavelength is also relatively temperature independent shifting by only a few nanometers over this broad temperature range. In contrast, the inorganic laser wavelength is expected to depend on its energy gap, which follows the empirical relationship:  $E_g(T) = E_g(0) - \alpha T^2/(T + \beta)$ , with  $\alpha = 5.4 \times 10^{-4}$  eV/K and  $\beta = 204$  K for GaAs (Sze, 1981). The small red shift of the organic is possibly due thermal expansion of the Fabry-Pérot cavity at high temperatures.

The extraordinary and intrinsic temperature independence of OSLs provides a compelling case for their use as wavelength standards whose intensities and wavelengths are independent of large temperature swings. The access to a broad range of emission wavelengths further suggests their suitability for a diversity of sensing, timing and communications applications.

(iii) *Ultra-narrow lasing linewidths.* In addition to stable wavelength operation, the linewidths of OSLs can be extraordinarily narrow. Indeed, Fourier transform limited linewidths have been observed for small molecule OVCSELS, as shown in Fig. 6.216. This

device comprises a single metal mirror and a DBR stack with a reflectivity of  $R_1 = 0.995$ . This gives a microcavity  $Q$  of

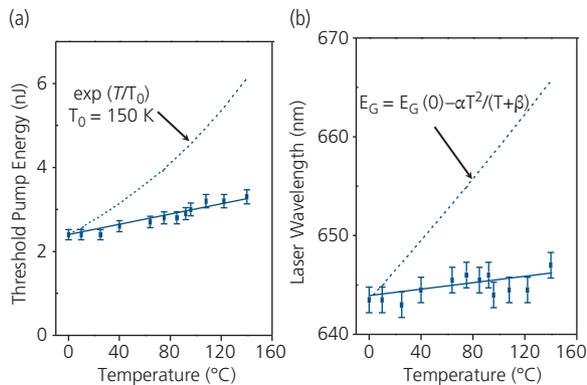

$$Q = \frac{\lambda_0}{\Delta\lambda} = \frac{2\pi}{\lambda_0} \frac{2\bar{n}L}{\ln(1/R_1R_2)} \approx 420, \quad (6.161)$$

where  $R_2 = 0.91$  is the Ag mirror reflectivity and  $\bar{n}L = 3.5\lambda$  is the effective optical cavity length. The measured linewidth above threshold is only  $\delta\lambda = 0.2$  Å (Bulovic et al., 1998b)

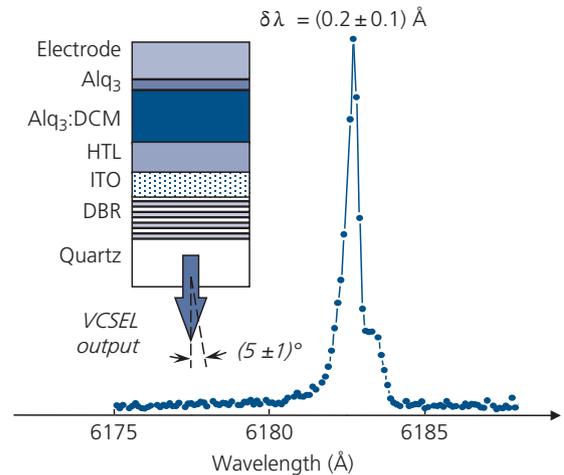

The Fourier transform limited beam width is determined by the laser bandwidth. That is, high bandwidth operation transforms into a spectrally broader line. The temporal response of the OVCSEL is shown in Fig. 6.217. The pulse response is characterized by a series of *relaxation oscillations* of period  $T = 100$  ps and a duration of  $\Delta t = 40$  ps. Relaxation oscillations arise from a mismatch between the spontaneous emission lifetime of the laser medium,  $\tau$ , and the photon lifetime in the cavity,  $t_c$ , which is simply the photon round trip time divided by the probability of escape per round trip. The relaxation oscillation frequency is given by

$$f_{ro} = \frac{1}{T} = \frac{1}{2\pi} \sqrt{\frac{(\rho - 1)}{t_c\tau} - \left(\frac{\rho}{2\tau}\right)}. \quad (6.162)$$

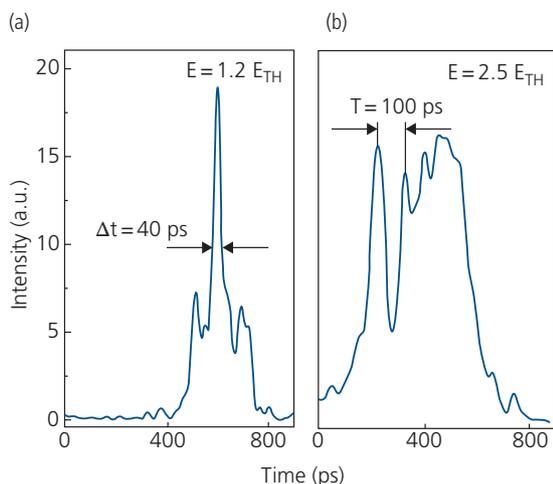

Here,  $\rho$  is called the pump parameter, which is the ratio of the pump power to its value at threshold (i.e.  $\rho = E/E_{TH}$  in Fig. 6.217). The Fourier transform time of 40 ps results in the observed linewidth of  $\delta\lambda = 0.2$  Å, indicating that this device has reached its theoretical bandwidth limit.

**Figure 6.215** (a) Threshold pump energy for an Alq<sub>3</sub>:DCM Fabry-Pérot laser vs. temperature. The dashed line is characteristic of GaAs lasers with  $T_0 = 150$  K, and the solid line is a fit to the data for the OSL with  $T_0 = 1000$  K. (b) Laser wavelength vs. temperature. The dashed line shows the change in GaAs energy gap with temperature, and the data show the dependence for the organic laser (Kozlov et al., 1997b).

**Figure 6.216** Single mode laser emission spectrum of the OVCSEL structure shown in the inset. The exit beam angle half-width is  $5^\circ$ , and the laser linewidth is  $0.2$  Å (Bulovic et al., 1998b)

**Figure 6.217** Temporal response of the OVCSL in Fig. 6.216 at two different pump excitation energies above threshold,  $E_{TH}$ . The relaxation oscillations have a period of  $T = 100$  ps and a duration of  $\Delta t = 40$  ps (Bulovic et al., 1998b).

Given this result, we are in the position to estimate the maximum bandwidth (or minimum linewidth) that can be achieved with an organic laser. This ultimately depends on the value of the threshold gain, the size of the cavity, and its  $Q$ -factor (Henry, 1986). Taking these factors into account, the power-bandwidth product for OSLs is  $P\Delta f = 1$  GHz mW, which is comparable to that achieved using inorganic semiconductor lasers (Bulovic et al., 1998b)

(iv) *Compatibility with flexible substrates.* A common property of all organic electronic devices is that they can be grown on almost any flat substrate without regard to its composition or mechanical properties. This property also applies to OSLs. Almost as soon as the first demonstrations of OSLs were announced, researchers reported OSLs fabricated on a variety of flexible substrates (Berggren et al., 1998, Kallinger et al., 1998, Kozlov et al., 1998, Herrnsdorf et al., 2010). The challenge is to fabricate high quality gratings that result in a low threshold and a well-defined output beam, even when the substrate is flexed. Single mode DFB lasers have been demonstrated by spin coating a photoactive polymer, or vacuum deposition of small molecule guest–host systems onto photopatterned or pressure-embossed gratings in plastic substrates (Berggren et al., 1998, Kallinger et al., 1998). To date, however, the lowest pump thresholds ( $\sim 2.7$  kW/cm<sup>2</sup>) (Herrnsdorf et al., 2010) on flexible substrates are almost two orders of magnitude higher than lasers on flat substrates (Xia et al., 2009). In spite of these deficiencies, the allure of fabricating

arrays of multicolor organic lasers on flexible and lightweight substrates has led to considerable developments of these structures.

### 6.8.3 Achieving electrically pumped OSLs

In Section 6.8.1 we showed that even the small number of residual triplets that are generated by optical pumping are sufficient to terminate lasing emission after a few hundred nanoseconds. The losses due to triplets are associated with triplet absorption and STA. These losses are enormously increased in electrically pumped devices, where 75% of the injected charges result in triplets. For example, in the Alq<sub>3</sub>:DCM Fabry–Pérot laser, it was found that the threshold gain corresponded to a cavity loss of  $\alpha_{CAV} \approx 30$  cm<sup>-1</sup>. Including mirror losses (with  $R = 7\%$ ) of  $\alpha_M \approx 25$  cm<sup>-1</sup>, the total loss at threshold was estimated to be  $\alpha_T \approx 55$  cm<sup>-1</sup>. However, at  $j = 100$  A/cm<sup>2</sup>, the loss increases nearly ten-fold, to  $\alpha_T \approx 400$  cm<sup>-1</sup> (Kozlov et al., 2000). Clearly, electrical pumping can induce very large losses that must be overcome by a commensurate amount of gain, presenting a daunting challenge to reaching threshold. We have already seen in Section 6.3.5 that triplet losses in high intensity OLEDs leads to a significant drop in efficiency as the triplet population increases over time.

Laser diodes are characterized by two features. There must be electrical confinement within the gain medium, that is, the charge balance factor defined for OLEDs must be  $\gamma \sim 1$  to ensure a very high density of excited states leading to population inversion in the active material. And there must be optical confinement within the gain region to ensure maximal overlap between the optical field and the charge/exciton distribution. Without both of these factors, it is unlikely that electrically pumped lasing can be achieved. The longitudinal laser structure in Fig. 6.218 possesses these characteristics, but it also illustrates the difficulties in reducing losses. Optical confinement is provided by the refractive index of the active region that is presumably higher than that of the surrounding HTL and ETL. Transparent contacts can be used to avoid the very high losses due to absorption and SPPs excited in the metal contacts. These losses are exacerbated by low index contrast between organic layers that lead to only weak optical confinement. To minimize mirror losses, a DBR or a DFB structure is required.

An advantage of the longitudinal arrangement is the extended gain region. However, contact losses are considerably easier to manage in a VCSEL where the

optical field has nodes at the contact surfaces. This must be traded off against a shorter gain region, and the need to make Ohmic contact to top and bottom surfaces that may also contain dielectric DBR mirror stacks.

The laser equations for electrical pumping are identical to those used for optical pumping (Eq. 6.155–6.158) except that the optical generation terms must be modified to account for electrical injection at current,  $j$ . Thus, we rewrite these expressions as

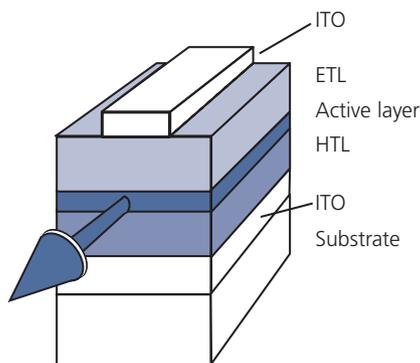

$$\frac{dS}{dt} = \frac{\chi_S j}{qd} - k_S S - k_{ISC} S - k_{ST} S T_G + \frac{1}{2} k_{TT} T_H^2 - \gamma_C \bar{n} P \quad (6.163)$$

and

$$\frac{dT_H}{dt} = \frac{(1 - \chi_S) j}{qd} + k_{ISC} S - k_{TT} T_H^2 - k_{HG} \exp\left(-\frac{2}{R_0} \sqrt{\frac{1}{N_0 - T_G}}\right) T_H. \quad (6.164)$$

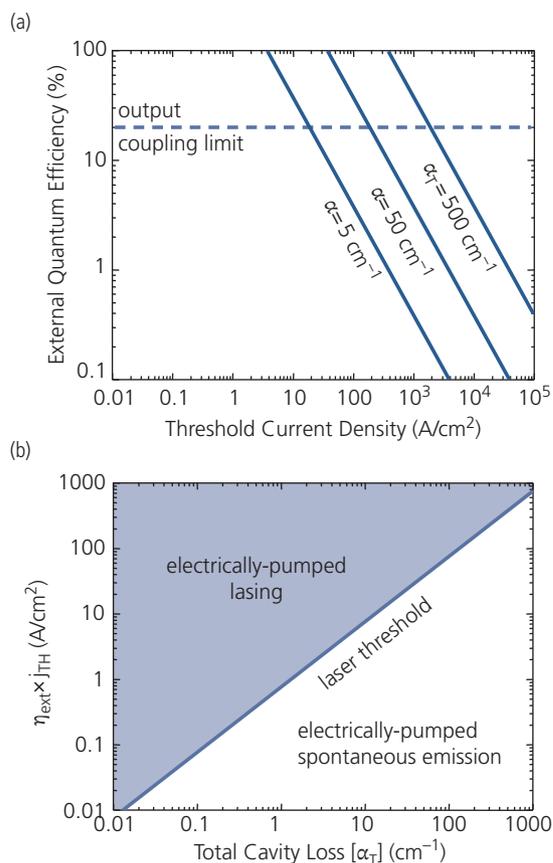

Here, we assume that the triplets are formed only on the host, and  $\chi_S$  is the singlet generation probability. Also, we have included the TTA rate,  $k_{TT}$ , to account for triplet interactions only on host molecules since the density of guests, and hence guest triplets, is expected to be considerably smaller. For electrical pumping,  $N_0$  approaches the total host concentration. Direct triplet formation on the guest requires analogous straightforward modifications of Eq. 6.158. The threshold condition in Eq. 6.159 also requires modifications consistent with the above expressions.

There have been only a few studies on the impact of triplet losses on the threshold currents of OSLs (Baldo et al., 2002, Giebink and Forrest, 2009). Figure 6.219a shows the results of one such theoretical analysis that

**Figure 6.218** Schematic illustration of an electrically pumped organic semiconductor laser.

summarizes the challenges in achieving lasing via current injection. This study considers losses due to mirrors, and optical and polaron absorption. For fluorescent materials, the upper limit to efficiency is determined by  $\chi_S = 1/4$ , although the external efficiency will almost certainly be less than 25% for most lasing systems. Even in this best case, the total cavity losses are *optimistically* on the order of  $500 \text{ cm}^{-1}$ , leading to a minimum threshold current density of  $\sim 10 \text{ kA/cm}^2$ , which is well beyond the steady-state damage threshold ( $10\text{--}100 \text{ A/cm}^2$ ) of most organic semiconductor materials. While  $j > 12 \text{ kA/cm}^2$  has been achieved in very small ( $25 \mu\text{m}$ ) CuPc thin film devices mounted on heat sinks sandwiched between ITO and Mg:Ag electrodes, this current is still at the lower limit expected for lasing in an OLED. Moreover, an Alq<sub>3</sub>:NPD device was electrically pumped with  $j > 500 \text{ A/cm}^2$ , reaching a maximum brightness of  $1.5 \times 10^6 \text{ cd/m}^2$ , yet no mention was made of observations of spectral

**Figure 6.219** Calculated relationship between (a) external quantum efficiency,  $\eta_{\text{ext}}$  and threshold current density,  $j_{\text{TH}}$  and its dependence on total cavity loss. (b) The product  $\eta_{\text{ext}} j_{\text{TH}}$  vs total cavity loss (Baldo et al., 2002).

narrowing or a superlinear  $j$ - $V$  characteristic indicative of ASE or superluminescence (Yamamoto et al., 2005).

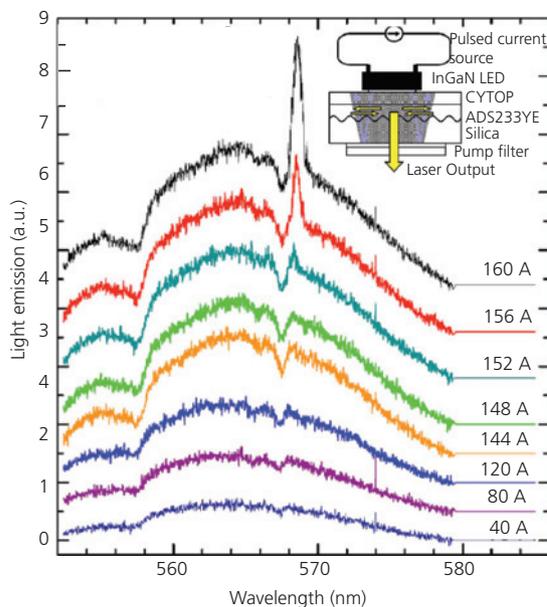

Finally, it is useful to consider the product of external quantum efficiency and threshold current density to determine the combined effects of materials and excitation. This is plotted in Fig. 6.219b. There, the regions between spontaneous emission and lasing are delineated as functions of cavity loss.

Since  $\chi_S = 1/4$  under electrical pumping leads to an extremely rapid build-up of triplets, the laser emission transient will be extremely short ( $\sim$ ns) in the absence of management strategies. Indeed, if the cavity losses are too high, lasing will not be reached at *any* value of  $j$  (Giebink and Forrest, 2009). Furthermore, even for low cavity losses, the device capacitance may lead to a turn-on time constant due to device charging that is too long to avoid the build-up of triplet losses.

In view of the foregoing considerations, it appears unlikely that a “conventional” OLED-like structure such as that in Fig. 6.218 will lead to electrically pumped OSLs. However, electrically pumped lasing may yet be achieved in structures where the gain region and that used for electrical excitation are separated. For example, it has been shown that a vertical cavity polymer lasing region can exhibit laser emission when integrated with a high intensity, pulsed InGaN LED pump. Using 36 ns pulses, a threshold was reached at an LED drive current of 156 A, as shown in Fig. 6.220 (Yang et al., 2008). This hybrid organic-inorganic laser suggests that spatially separating these functions may indeed eventually lead to an all-organic laser. But it appears that this will occur only when the effects of triplet annihilation and absorption are eliminated from the lasing region. Should that be accomplished, the rapid degradation of organic materials under intense excitation found in laser cavities still constitutes a significant barrier to their practicality.

## 6.9 Summing up

In this chapter, we have found that OLEDs are the driving force behind the organic electronics “revolution.” They have many attractive features that make them compelling solutions for displays and lighting, including high brightness and efficiency, access to a wide color gamut, flexible substrates, etc. The list of attributes is extensive, and has led to a rapidly growing industry with OLED displays becoming dominant in mobile applications. These displays have also made significant inroads into the television and monitor

**Figure 6.220** Externally, InGaN LED pumped polymer laser spectrum as a function of LED drive current. Lasing threshold is at 156 A. The DFB structure using a CYTOP™ fluoropolymer buffer layer and the luminescent molecule ADS233YE is shown in the right inset. The DFB grating period is 350 nm and its depth is 70nm (Yang et al., 2008).

markets. The prospects for OLED lighting are also becoming increasingly bright!

While organic light emission science and technology has made enormous strides since the invention of the low voltage, bilayer OLED in the mid-1980s, there are still major challenges that must be overcome for this technology to reach its full potential. In the chapter, we have discussed many of those challenges, which we summarize here.

- (i) *Phosphorescent blue OLED lifetime:* We noted that achieving acceptably long lifetimes for blue PHOLEDs is arguably one of the most difficult yet most important challenges facing the field of organic electronics today. The increase in display and lighting efficiencies that would accompany replacing the longer-lived blue fluorescent devices is approximately 25%, leading to a substantial boost in mobile display battery lifetimes. Yet, we have seen that the lifetime is intrinsically limited by energy-driven molecular dissociation. The degradation can partially be mitigated by decreasing the exciton density in the device emission zone, decreasing the emission lifetime of the phosphor (or TADF) molecule, or by siphoning off excess energy of hot excited states using managers. These methods have not yet led to sufficiently long deep blue PHOLED lifetimes to bring them anywhere

near a practical solution for displays. Armed with insights into the chemical origins of the electronic defects, it may be possible to engineer even more robust molecular materials systems that will eventually lead to acceptable performance.

- (ii) *Outcoupling all of the photons.* Modern PHOLEDs and TADF molecules can have 100% internal quantum efficiencies, yet most of the light (as much as 80%) is trapped within the device. We have found that the trapped light is launched into substrate, waveguide, SPP, and lossy modes. Numerous creative schemes have been demonstrated to extract each of these modes from OLEDs, with maximum efficiencies approaching ~80%. For a solution to be practical, it must allow for the emission to be independent of wavelength and viewing angle, it should not “disturb” the construction of the OLED itself, nor put demands on the materials sets employed, degrade the OLED performance in any way, and it should be very low cost when applied over large substrate areas. Clearly, much progress is still needed to fully solve this high value problem.
- (iii) *Low cost, high resolution patterning for high definition and large area displays.* While this was primarily a topic of Chapter 5, the ubiquity of OLED displays in applications from virtual reality to large screen televisions requires that considerable progress must still be made to achieve low cost, high yield pixel patterning. Currently, displays use fine metal shadow masks that require constant cleaning and are a challenge to implement over large areas. High speed direct patterning, either by ink or vapor jet, appear to be far better suited for pixelation at “any scale, over any area,” as required for these applications.
- (iv) *Long lifetime, flexible encapsulation.* Already, flexible, ultrathin and lightweight OLED displays are appearing in the marketplace due to their compelling form factors. Indeed, flexibility appears to be a unique feature of organic display and lighting technology. However, we have shown that the water and oxygen permeability of plastic substrates is unacceptably high. This problem has been partially solved by using inorganic moisture and oxygen barriers deposited by ALD or plasma chemical vapor deposition onto the plastic, and directly within the OLED encapsulating layer itself. These coatings are not completely effective, nor are they low cost. However, achievement of long-lived OLEDs on plastic substrates leads to applications that extend beyond

just their attractive performance characteristics. High speed patterning along with manufacturing by roll-to-roll processes require flexible substrates. Their achievement would ultimately result in realizing the dream of printing optoelectronic devices “on demand” and “by the kilometer.”

- (v) *Electrically pumped OSLs.* While optically pumped OSLs were initially demonstrated more than two decades ago, electrical pumping has yet to be convincingly achieved. We have shown that, like long lifetime blue PHOLEDs, there are intrinsic limitations to realizing such a device. The losses due to triplets often overwhelm the gain achieved by the fluorophores in the active media. Thus, electrically pumped organic laser diode designs should separate the zones where excited states are created via current injection, and the light generation (i.e. the exciton recombination) region. Ultimately the solution to this problem will be found since the interest in OSLs is driven by their wavelength versatility, temperature independent operating characteristics, and compatibility with plastic substrates.

These are only five of the many remaining challenges facing OLEDs today. Nevertheless, OLEDs are, and remain likely to continue to be well into the future, the most successful organic electronic device technology. Indeed, their development and continuous improvement over the three decades since their invention are already leading the way toward realizing numerous other practical organic electronic devices such as detectors, solar cells and transistors, to be discussed in the following chapters.

## Problems

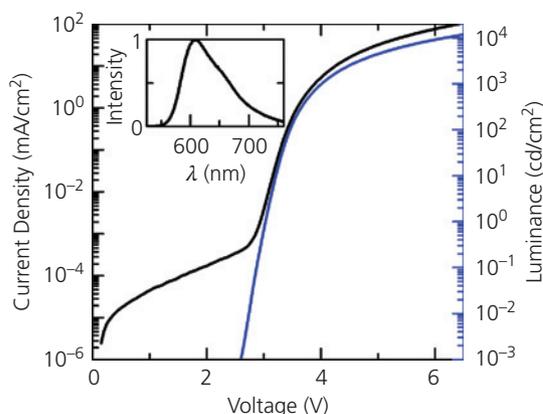

- From the three PHOLED spectra in Fig. 6.15a:
  - Calculate the color coordinates for each spectrum to verify the gamut shown in Fig. 6.15b.
  - All spectra are approximately equally broad and unsaturated. Why does the red spectrum appear nearly saturated in the CIE chart, appearing closest to the color locus?
  - Assuming that the peak intensities of the three colors are in a ratio of  $\frac{1}{4}$ , 1,  $\frac{1}{2}$  in blue, green, and red, what is the CRI and CCT that can be achieved by the combination of these three color elements? Plot this point on the 1931 CIE chromaticity chart.
- Figure P6.2 shows the emission spectrum of the white OLED used in LG's 55" TV.
  - From this spectrum calculate the CRI, CCT, and  $(u, v)$  1964 CIE color coordinates of the WOLED source.
  - Would this WOLED be considered a good room illumination source? Explain.
- Figure 6.111 shows the spectrum at four different current densities from a two-color WOLED based on a combination of TADF and Ir-phosphor emitting molecules.
  - Calculate the CRI, CCT, and color coordinates at the current densities shown.
  - Plot the coordinates on the 1931 CIE chromaticity chart. What are the  $\Delta u$ ,  $\Delta v$  distances to the Planckian locus?

**Figure P6.2** Normalized emission spectrum of a WOLED.

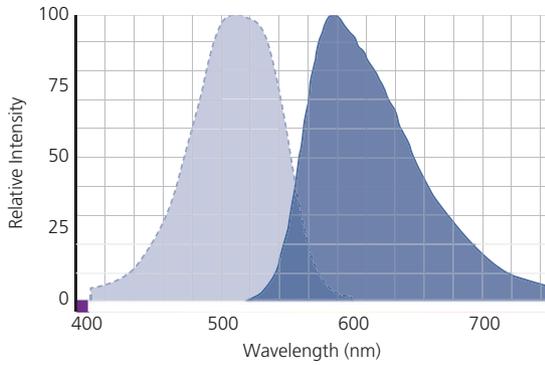

- Figure P.6.4 shows the  $j$ - $V$  and  $L$ - $V$  characteristics of a red emitting OLED, along with its emission spectrum in the inset.

- What are the CIE coordinates of this device?
- Plot the photometric characteristics of luminous efficiency and luminous power efficiency as functions of  $j$ .
- Plot the equivalent radiometric units as those in (b).
- Is this a PHOLED or fluorescent OLED? Explain your answer.

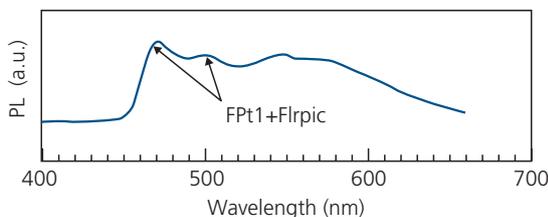

**Figure P6.4** Performance characteristics of a red OLED.

- Figure P.6.5 shows the emission spectrum (blue) of a host, and the absorption spectrum (red) of a guest molecular pair for an infrared emitting OLED. The effective radius of the host is  $r_H$  and the guest is  $r_G$ .
  - Plot the dependence of the Förster transfer radius,  $R_0$ , and the FRET transfer efficiency vs. guest concentration,  $N_G$ .
  - At what concentration is the efficiency maximized for a fluorescence lifetime of the guest,  $\tau_D$ ? Assume that the non-radiative concentration quenching rate is given by  $k_{cc} = k_{cc0} \exp(-r/(r_G + r_H))$ , where  $r$  is the molecular separation.
  - Repeat part (b) for Dexter transfer.

**Figure P6.5** The emission (blue) and absorption (red) spectra of a guest–host molecular pair.

6. Analysis of delayed fluorescence in Section 6.3.5 is based on the assumption that singlet and triplet excitons are electrically generated according to random statistics. Here we explore situations where this might not be the case.
  - (a) Write the coupled rate equations for triplet and singlet concentrations in OLEDs with singlet–triplet statistics of  $\chi_{ST} = 0, 0.1, 0.25,$  and  $0.5$ .
  - (b) Plot the ratio of delayed fluorescence vs.  $j$  assuming that  $k_{TA-S}T = k_F = 100k_{ph}$  as a function of  $\chi_{ST}$  over the same domain as in (a).
  - (c) What is the maximum quantum efficiency that can be attained in each case of  $\chi_{ST}$  as in (a)?
  - (d) Plot the effective triplet current density ( $j_T$  in Eq. 6.58) vs.  $j$  for a device with an EML thickness of  $d = 50$  nm and  $\gamma = 1$ , independent of the  $j$  vs.  $\chi_{ST}$  with the values in (a).
7. The excimer dynamics are described by the rate equations in Section 6.5.3 for a guest–host system.
  - (a) Plot  $M^*(t), E^*(t),$  and  $H^*(t)$  with the following initial conditions:  $t = 0, G = 0, {}^3M^*(0) = (0.001)^{-1}M(0), f = 0.1,$  and  $k_{ph} = 0.01k_{ET} = 0.1k_T \ll k_X$  in the absence of other non-radiative recombination processes.
  - (b) Under these conditions, sketch the time evolution of the spectra for the FPT1+Flrpic diode in Fig. P6.7.

**Figure P6.7** Blue monomer/excimer emission.

8. The *transfer matrix approach* is a simple and accurate means for calculating wave propagation through multilayer media, such as that encountered in OLEDs and OPVs. There are many elementary texts and sources for learning about this powerful method of field

calculation (see, for example, Heavens, 1991). Briefly, the electric field incident on a medium along the propagation direction,  $z,$  is written  $F(z) = F_r e^{ikz} + F_l e^{-ikz},$  where subscripts  $r, l$  refer to the right, left propagating waves, respectively, with wavevector  $k = 2\pi \tilde{n} / \lambda_0,$  where  $\tilde{n}$  is the complex index of refraction of the medium, and  $\lambda_0$  is the wavelength in free space. For the purposes of this discussion, we will only consider plane waves incident normally on a stratified medium lying in the  $x$ - $y$  direction. Then, after propagating through a layer of thickness  $d,$  the field and its derivative,  $F'_z(d) = dF/dz|_{z=d}$

$$\begin{pmatrix} F(z+d) \\ F'_z(z+d) \end{pmatrix} = M \begin{pmatrix} F(z) \\ F'_z(z) \end{pmatrix} \tag{6.P8a}$$

where

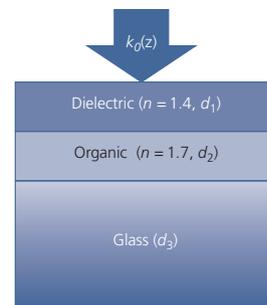

$$M = \begin{pmatrix} \cos kd & \frac{1}{k} \sin kd \\ -k \sin kd & \cos kd \end{pmatrix} \tag{6.P8b}$$

is called the transfer matrix. For a series of  $N$  layers, and with the  $i$ th layer with thickness and wavenumber ( $d_i, k_i$ ), then,

$$\begin{pmatrix} F(z+L) \\ F'_z(z+L) \end{pmatrix} = \prod_{i=1}^N M_i \begin{pmatrix} F(z) \\ F'_z(z) \end{pmatrix}, \tag{6.P8c}$$

where  $L = \sum_{i=1}^N d_i$  is the total thickness of the stack.

- (a) Generalize Eq. 6.P8b for a plane wave arriving at any angle,  $\theta,$  relative to the normal at  $\theta = 0.$
  - (b) Write expressions for the reflectivity and transmissivity of the stack in terms of the amplitude of a wave normally incident from the  $-z$  direction.
  - (c) Now consider the three-layer medium in Fig. P6.8. Calculate the field exiting from the soda-lime glass substrate into air, that is, calculate the transmissivity of the stack for light normally incident on the surface with wavevector  $k_0.$
9. Since the device in Fig. P6.8 is approximately what an OLED structure might look like, we would like to enhance outcoupling from the glass substrate using an anti-reflection coating (ARC).

**Figure P6.8** Three-layer medium bounded by air, with an electric field propagating in the  $z$ -direction with wavevector  $k_0(z).$

- (a) We want to use a two-layer ARC at the glass/air interface comprising  $\text{TiO}_2$  and silicon dioxide with indexes of refraction of  $n_{\text{TiO}_2} = 2.61$ , and  $n_{\text{SiNx}} = 1.45$ . What are the optimal thicknesses of the individual layers in the bilayer coating to maximize the field intensity transmitted into the glass substrate? In what order should these two materials be placed on the glass surface?
- (b) Very low index *aerogels* have also been used as antireflection coatings. What is the transmittance of the stack in the figure for such a porous, lossless silica medium with  $n = 1.15$  and  $d = 0.5$  mm?
10. Microlens arrays have been shown to outcouple light by increasing the light cone angle that can escape from the glass substrate into the air modes.
- (a) Assuming that the EML emits isotropically into  $4\pi$  solid angle, plot the approximate outcoupling efficiency as a function of microlens diameter,  $d_{\mu l}$ , from a bottom emitting OLED (index  $n_{\text{OLED}} = 1.7$ ) with a perfectly reflective top contact, and where the EML is located sufficiently far from the emitting dipole layer so as not to generate SPP modes. The glass substrate has a thickness  $d_{\text{sub}}$ . Assume that the microlens array (index  $n_{\mu l} < n_{\text{OLED}}$ ) forms a two dimensional, closely packed hexagonal lattice, and that the OLED diameter,  $d_{\text{OLED}}$ , is much smaller than  $d_{\text{sub}}$ . (Hint: Ray tracing is a good method to solving this problem.)
- (b) Plot the outcoupling enhancement fraction for the device with the microlens array compared to one with a flat glass substrate using the same geometry as in (a)?
- (c) Plot the dependence of outcoupling efficiency on  $n_{\mu l}$  for a fixed  $d_{\mu l} \ll d_{\text{OLED}}$
11. Calculate the approximate polar emission profile (i.e. intensity vs. angle,  $\theta$ ) of a microlens array comprising 10  $\mu\text{m}$  diameter close-packed hemispherical lenses with indexes of refraction of  $n = 1.3$  and  $1.7$  from:
- (a) A bottom emitting OLED on a 0.3 mm thick glass substrate.
- (b) A top emitting OLED with a transparent top cathode.
- (c) What is the deviation from Lambertian for the two devices in (a) and (b)? That is, calculate the fraction of the total emission that falls outside a perfect Lambertian emitter.
- (d) What effect will the differences with a Lambertian source have on the image resolution and other appearances of the devices?
12. Calculate the dependence of dipole field intensity as a function of angle for a molecule with a transition dipole moment aligned  $30^\circ$  with respect to the substrate plane.
13. Figure P6.13 shows the luminance lifetime data for an OLED driven at the current densities of 10, 20, 30, 50, and 100  $\text{mA}/\text{cm}^2$ . The initial luminances,  $L_0$ , are provided in the figure. Assume that the emission spectrum of this device is the same as  $\text{Ir}(\text{ppy})_3$  (although do not assume the device is  $\text{Ir}(\text{ppy})_3$ ).
- (a) What are the device efficiencies ( $\eta_L$  and  $\eta_{\text{ext}}$ ) at  $t = 0$  at each current? Is this likely to be a fluorescent OLED or a PHOLED?

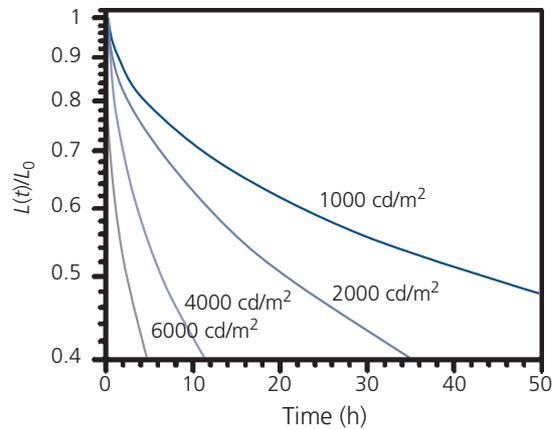

Figure P6.13 Aging data for an OLED. Initial luminances are indicated.

- (b) Fit the curves to the stretched exponential and the sum of exponentials expressions in Section 6.7.1. What do best fits yield for the time constants and acceleration factors  $\tau$ ,  $\tau_1$ ,  $\tau_2$ ,  $\beta$ , and  $n$ ? (Since lifetime analyses are based on statistical approaches, the best fits should be selected by a minimization of mean square deviations,  $\chi^2$ , of the data from the lifetime expressions).
- (c) Write a general expression for  $L(t)$  in terms of  $L_0$  and  $j$  that best predicts the lifetime of the devices. What is  $LT80$  and  $j_0$  for this device at  $L_0 = 100$   $\text{cd}/\text{m}^2$ .
14. For the blue PHOLED structure that generated the data and fits in Fig. 6.192, and assuming only TPA is active in aging,
- (a) Plot the  $LT70$  of the device as a function of recombination zone thickness, from  $d_{\text{rec}} = 5$  nm to 100 nm.
- (b) Assuming that the voltage of the device increases as  $\frac{dV}{d(d_{\text{rec}})} = Ad_{\text{rec}}^2$  where  $A = 0.001\text{V}/\text{nm}^3$ , what is the optimal EML thickness that gives the largest  $LT70 \times \eta_p$  figure of merit?
15. We have seen that the OLED lifetime is thermally activated, that is, as temperature increases by  $10^\circ\text{C}$ , the lifetime decreases by approximately a factor of 1.6–1.7. Hence, it is important to understand the change in temperature with drive current in both display and lighting appliances. Consider a green OLED ( $\lambda_{\text{max}} = 520$  nm) with an internal quantum efficiency of 50% comprised of a 100 nm thick Al cathode, a 100 nm thick organic active region, and a glass substrate of thickness,  $d_{\text{sub}}$ . Assume the top and bottom surfaces are maintained at the ambient temperature,  $T_0$ . The materials parameters for these several layers are given in Table 6P.15.
- (a) Based on the power balance Eq. 6.128, plot the steady state OLED active region temperature over the domain  $0 < j < 100$   $\text{mA}/\text{cm}^2$  for  $d_{\text{sub}} = 0.1, 0.3, 1,$  and 5 mm?
- (b) Calculate the junction temperature in (a) allowing the top contact to reach its own equilibrium temperature.

**Table 6P.15** Thermal parameters used in Problem 6.15

Material	Heat capacity (J/kg K)	Density (kg/m <sup>3</sup> )	Thermal conductivity (W/m K)
Al	900	0.0027	237
Organic	1500	0.0017	0.2
Glass	840	0.0025	1.1

- (c) Assume that a current step,  $j$ , is applied to the device at  $t = 0$ . What is the equilibration time constant as a function of organic layer thickness,  $d_{\text{org}} = 10\text{--}200$  nm?
16. An organic semiconductor laser has mirror reflectivities of  $R_1 = R_2 = 0.6$ , a radiative lifetime of 5 ns, an effective index of  $\bar{n} = 1.7$ , and a wavelength of  $\lambda_0 = 600$  nm.
- (a) Plot the transform-limited bandwidth vs. the cavity of length  $L$  in the domain of  $50\ \mu\text{m}$  to  $500\ \mu\text{m}$  at twice the threshold.
- (b) Plot the laser linewidth over the same domain in  $L$  as (a).

# Organic light detectors

---

*"I'd put my money on the sun and solar energy. What a source of power! I hope we don't have to wait until oil and coal run out before we tackle that."*

**Thomas A. Edison, Inventor, 1931**

What prophetic words from Thomas Edison, 23 years before the invention of the solar cell! Yet, here we are in the twenty-first century, and solar power generation has finally taken root as a significant (but far from dominant) alternative to fossil fuels. Our question in this chapter, however, is not whether solar power will play a significant role in the production of clean, abundant, and inexpensive renewable energy (it already does), but whether organic thin film materials, with their ultra-lightweight form factor along with their ability to be deposited onto virtually any reasonably smooth surface including flexible plastic and metal foils, will contribute to the explosively growing field of solar electricity production. But solar cells are not the only organic detector technology. Solar cells, also known as organic photovoltaics (OPVs), are a member of a broader class of photodetectors that includes organic photodiodes, photoconductors, and phototransistors. It is the former two types of detectors that are the subject of this chapter. Phototransistors, which are a combination of the photodetection and gain/switching elements, are treated in Chapter 8. As always, our discussion relies heavily on the foundations laid in Part I on the processes of photogeneration and charge conduction in organic materials.

To fully understand the process of photogeneration of charge, we begin with a discussion of the fundamentals of the organic photodetection process. The types of organic detectors will then be described in broad terms, before we engage in a detailed discussion of photodiodes. Their performance characteristics, including spectral sensitivity (i.e. their external quantum efficiency spectrum), noise, and bandwidth characteristics form the basis of this part of the chapter. This sets the groundwork for discussing specific photodetector architectures and applications.

While developments in photoconductors and photodiodes have led to impressive device performance characteristics, the vast majority of research has focused on solar cells since these are inherently large area devices; an application for which organic electronics is optimally suited to fill. Hence, the bulk of this chapter will focus on organic solar cells, principally in what differentiates them from incumbent technologies, and the mechanisms that govern their performance. After discussing the basics of solar cell operation including the thermodynamic limits to organic solar cell efficiency, we will describe the various types and structures of devices developed to reach the highest possible efficiencies. Indeed, progress in OPVs has largely been paced by developments in materials and device architectures. Hence, we will introduce several of the most interesting materials that have been developed for use in the various device regions including the active, blocking, and transport layers, the morphologies of the thin films that lead to efficient exciton dissociation and charge collection, and the device architectures that provide the highest power conversion efficiencies. Efficient solar

power harvesting requires specialized devices, with the highest performance often achieved with multijunction cells. The design of such cells can be quite complex due to the dependence of efficiency on balancing the charge generation and extraction in multiple stacked elements. And a transparent charge recombination zone must exist between each element. The design principles of multijunction cells will therefore be discussed in detail.

Beyond bulk and mixed heterojunctions, there are many other architectures that have been explored. These include cascade and blended donor or acceptor cells, ternary mixtures used to achieve broad spectral coverage, hybrid organic/inorganic quantum dot semiconductor structures, and structures exploiting singlet fission. This latter process involves the formation of two low energy triplet excitons for each high energy singlet generated on photon absorption. These interesting structures and phenomena introduce important physical and device concepts that may eventually bear fruit.

The chapter closes with a discussion of device reliability and the potential for large-scale, low cost manufacture. Indeed, it is these two features that will ultimately determine whether or not OPVs become a practical source of solar energy harvesting. It will become apparent that, given some additional progress in achieving low cost and high efficiency, OPVs are indeed well-positioned to become a vital source of electricity derived from the nearly limitless supply of solar energy arriving every day on the Earth's surface. Given that providing an ubiquitous source of clean energy to fulfill humankind's needs over the long term is imperative, we must continue to work to improve, and to provide solar energy via large-area organic electronic technology that is so well suited to the purpose.

## 7.1 Operating principles of organic photodetectors

A photodetector is a transducer that converts photons to an electric current. There are numerous types of photodetectors ranging from bolometers to avalanche photodiodes. In this chapter, however, we focus our attention on only the primary types of detectors that employ organic electronic active materials. These respond in the spectral region ranging from the ultraviolet (with wavelengths  $\lambda > 300$  nm) into the near infrared (NIR, at  $\lambda < 1500$  nm). The NIR wavelengths of interest are also known as the *short wavelength IR*, or *SWIR* band. Within these visible to near-visible spectral regions, organic electronic devices fall into three classes: *photoconductors*, *photodiodes*, and *phototransistors*. The principal difference between them is that the photodiode comprises an internal junction that actively separates photogenerated excitons, while the photoconductor and phototransistor lack a junction. The latter two devices exhibit *photocurrent gain* (i.e. more than one electron is produced per incident photon) although their bandwidth is usually far lower than the photodetector that has an internal field to rapidly sweep out charge. To understand phototransistors, knowledge of transistor operation is required, and hence is treated separately in the following chapter.

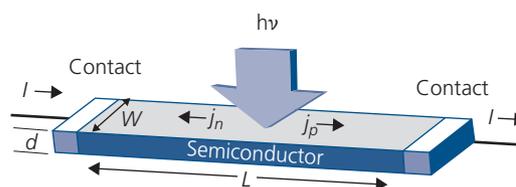

Photocurrent in organic semiconductor devices is generated by absorption of a photon of energy  $h\nu$ ,

greater than the HOMO–LUMO gap energy of the semiconductor,  $E_G$ . Here,  $h$  is Planck's constant, and  $\nu$  is the frequency of the incident radiation. While this fundamental absorption process is dominant in most devices, there can be other, lower energy sites that absorb photons with  $h\nu < E_G$ . For example, charge transfer (CT) states at the heterojunction formed between a donor and acceptor in a photodiode (Section 4.7.2), or at the semiconductor/metal contacts can add to the absorption, creating a tail that extends deep into the energy gap. We will find that CT state absorption plays a vital role in the efficiency and photodetection process at photodiode junctions.

### 7.1.1 Photoconductivity and photoconductors

#### 7.1.1.1 General considerations

A schematic illustration of an in-plane photoconductor is shown in Fig. 7.1. Photoconductivity is a

**Figure 7.1** Schematic illustration of a photoconductor showing the electron ( $j_n$ ) and hole ( $j_p$ ) current densities generated by an incident photon of energy  $h\nu$ . The current in the external circuit is  $I$ .

fundamental property of all semiconductors, and hence this property was demonstrated long before the first junction photodiodes were reported. Photoconductivity in triphenylmethane under pressure was observed in 1930 (Petrikaln, 1930), which predated the first clear identification of an organic semiconductor, violanthrone (see Chapter 1) (Akamatu and Inokuchi, 1950). The first systematic studies of photoconductivity in organics were apparently based on the small molecule rhodamine B (Nelson, 1954).

As illustrated, the photoconductor is simply a slab of semiconductor that is sandwiched between ohmic metal contacts. Light incident on the semiconductor generates excitons that dissociate into free electrons and holes. These carriers subsequently drift to opposite contacts due to a small electric field placed across the semiconductor by an externally applied voltage. The source of charge can be either via excitation across the energy gap to generate an intrinsic photocurrent, or via excitation from deep trap levels to a conduction (HOMO or LUMO) energy level. This latter process is extrinsic, in that it requires a defect or dopant that is not native to the semiconductor itself. In the following discussion we will consider only intrinsic processes, since the effects of traps can greatly complicate (and potentially obscure) the analysis of this deceptively simple process.

Rose first elegantly elucidated the general problem of photoconductivity in inorganic semiconductors (Rose, 1955a, 1955b, 1963). The conductivity of the semiconductor is

$$\sigma = q(\mu_n n + \mu_p p), \quad (7.1)$$

where  $\mu_n$  and  $\mu_p$  are the bulk electron and hole mobilities and  $n$  and  $p$  are the total densities of electrons and holes. In the presence of illumination, we have  $n = n_{ph} + n_0$  and  $p = p_{ph} + p_0$ , where  $n_{ph}$  ( $p_{ph}$ ) and  $n_0$  ( $p_0$ ) are the densities of photogenerated and background free electrons (holes), respectively. The background free charge densities are subject to the law of mass action:

$$n_0 p_0 = n_i^2, \quad (7.2)$$

where  $n_i$  is the intrinsic carrier concentration. In the absence of background doping,  $n_0 = p_0 = n_i$ . Also, conservation of charge requires that  $n_{ph} = p_{ph}$ . In an intrinsic inorganic semiconductor where excitation is simply between the valence and conduction bands, Rose asserts that "only the life time of a free carrier describes the essential performance and contains the essential physics of a photoconductor" (Rose, 1955a). Thus, we can write for the carrier generation rate,  $G_{ph}$ , under illumination:

$$G_{ph} = k_D n_{ph} = \frac{\eta_{ext}(P_{inc}\lambda/hc)}{dWL}, \quad (7.3)$$

where  $k_D = 1/\tau_D$  is the rate of photogeneration of carriers equal to the reciprocal of its lifetime,  $\tau_D$ ,  $P_{inc}$  is the incident optical power,  $c$  is the speed of light,  $d$  is the thickness of the semiconductor,  $L$  is its length, and  $W$  is its width (cf. Fig. 7.1). Also,  $\eta_{ext}$  is the *external quantum efficiency* of the photoconductor, which is equal to the total number of photons incident to the electrons generated. In Eq. 7.3 we assume that all photons are absorbed in the semiconductor, that is,  $d \gg 1/a(\lambda)$ , where  $a$  is the optical absorption length at wavelength,  $\lambda$ .

From the above, we obtain the total photocurrent density (in one dimension):

$$\begin{aligned} j_{ph} &= \sigma F = q n_{ph} (\mu_n + \mu_p) \frac{V_a}{L} \\ &= q \frac{\eta_{ext}(P_{inc}\lambda/hc)}{k_D} (\mu_n + \mu_p) \frac{V_a}{dWL^2}, \end{aligned} \quad (7.4)$$

where  $V_a$  is the voltage across the sample of length,  $L$ . Also,  $F$  is the electric field, which in a resistor is  $F = V_a/L$ . By the same reasoning, the dark current for an intrinsic semiconductor is given by

$$j_D = q n_i (\mu_n + \mu_p) \frac{V_a}{L}, \quad (7.5)$$

giving a total current of

$$j_T = j_{ph} + j_D = q(n_{ph} + n_i) (\mu_n + \mu_p) \frac{V_a}{L}. \quad (7.6)$$

The foregoing discussion is based on the premise that a photoconductor is a simple resistor, following Ohm's law in Eqs. 7.4–7.6. Barriers due to non-Ohmic contacts, traps, or morphological irregularities within the bulk of the photoconductor can result in significant deviations from the ideal case considered here. The existence of energy barriers results in the local depletion of charge, creating a deviation from the linear field approximation of  $F = V_a/L$ . In situations that exist at high voltage or intensity, or for photoconductors with poor contacts, therefore, our analysis breaks down and a model that includes extrinsic factors is required.

### 7.1.1.2 Gain and bandwidth

Returning to the photocurrent in Eq. 7.4, and defining  $j' = q\eta_{ext}(P_{inc}\lambda/hc)/dW$ , then the *photocurrent gain* is given by

$$g = \frac{j_{ph}}{j'} = \tau_D (\mu_n + \mu_p) \frac{V_a}{L^2}. \quad (7.7)$$

That is, the photoconductor has gain whereby one photon can generate more than one electron. Then, in some cases,  $g_{\eta_{EQE}} > 1$ . Indeed,  $g$  has been observed for many inorganic photoconductors to be as high as  $10^6$ .

The carrier velocity is related to mobility via  $v = \mu F$ , and since the carrier transit time is  $t_{tr,n(p)} = L/v_{n(p)} = L^2/(\mu_{n(p)}V_a)$  for electrons (holes), then it follows that

$$g = \tau_D \left( \frac{1}{t_{tr,n}} + \frac{1}{t_{tr,p}} \right). \quad (7.8)$$

Thus, we have the remarkable result that the gain is equal to the ratio of the carrier lifetime to its transit time. Indeed, if the mobility of one carrier type is substantially larger than the other, then the gain is simply the ratio of the lifetime to the transit time of that charge.

Photoconductors operate in quasi-equilibrium, that is, in the regime where the applied voltage is low enough to avoid injection of charge from contacts. Hence all regions of the device are undepleted, and conduction is strictly ohmic, as stated in in Eq. 7.4. If a charge is swept out of the sample by the applied voltage in time,  $t_{tr} < \tau_D$ , the semiconductor is forced out of equilibrium until a like charge is injected from the opposite contact. This process of charge transit followed by injection to re-establish equilibrium repeats itself until the excess charge recombines, and the sample is once more charge-neutral. During time,  $\tau_D$ ,  $g$  charges are injected following the absorption of a single photon, thus giving rise to photoconductive gain.

The time to reestablish equilibrium is  $\tau_D$ , and hence the photogenerated charge has a transient response to a light pulse following

$$n_{ph}(t) = n_{ph0} \exp(-t/\tau_D). \quad (7.9)$$

This leads to a bandwidth of  $\Delta f = 1/2\pi\tau_D$ , or a *gain-bandwidth product* of

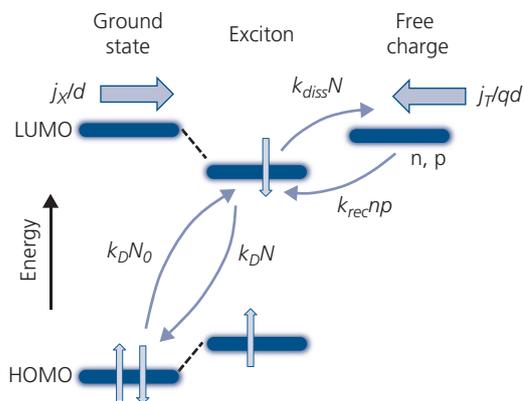

$$g\Delta f = \frac{1}{2\pi} \left( \frac{1}{t_{tr,n}} + \frac{1}{t_{tr,p}} \right), \quad (7.10)$$

which is the inverse of the transit time of the charges. The gain-bandwidth product expresses a fundamental trade-off of all photodetectors that determines its viability for a particular application. Unfortunately, photoconductors generally have a slow recovery time as well as a long transit time, leading to a small  $g\Delta f$  compared to photodiodes that operate under reverse bias.

### 7.1.1.3 Photogeneration in excitonic photoconductors

Thus far we have considered the simple case of an inorganic semiconductor device in the absence of traps. An organic photoconductor is substantially more difficult to analyze since the fundamental excitation does not directly generate free charge in the bands, but rather it proceeds via the intermediate generation of an exciton. In Chapter 4.7.2, we analyzed charge generation at an organic type II heterojunction. There, excitons drift to a donor-acceptor junction where they separate into a more loosely bound PP state that eventually dissociates into free charge. A photoconductor lacks a heterojunction, and hence the exciton must dissociate directly into free charges, an often inefficient process that lacks an energetic driving force. Of course, excitons may diffuse to a contact that can lead to efficient charge generation, or it can dissociate at a defect within the semiconductor bulk. Notwithstanding these secondary processes with their own inherent inefficiencies (i.e. the exciton may have to diffuse long distances before finding a dissociation site), organic photoconductors consequently have considerably lower efficiencies than do organic photodiodes and solar cells.

The energetics of exciton dissociation is illustrated in Fig. 7.2. This scenario shows that a photogenerated exciton current,  $j_x$ , is generated by absorption of a photon of energy  $h\nu$  greater than the HOMO-LUMO gap of the semiconductor. The exciton then can recombine at rate  $k_D$ , or it can dissociate into a free electron-hole pair at rate  $k_{diss}$ . Recombination of free electrons and holes at rate  $k_{rec}$  leads to a loss in

**Figure 7.2** Schematic of the energetics of free charge generation in an organic photoconductor. Rates are denoted by  $k$ , the exciton density is  $N$ , the free charge densities are  $n$ ,  $p$ , the total current is  $j_T$  and the exciton current is  $j_x$ . The vertical arrows indicate electrons and their spins.

the photocurrent,  $j_{ph} = j_r - j_D$ . Excitons can also be thermally generated at rate  $k_D$ . Once again ignoring complications due to recombination at traps, the steady state rate equations governing photo-generation are

$$\frac{j_{ph}}{dq} - k_{rec}(n^2 - n_i^2) + k_{diss}(N - N_0) = 0 \quad (7.11)$$

and

$$\frac{j_x}{d} - k_D(N - N_0) - k_{diss}N + k_{rec}n^2 = 0. \quad (7.12)$$

Here,  $N$  is the exciton density with value  $N_0$  at equilibrium (i.e. in the absence of illumination), and we assume that the material is undoped, that is,  $n_0 = p_0 = n_i$ . Now, when  $j_x = 0$ , then  $N = N_0$  and from Eq. 7.12 we obtain

$$\frac{k_{rec}n_i}{k_{diss}} = \frac{N_0}{n_i}, \quad (7.13)$$

which is a consequence of detailed balance.

We can define the *internal quantum efficiency* as the ratio of the number of electrons generated per photon absorbed in the device active region, which differs from  $\eta_{ext}$  by ignoring reflections from the surface or absorption in electronically inactive areas of the sample. This can be expressed as the ratio of rates:

$$\eta_{int} = \frac{k_{diss}}{k_{diss} + k_D}. \quad (7.14)$$

Then it follows that

$$\eta_{int}k_D = (1 - \eta_{int})k_{diss}. \quad (7.15)$$

Finally, as in Chapter 4, the Langevin recombination rate between free carriers is given by

$$k_{rec} = \frac{q}{\epsilon} (\mu_e + \mu_p), \quad (7.16)$$

where  $\epsilon = \epsilon_r \epsilon_0$  is the semiconductor permittivity,  $\epsilon_r$  is the relative dielectric constant, and  $\epsilon_0$  is the permittivity of free space. Using Eq. 7.5, we can replace the photocurrent with

$$j_{ph} = k_{rec}n_{ph}D, \quad (7.17)$$

where  $D = \epsilon F$  is the electric displacement field. Substituting for  $N$  by using Eq. 7.11 in Eq. 7.12 gives

$$j_{ph} = dq(1 - \eta_{int}) \left[ \frac{j_{ph}^2}{k_{rec}D^2} + \frac{2n_i j_{ph}}{D} \right] - q_{int} j_x. \quad (7.18)$$

The quadratic term in the photocurrent results from the two step recombination process via the exciton that does not exist in non-excitonic, inorganic semiconductors. This expression, unfortunately, does not

have a tidy solution. It is helpful at this point to define the recombination current as

$$j_{rec} = \frac{k_{rec}D^2}{dq(1 - \eta_{int})}, \quad (7.19)$$

which represents the reverse current due to Langevin recombination of photogenerated electrons and holes back to the bound exciton state. Then, the number of photogenerated charges from Eq. 7.18 is given by

$$n_{ph} = \frac{j_{rec}}{k_{rec}D} \left\{ 1 - \frac{2dq n_i}{D} (1 - \eta_{int}) - \left[ \left( 1 - \frac{2dq n_i}{D} (1 - \eta_{int}) \right)^2 + 4q \eta_{int} \frac{j_x}{j_{rec}} \right]^{\frac{1}{2}} \right\}. \quad (7.20)$$

For unipolar conduction in a doped semiconductor,  $n_i$  is replaced by the majority background carrier density. For example, for electrons,  $n_0 \gg n_i$ , and  $n_0$  is substituted in Eq. 7.20. For bipolar conduction, the definition of  $j_{rec}$  must be adjusted accordingly.

There are a couple of notable aspects to this otherwise ungainly expression. First, if  $\eta_{int} = 0$ , this implies that  $j_x = 0$ , in which case  $n_{ph}$  also vanishes. On the contrary, the expression is undefined as  $\eta_{int} \rightarrow 1$ , since in this limit,  $j_{rec}$  blows up. Outside of these limits, we see that  $n_{ph}$  is, to first order, linear in  $D^{-1}$  (and therefore  $L/V_a$ ) consistent with Ohm's law, although the detailed dependence of  $n_{ph}$  on  $V_a$  departs significantly from linearity as the terms in  $D^{-2}$  become large at very low electric fields. However, this only occurs when the background charge concentration,  $n_0$  is also large. Indeed, for an intrinsic semiconductor or when  $n_0$  is small, the expression to first order simplifies to

$$n_{ph} = \frac{j_{rec}}{2k_{rec}D} \left\{ 1 - \left[ 1 + 4q \eta_{int} \frac{j_x}{j_{rec}} \right]^{\frac{1}{2}} \right\} \approx q \eta_{int} \frac{j_x}{k_{rec}D}. \quad (7.21)$$

The last approximation on the right is valid at low light levels (i.e.  $j_x$  small). In this limit, the expression leads to the obvious conclusion that in the absence of a significant background charge density and recombination,  $j_{ph} \approx q \eta_{int} j_x$ .

We emphasize that the treatment assumes that the photoconductor is in equilibrium, that is, the dark current is conducted by charge native to the device, whether it be due to intrinsic thermal generation (with density  $n_i$ ), or due to extrinsic charge introduced via impurity doping (e.g. with density  $n_0$ ). As seen in Section 4.4.2, charge injection whereby  $n_0 \rightarrow n_0 + n_{inj}$ , with  $n_{inj}$  equal to the injected charge

density, results in a significant departure from ohmic conduction used in the derivation of Eq. 7.21.

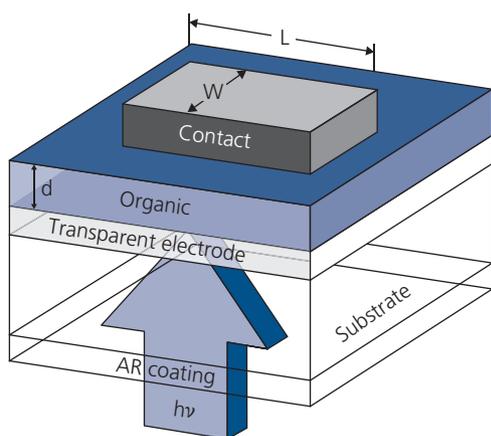

The intermediate generation of an exciton also results in a slower response to an optical impulse compared to an inorganic semiconductor since the exciton diffusion time ( $\tau_{ED}$ ) must be added to the carrier lifetime in Eq. 7.8. That is the excitonic photoconductor has a bandwidth of

$$\Delta f = \frac{1}{2\pi} \left( \frac{1}{\tau_D + \tau_{ED}} \right) \approx \frac{1}{2\pi\tau_D}, \quad (7.22)$$

where the term on the far right hand side is the expression for the bandwidth of a conventional photoconductor, since in general  $\tau_D \gg \tau_{ED}$  (i.e.  $\tau_D \sim$  microseconds, whereas  $\tau_{ED} \sim$  nanoseconds). If this inequality is not valid,  $g\Delta f$  in Eq. 7.10 must be modified accordingly.

#### 7.1.1.4 Quantum efficiency and responsivity

Equation 7.3 was used to define the external quantum efficiency in terms of the charge generation rate, assuming that all photons are absorbed within a thickness,  $d$ . This is rarely the case. Indeed, in organics, the lateral photoconductor configuration is the exception rather than the rule due to the very short exciton and charge diffusion lengths, and low charge mobilities in these inherently disordered materials. Hence, many photoconductors have a vertical geometry, that is similar to OLEDs and photodiodes (see Fig. 7.3). An *antireflection coating* (ARC) is often deposited on the light incident surface to reduce or eliminate Fresnel reflections, increasing the photon intensity arriving at the absorbing photoconductive layer. The photoconductive layer itself is sandwiched between a transparent and a reflective metal contact, and hence light undergoes two passes through the

**Figure 7.3** Schematic illustration of a vertical photoconductor.

organic layer. Note that the convention used in specifying device dimensions is different from that used in lateral geometry devices in Fig. 7.1. In the vertical geometry, the length of the photoconductor is defined by the layer thickness,  $d$ . Hence, the device area is  $LW$ , whereas in the lateral geometry it is  $dW$ .

The flux light at position  $x$  within a film follows the *Beer–Lambert law*, that is,  $\Phi(x) = \Phi_0 \exp(-a(\lambda)x)$ , where  $\Phi_0$  is the incident flux intensity. Thus, after propagating a distance  $2d$ , and ignoring losses due to reflection at the metal contact and at the dielectric boundaries within the multilayer structure, the total number of absorbed photons is

$$\begin{aligned} G_{ph} &= \frac{(1-R)(P_{inc}\lambda/hc)}{dWL} \\ &\times \left[ \int_0^{2d} \exp(-a(\lambda)x) dx / \int_0^\infty \exp(-a(\lambda)x) dx \right] \quad (7.23) \\ &= \frac{(1-R)(P_{inc}\lambda/hc)}{dWL} [1 - \exp(-2a(\lambda)d)] \end{aligned}$$

where  $R$  is the reflectivity of the incident surface. Comparing this with Eq. 7.3 gives

$$\begin{aligned} \eta_{ext}(\lambda) &= (1-R)\eta_{int}(\lambda)\eta_A(\lambda) \\ &= (1-R) \left( \frac{k_{diss}}{k_{diss} + k_D} \right) [1 - \exp(-2a(\lambda)d)], \end{aligned} \quad (7.24)$$

where  $\eta_A$  is the absorption efficiency in the active region. This expression gives the quantitative relationship between the internal and external quantum efficiencies. That is,  $\eta_{int}$  includes only those photons that reach the active semiconductor region. We emphasize that Eq. 7.24 is approximate in that it replaces the actual optical field intensity distribution within the multilayer device stack with a simple exponentially decaying flux density. However, we have seen in the previous chapters that devices as in Fig. 7.3 form weak microcavities that can substantially impact the photon distribution within the active layer. A more precise calculation of the optical field distribution and its relation to detector efficiency is found in Section 7.1.2.

A representative compilation of the absorption coefficients of the molecular donors DBP, DPSQ, and DTDCPB, and the fullerene acceptors  $C_{60}$  and  $C_{70}$  are compared to the common inorganic semiconductors, Si, Ge and GaAs, in Table 7.1. The absorption coefficients for the organics are at least one order of magnitude higher than the inorganics. In particular, the organics have  $a > 10^5 \text{ cm}^{-1}$ , compared to the indirect band gap Si and Ge with  $a = 10^2\text{--}10^3 \text{ cm}^{-1}$ , and the

**Table 7.1** Absorption coefficients ( $\alpha$ ) and refractive indexes ( $n$ ) for representative organic and inorganic photodetector materials

Material	$\lambda_{max}^a$ (nm)	$\alpha$ (cm <sup>-1</sup> )	$n^b$ (at $\lambda_{max}$ )
Si	800	$3 \times 10^2$	3.42
Ge	1300	$7 \times 10^3$	3.68
GaAs	800	$1.3 \times 10^4$	4.1
C <sub>60</sub>	345	$3.20 \times 10^5$	2.14
C <sub>70</sub>	385	$2.01 \times 10^5$	1.99
DBP	605	$2.70 \times 10^5$	2.5
DPSQ	690	$3.23 \times 10^5$	1.9
DTDCPB	590	$1.09 \times 10^5$	1.75

<sup>a</sup>  $\lambda_{max}$  for inorganic semiconductors taken at a point approximately 0.2 eV above the band edge.

<sup>b</sup>  $gn$  for inorganic semiconductors taken approximately 0.2 eV below the band edge.

direct gap GaAs at  $10^4$  cm<sup>-1</sup>. The higher absorption coefficient is due to the molecular (i.e. non-chemical bonded) nature of organics leading to high oscillator strength for  $S_1 \leftarrow S_0$  transitions. This is compared to transitions in inorganics where the oscillator strength is distributed over the high density of states within the broad energy bands. The consequence of the higher absorption coefficient is the ability to use thinner layers to absorb the incident light in an organic photodetector.

The reflectivity at the interface between two non-absorbing layers with indexes of refraction of  $n_1$  and  $n_2$  at normal incidence is

$$R = \frac{(n_1 - n_2)^2}{(n_1 + n_2)^2}. \quad (7.25)$$

The more general case of incidence as a function of angle relative to the substrate plane is discussed further in Section 7.2.2. Generally, illumination is incident from free space with  $n_1 = 1$ , and  $n_2 = n_{sub}$  is the refractive index of the substrate. Then,

$$R = \frac{(1 - n_{sub})^2}{(1 + n_{sub})^2}. \quad (7.26)$$

Equation 7.24 requires knowledge of the rates of dissociation and recombination. It is, therefore, more convenient to express the external efficiency in terms of the measured photocurrent density,  $j_{ph}$ . Then, using Eq. 7.3 it is apparent that

$$g\eta_{ext} = \frac{j_{ph}A}{q(P_{inc}\lambda/hc)}, \quad (7.27)$$

where  $A = WL$  is the sample area. This is the most common and useful expression for calculating the change generation efficiency using all easily measurable quantities without knowing the details of the detection process. However, in a photoconductor or for that matter any detector that exhibits gain, a measurement of the photocurrent does not directly provide  $\eta_{ext}$ . Rather, we can only measure the *gain-efficiency product*,  $g\eta_{ext}$ , since the total number of electrons per photon is the observable quantity.

Finally, it is useful to define the detector *responsivity*,  $\mathcal{R}$ , that is, the current generated per incident unit of optical power. From Eq. 7.27,

$$\mathcal{R} = \frac{j_{ph}A}{P_{inc}} = qg\eta_{ext} \left( \frac{\lambda}{hc} \right) [A/W]. \quad (7.28)$$

Thus, the responsivity increases with wavelength since the photodetector is essentially a photon counter. Absorption of low energy photons (corresponding to longer wavelengths) generates the same number of photons as higher energy photons as long as all the photons have energy that exceeds the energy gap. Since power decreases with increasing wavelength, the responsivity correspondingly increases.

#### 7.1.1.5 Noise, detectivity, and dynamic range

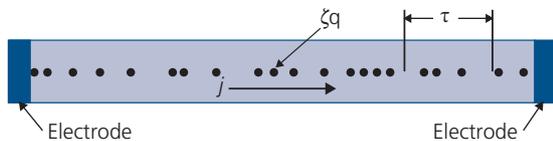

There are three principal noise sources for all detectors: *shot noise*, *thermal* (or *Johnson*) *noise*, and *1/f noise* (Rose, 1955a, 1963, van der Ziel, 1986). Noise has its origins in the uncertainty in the random arrival of charge at an electrode. The noise currents, therefore, can be determined using statistical analysis. Since the more rigorous approaches are beyond the scope of this book, here we will use a more intuitive method introduced by Albert Rose to derive the expressions for calculating noise currents in photodetectors (Rose, 1963). As we will see in Chapter 8, many of these same expressions are also used to quantify transistor noise.

The noise current is the product of the root mean square (rms) fluctuation in the average number of electrons arriving at an electrode per time interval,  $\tau$ , and the amount of charge contributed ( $\zeta q$ ) on each arrival, as illustrated in Fig. 7.4. If  $\langle n \rangle$  is the average number of charges, then the rms fluctuation is  $\langle n \rangle^{1/2}$ . Thus, the rms noise current is

$$\langle i_n^2 \rangle^{1/2} = \frac{\langle n \rangle^{1/2}}{\tau} \zeta q, \quad (7.29)$$

yielding a mean square fluctuation of

$$\langle i_n^2 \rangle = \frac{\langle n \rangle}{\tau^2} (\zeta q)^2 = \frac{q i_T \zeta}{\tau}. \quad (7.30)$$

**Figure 7.4** Illustration of charges carrying current,  $j$ , in a photoconductor arriving at an electrode. The amount of charge delivered per event is  $\zeta q$ , and the measurement interval is  $\tau$ .

Here,  $i_T = q\langle n \rangle / \tau$  is the mean total current. The time interval is related to the bandwidth,  $\Delta f$ , via  $\tau = 1/2\Delta f$ . In traversing the distance between electrodes, carriers undergo a gain,  $\zeta = g$ . This results in a mean square shot noise current of

$$\langle i_s^2 \rangle = 4qgi_T\Delta f. \quad (7.31)$$

The extra factor of 2 arises since the charges in a photoconductor can either be generated (i.e. they add to the current) or recombine (they reduce the current). However, since both are random processes, they contribute equally to the current fluctuation and hence must be included in Eq. 7.31.

The situation is somewhat different when  $V_a \rightarrow 0$ . By illuminating or heating the semiconductor, we generate charges that recombine after traveling a distance equal to their diffusion length,  $L_D$ . Then each generated charge contributes, on average,  $qL_D/L$  to the total current, where  $L$  is the length of the photoconductor in the lateral geometry in Fig. 7.1. Then, from Eq. 7.30, the total noise current in the frequency interval,  $\Delta f$ , is

$$\langle i_n^2 \rangle = 4 \frac{\langle n \rangle}{\tau} \left( q \frac{L_D}{L} \right)^2 \Delta f. \quad (7.32)$$

Again, we must include contributions from charge diffusing either toward or away from an electrode, accounting for the extra factor of 2. The diffusion length is related to the carrier lifetime via:  $L_D^2 = D\tau$ , and from the Einstein relation in thermal equilibrium,  $\frac{D}{\mu_n} = \frac{k_B T}{q}$ , we obtain

$$L_D^2 = \frac{k_B T \mu_n \tau}{q}. \quad (7.33)$$

For simplicity, we assume that the hole mobility is smaller than the electron mobility, and hence can be ignored. Substituting Eq. 7.33 into 7.32, and relating the average number of charges to their density via  $\langle n \rangle = nLA$ , then mean square thermal or Johnson noise current is

$$\langle i_{th}^2 \rangle = \frac{4k_B T \Delta f}{R_{PC}}, \quad (7.34)$$

where  $R_{PC} = L/\sigma A$  is the series resistance of the photoconductor under illumination.

It is interesting to note the voltage at which the shot and thermal noise contributions in photoconductors are equal. In the shot noise limit, the gain is  $g = \tau/t_{tr} = \tau\mu F/L$ . Recall, the thermal noise was calculated assuming  $V_a \rightarrow 0$ . In this case, the gain is  $g_0 = L_D/L$ ; that is additional carriers are drawn into the photoconductor to maintain equilibrium until the diffusing charge arrives at the contacts. In many organic photoconductors,  $g_0 < 1$ , whereas  $g > 1$ . Writing  $g_0$  in terms of the mobility, using Eq. 7.33 we obtain

$$g_0 = \frac{k_B T \mu_n \tau}{qL_D L}. \quad (7.35)$$

Setting  $g = g_0$ , then the thermal and shot noise contributions are equal at:

$$F_{diff} = \frac{k_B T}{qL_D}. \quad (7.36)$$

Here,  $F_{diff}$  is the *diffusion field*, above which shot noise dominates thermal noise. Indeed,  $F_{diff}$  is a convenient means to identify the transition between diffusion (i.e. equilibrium) and drift in a photoconductor.

Thus far we have considered a trap-free photoconductor. Both static and dynamic disorder makes this the exception rather than the rule in organic semiconductors. As a charge traverses the conductor, it can be trapped after a time,  $\tau_t$  in an energy level within the HOMO–LUMO gap, where it subsequently recombines. The lifetime of the carrier fluctuates due to randomness of the trapping process, and this in turn introduces randomness in the charge arrival time at the electrodes. Taking the example where  $\tau_t \ll \tau$ , then the gain is reduced to:  $g_t = \tau_t/t_{tr} = \tau_t\mu F/L$ , and the bandwidth becomes  $\Delta f_t = 1/2\tau_t$ . The shot noise in this instance is, from Eq. 7.30,

$$\langle i_{st}^2 \rangle = 4qg_t i_T \Delta f_t. \quad (7.37)$$

The spectral densities, that is, the noise per unit bandwidth,  $\langle i_n^2 \rangle / \Delta f$ , of both shot and thermal noise is bandwidth-independent. Thus, both of these are white noise sources. An additional and important source of noise is  $1/f$  or *flicker noise*. This is not a white noise source since its spectral density follows

$$\langle i_f^2 \rangle = \frac{\kappa \Delta f}{f^a}, \quad (7.38)$$

where  $a \geq 1$  depends on the specific nature of the noise source and  $\kappa$  is a constant. The origins of flicker noise are not as well understood as thermal or

shot noise, although it is often attributed to poor contacts or trapping at defects within the semiconductor. Its functional dependence indicates that  $1/f$  noise dominates at low frequencies, but then is overcome by white noise sources as the frequency is increased.

An illustration of the several noise contributions and their frequency domains is shown in Fig. 7.5. Note the frequency independence of the white noise sources compared to the  $1/f$  noise spectrum.

The total noise current of the photoconductor is found by adding all of the mean square currents, viz.

$$\langle i_n^2 \rangle = \langle i_s^2 \rangle + \langle i_{st}^2 \rangle + \langle i_{th}^2 \rangle + \langle i_f^2 \rangle. \quad (7.39)$$

For a time-averaged incident optical power (assuming a sinusoidal signal of frequency  $\ll \Delta f$ ) of  $\bar{P}_{inc} = P_{inc}/2$ , the time averaged signal current is, from Eq. 7.27,

$$i_{ph} = qg\eta_{ext}(\bar{P}_{inc}\lambda/hc), \quad (7.40)$$

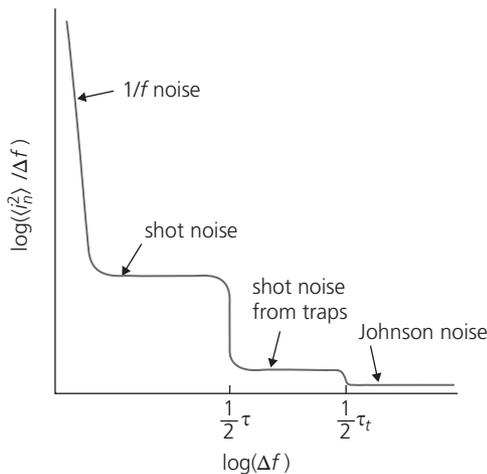

leading to a signal-to-noise power ratio (which is proportional to  $i^2$ ) of:

$$\frac{S}{N} = \frac{\langle i_{ph}^2 \rangle}{\langle i_n^2 \rangle}. \quad (7.41)$$

In Eq. 7.40 we assume a sinusoidal input power of  $P(t) = P_{inc}e^{-j\omega t}$ , where the modulation frequency is  $\omega \ll 2\pi\Delta f = 1/\tau_D$ . The noise equivalent power,  $NEP$ , is defined as the rms optical power required to achieve  $S/N = 1$  per unit bandwidth. That is,

$$NEP = \frac{\sqrt{\langle i_n^2 \rangle / \Delta f}}{\mathcal{R}}. \quad (7.42)$$

Then the detectivity is simply the inverse of the  $NEP$ , that is,

**Figure 7.5** Mean square current noise spectral density in a photoconductor.

$$D = \frac{1}{NEP}. \quad (7.43)$$

To compare devices of different areas, it is convenient to normalize  $D$  to the device area and bandwidth. For this purpose, we define use the *specific detectivity*, given by

$$D^* = \frac{\sqrt{A\Delta f}}{NEP} = \mathcal{R} \sqrt{\frac{A\Delta f}{\langle i_n^2 \rangle}}, \text{ [Jones]} \quad (7.44)$$

where the units of Jones are  $[\text{cm Hz}^{1/2}/\text{W}]$ . Then, for a trap-free photoconductor operating near  $V_a = 0$ ,  $\langle i_n^2 \rangle \approx \frac{4k_B T \Delta f}{R_{PC}} + \frac{\Delta f}{f^a}$  we obtain

$$D^* = q\eta_{ext}(\lambda/hc) \sqrt{\frac{A}{(4k_B T)/R_{PC} + \kappa/f^a}}. \quad (7.45)$$

At higher voltages, or in the presence of traps, the detectivity is dominated by thermal or trap shot noise, which all decrease with the square root of the noise current.

One final quantity defining detector performance is its *dynamic range*,  $DR$ , that is, the range over which the detector response is linear. If we assume that  $i_{ph}^{max}$  is the maximum photocurrent that can be sourced by the photoconductor before there is a noticeable departure from linear behavior (i.e.  $\eta_{ext}$  decreases from its maximum value), then the dynamic range is defined as:

$$DR = 20 \log_{10} \left( \frac{i_{ph}^{max}}{i_{ph}^{min}} \right) \text{ [dB]} \quad (7.46)$$

where  $i_{ph}^{min}$  is the minimum photocurrent that delivers the least acceptable  $S/N$ . The maximum photocurrent is sometimes defined as the point at which  $i_{ph}$  departs from its linear value by  $-1$  dB (corresponding to  $i_{ph}$ ). Often this decrease in efficiency is due to voltage drops across the contacts or other regions of the photodetector structure, which introduce a parasitic resistance,  $R_{contact}$ , in series with the photoconductive semiconductor. Then from Eq. 7.41 and assuming  $S/N > 1$ ,  $i_{ph}^{min} = \langle i_n^2 \rangle^{1/2}$ :

$$DR = 10 \log_{10} \left( \frac{i_{ph}^2}{\langle i_n^2 \rangle} \right), \quad (7.47)$$

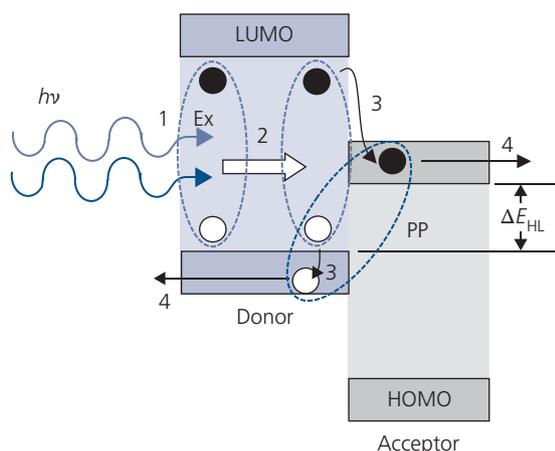

where the noise current is given by the appropriate expressions.

### 7.1.2 Photodiodes and solar cells

The primary difference between a photodiode and a photoconductor is that the photodiode has a

rectifying junction and is operated away from equilibrium due to a combination of internal and applied electric fields. We also distinguish between a photodiode operated under reverse bias and at zero bias. A reverse bias is applied to increase the charge collection efficiency beyond that attained with only the internal field due to the junction, as well as to increase the detector bandwidth by accelerating photogenerated charges toward their respective contacts. This mode of operation is known as the *photodetector mode*. Under reverse bias, the detector is a shot-noise-limited current source that can be sensitive to very small photocurrents for a small  $j_D$ . Alternatively, the detector can be operated at  $V_a = 0$ , relying only on the internal field to separate and sweep out the charges. This results in slower response and often lower efficiency, although the biasing scheme complexity is reduced from that needed to apply an external reverse bias. This is known as the *photovoltaic mode* of operation, and is universally used for photodiodes employed as solar cells (Section 7.3), but is also often used for photodetector sensor applications.

The organic photodiode (OPD) comprises a donor/acceptor (D-A) type II heterojunction (HJ) that separates a photogenerated exciton into a polaron pair, which subsequently dissociates into a free electron and hole. The multistep photogeneration process in the HJ introduced in Section 4.7.2 is illustrated in Fig. 7.6. The process is initiated by absorption of a photon in either the donor or acceptor (step 1, Fig. 7.6). The photon generates an exciton that diffuses toward the D-A junction (step 2). At

**Figure 7.6** Illustration of the photogeneration process in a D-A heterojunction. Ex = exciton, PP = polaron pair. The dashed lines indicate Coulomb binding between electrons (solid circles) and holes (open circles).

the HJ, the electron transfers from the donor to the acceptor, and the hole remains in the donor (step 3). If absorption occurs in the acceptor, the electron stays within that layer while the hole transfers to the donor. The driving force for the transfer is the offset in energies between the LUMOs and HOMOs of the two layers, whose magnitude is determined by the energy gaps and the HOMO–LUMO energy difference,  $\Delta E_{HL}$ . The new state originating from exciton dissociation is the *polaron pair*, or CT state (shown prior to relaxation in step 3). Processes 1–3 are collectively known as *photoinduced charge transfer*. Finally, the electron and hole are dissociated from the bound PP state via thermal excitation. The free polarons drift away from the junction and are collected in the external circuit (step 4).

The energy level diagram in Fig. 7.6 represents the equilibrium condition where  $V_a = 0$ . This is known as *short circuit operation*. Photodiodes are often reverse-biased to achieve both high bandwidth and high efficiency. Under reverse bias, the bands are tilted downward from left to right, thus resulting in efficient hole collection at the anode contact, and electron collection and at the cathode.

Figure 7.6 implies that internal quantum efficiency for photogeneration is the product of the efficiencies of each of the four steps:

$$\eta_{ext} = \eta_A \eta_{int} = \eta_A \eta_{ED} \eta_{CT} \eta_{CC}, \quad (7.48)$$

where  $\eta_A$  is the absorption efficiency (step 1),  $\eta_{ED}$  is the exciton diffusion efficiency (step 2),  $\eta_{CT}$  is the charge transfer efficiency (step 3), and  $\eta_{CC}$  is the charge collection efficiency (step 4). Since each of these processes has  $\eta < 1$  (particularly  $\eta_{ED}$  and  $\eta_{CT}$ ) the total efficiency can be small. We will find, however, that control of the morphology of the D-A junction that removes some of the limitations of a planar HJ illustrated in Fig. 7.6 can result in an internal efficiency that approaches unity.

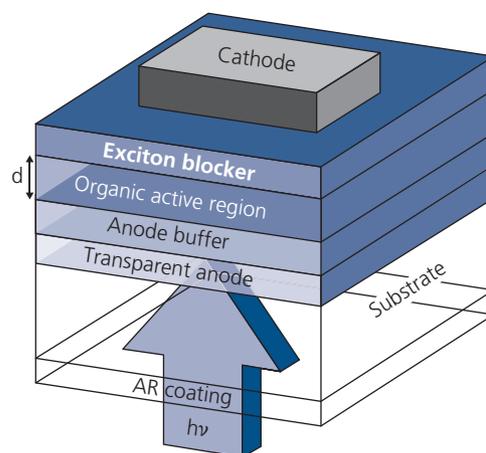

Photogeneration in organics differs from the process in inorganic semiconductors, in that the latter does not proceed via the generation and dissociation of tightly bound excitons. In inorganic semiconductors, absorption results in the direct promotion of free carriers to the conduction and valence bands that are subsequently collected at the adjacent contacts. Thus,  $\eta_{int} = \eta_A \eta_{CC}$ , thereby eliminating the two most inefficient steps required in organic detectors (i.e. it eliminates  $\eta_{ED}$  and  $\eta_{CT}$ ). Band-to-band excitation also simplifies the device structure, which does not require a HJ to provide the necessary energy for exciton dissociation.

### 7.1.2.1 Photodiode and solar cell architectures and energetics

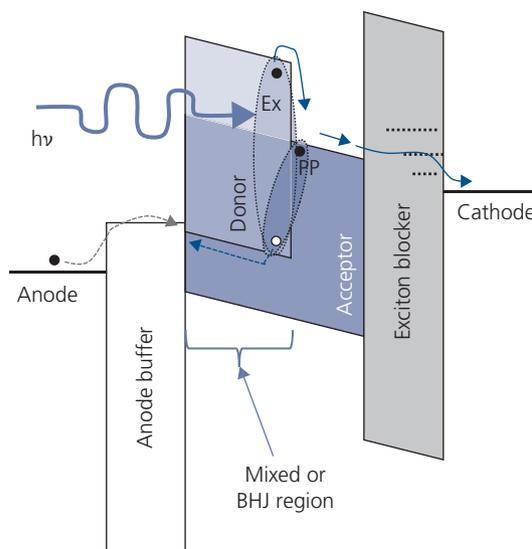

Figure 7.7 provides an archetype layering scheme of an OPD, although actual structures can be significantly more complex than illustrated. The substrate-illuminated device begins with a transparent anode, typically ITO. This is followed by a transparent anode buffer layer that reduces the barrier to charge injection. Typical materials used for this purpose are PEDOT:PSS or  $\text{MoO}_3$ . Next is the organic active region. We will find in subsequent sections that this can be a bilayer D-A HJ, a bulk HJ, or a homogeneously mixed HJ. Often neat planar layers are included in the active region along with the blended film to increase absorption and/or ensure that there are no continuous pathways for charge to transit from cathode to anode that create shorts. The active region is often capped by a transparent exciton blocking/electron conducting layer (EBL). The wide energy gap EBL has multiple purposes (Peumans and Forrest, 2001, Peumans et al., 2003b). Energy barriers formed at the LUMO and HOMO edges and its wide energy gap prevents excitons generated in the active region from diffusing to, and recombining at the cathode. It is a transparent spacer that ensures that the incident optical field is maximized within the active region. And finally, the EBL serves as a buffer that prevents damage to the active region during deposition of the metal cathode.

There are several variants to this basic design. A transparent metal oxide cathode can be employed if device transparency at wavelengths other than those absorbed in the active region is required for use as an energy-generating window, for example. Furthermore, top-illuminated detectors are enabled using a metal contact on the substrate and a transparent top contact. Top illumination is often more convenient for integration with backplane circuits and for use in modules. Also, inverted structures reverse the positions of the cathode and anode from that shown in Fig. 7.7 to improve electrode performance for some organic active layer combinations.

The energy level diagram of the notional OPD in Fig. 7.7 is shown in Fig. 7.8 to illustrate the functions of the various layers. Starting from the anode side, light is absorbed in the organic active region, in this case comprising a mixed D-A region with an additional region formed by a layer of the neat acceptor material. In fact, light can be absorbed across the entire active region although we show here only processes that arise from absorption in the mixed region itself. While this device has a conventional planar-mixed architecture used in small molecule

**Figure 7.7** Illustration of an archetype, substrate-illuminated organic photodiode.

**Figure 7.8** Energy level diagram of an archetype OPD illuminated via the anode. In this diode, the anode buffer has a deep LUMO level that promotes transport of electrons (filled circles) to the mixed D-A layer where they can recombine with photogenerated holes (open circle). The process of exciton (Ex) diffusion and polaron pair (PP) formation prior to dissociation are illustrated. Horizontal dashed lines in the exciton blocker indicate defect levels that enable electron transport to the cathode. Excitons are indicated by ovals.

OPVs, the neat acceptor region is often absent. The excitons (Ex) dissociate into polaron pairs (PPs) throughout the mixed or BHJ region, or they diffuse to the D-A junction in planar structures. The PPs then dissociate (or recombine) to generate free electron polarons in the acceptor, and hole polarons in the donor that move along continuous percolating paths in the mixed or BHJ region toward their respective electrodes.

The anode buffer is a transparent layer that is analogous to the hole injection layer in OLEDs (Section 6.1). As shown in the figure, the buffer has a very deep LUMO energy characteristic of MoO<sub>3</sub> or HAT-CN. It transports electrons from the anode contact to its interface with the donor layer where they recombine with photogenerated holes, thus “completing the circuit.” Alternatively, the buffer can have a very shallow HOMO energy that aligns with the donor HOMO. In this modality, holes are transported from the donor, through the buffer, and to the anode.

There are several different designs for the EBL that will be discussed in Section 7.4. The embodiment in Fig. 7.8 comprises a wide energy gap organic layer that results in transparency. While the wide energy gap provides for efficient blocking of excitons from reaching the cathode, it likewise confines electrons within the acceptor. Electronic defect levels (illustrated by dashed lines in the energy gap) may be generated during deposition of the cathode contact. These defects provide sites for electron hopping, thus allowing their transport to the cathode. The presence of such defects depends on the blocking material used, that is, it must be susceptible to damage inflicted by energetic metal atoms. The defects must also extend across the layer at sufficiently high densities to create low resistance conducting paths. This condition limits the thickness of the blocking layer to a range that may not be optimal to ensure that the optical field is also maximized within the active layer. Hence, several alternative blocking layer architectures have been demonstrated that do not depend on damage from the cathode. Due to the important role that EBLs play in high efficiency detection, alternative schemes to that in Fig. 7.8 are discussed in Section 7.4.1.

In contrast to photodiodes used in sensing applications that are optimized to detect a comparatively narrow spectral band, a solar cell must maximize its power output by harvesting photons generated across a broad range of the solar spectrum. Excitonic absorption linewidths are insufficiently broad to harvest sunlight across the entire visible and near IR spectra, hence both the donor and acceptor layers should be comprised of materials whose absorption bands do not entirely overlap. It is rarely the case that even two materials are sufficient to achieve optimal solar coverage that should extend over a wavelength range of at least  $400 \text{ nm} < \lambda < 1100 \text{ nm}$  (corresponding to photon energies  $1.1 \text{ eV} < E_{ph} < 3.1 \text{ eV}$ ). Furthermore, a single junction cell must absorb photons from the blue into the NIR to provide good coverage of the solar spectrum. This implies that only one, or at most two

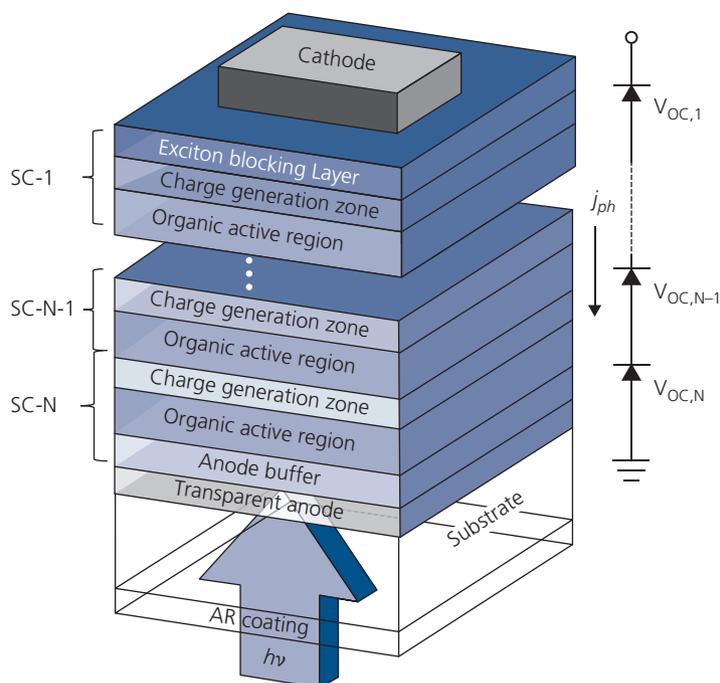

(donor and acceptor) narrow energy gap materials comprise the cell. This results in a low open circuit voltage determined by the smallest energy gaps employed. Shorter wavelength photons thermalize after absorption in the narrow gap region, thus surrendering much of their energy to heat. Thermalization losses are reduced by combining multiple cells, some absorbing at short wavelengths while others absorbing deeper into the red. For these reasons, the highest efficiency cells are configured into stacks of subcells, each comprising donor and acceptor materials that absorb in different, partially overlapping absorption bands (Hiramoto et al., 1990, Yakimov and Forrest, 2002, Peumans et al., 2003b, Ameri et al., 2009, Che et al., 2014, 2018b).

A schematic illustration of a multijunction cell is shown in Fig. 7.9. The cell consists of  $N$  subcells (SC-1 to SC- $N$ ) separated by nearly electrically and optically lossless *charge recombination zones* (CRZs). The CRZ may consist of an exciton blocking layer, a charge recombination region and an anode buffer that share an interface between the two adjacent subcells, or it may consist of only a single layer that serves all of these purposes. An equivalent circuit of the stack is also shown in Fig. 7.9. Each of the subcells is a separate, current-generating diode. If each of the CRZs is electrically lossless, then the total open circuit voltage (see the following section) is equal to the sum of the voltages across each of the subcells. The maximum output voltage is thus the sum of the individual open circuit voltages ( $V_{OC}$ ), viz.

$$V_{OC,T} = \sum_{i=1}^N V_{OC,i}. \quad (7.49)$$

In a bottom illuminated device, the top-most cell (SC-1) is known as the *back cell*, and SC- $N$  upon which the light is initially incident is the *front cell*. Since the cells are in series, the current across each of the cells must be equal. Hence, the photocurrent,  $j_{ph}$ , is limited by the subcell generating the lowest photocurrent. By convention, in the photovoltaic mode, the photocurrent is positive.

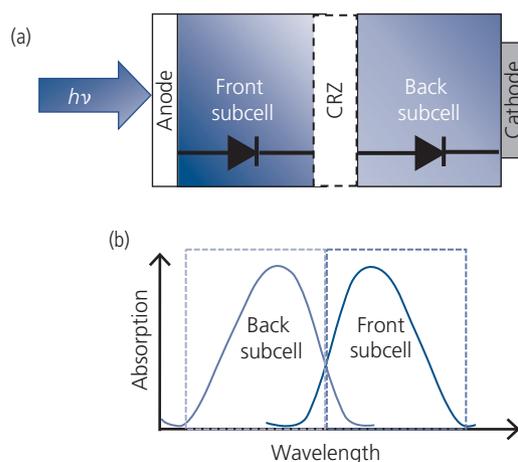

The CRZs must be transparent such that the light arriving via the substrate (or via transparent contact in a top illuminated device) is not absorbed before arriving at one of the subcells. The purpose of the CRZ is to provide sites for charge recombination between each of the cells. For the example in Fig. 7.9, a photon absorbed in SC- $N$  results in a hole collected at the anode and an electron that drifts toward the CRZ separating this subcell from SC- $(N-1)$ . Similarly, the hole generated in SC- $(N-1)$  drifts

**Figure 7.9** Schematic illustration of an archetype, multijunction photodiode or solar cell. Its equivalent circuit is shown on the right, with  $j_{ph}$  the photocurrent and  $V_{OC,i}$  the open circuit voltage of the  $i$ th subcell (SC- $i$ ).

toward that same CRZ whereas its electron drifts toward the next subcell (SC-( $N-2$ )) in the stack. The electron and hole arriving at the CRZ between the two lower subcells recombine without loss within this layer. This is analogous to charge generation layers (CGLs) used in stacked OLEDs. Their different nomenclatures suggest that the opposite processes occur in these two types of zones found between stacked elements, yet in fact their operating principles are essentially identical.

The spectral separation in a dual junction (tandem) solar cell is shown in Fig. 7.10a. This arrangement places the long wavelength absorbing subcell adjacent to the anode, and the short wavelength subcell nearest to the cathode. In Section 7.1.2, we show that this is the optimal arrangement for multijunction organic cells since the intensity of short wavelength illumination is highest near the reflecting cathode, where there is a node in the standing wave amplitude. This is similar to inorganic cells where the high-energy absorbing cell is placed in the front cell position. The onset of absorption in an inorganic semiconductor is at the gap energy, but due to their very broad bands, absorption extends deep into the blue from the longest wavelength onset. Hence, a narrow band gap, red absorbing subcell must be placed at the back position, otherwise it blocks the higher energy photons from being absorbed in a

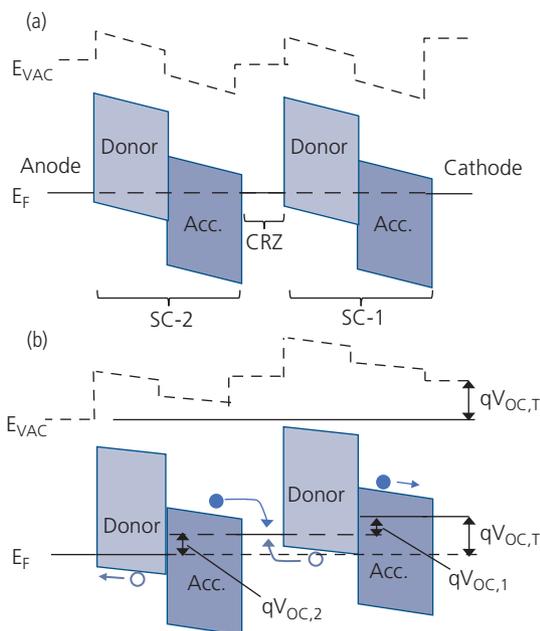

**Figure 7.10** Each subcell in a multijunction OPV absorbs a different part of the solar spectrum. (a) A schematic illustration of a tandem cell with a red absorbing front subcell and a blue-green absorbing back subcell. (b) The excitonic absorption spectra are sufficiently narrow to only harvest photons over a limited spectral range.

short wavelength (large band gap) absorbing cell placed behind it.

In contrast, organic excitonic absorption bands are relatively narrow, as illustrated in Fig. 7.10b. Hence, the subcells do not require this same ordering of absorption bands, giving an increased flexibility in

cell design. The ordering of organic absorbing cells can thus be optimized to maximize absorption of specific wavelengths, depending on the field profile within the multilayer stack without being overly concerned about whether light from a front cell will be blocked from the cell behind it (see Section 7.1.2). Of course, this assumes that the absorption spectra of the various subcells do not significantly overlap, as is the case for the cell in Fig. 7.10.

Energy level diagrams for a series-stacked tandem photodiode in equilibrium and under illumination are shown in Figs. 7.11a and b, respectively (the anode buffer and exciton blocking layers are omitted for clarity). The recombination of photogenerated electrons and holes within the CRZ is illustrated in Fig. 7.11b. The CRZ itself may be a thin, semitransparent metal such as Ag, or a transparent metal oxide such as MoO<sub>3</sub> or ZnO with a large electron affinity. The composition of this and other layers are discussed further in Section 7.4. Without the CRZ, the electrons and holes build up at the D-A interface between SC-1 and SC-2. This results in a potential that tilts the bands to reduce  $V_{OC,T}$  back towards its equilibrium value of  $V_{OC,T} = 0$ , at which point the device no longer conducts. Note that the energy level diagrams imply a planar cell architecture. That is, the donor and acceptor layers are continuous layers meeting at a single, flat

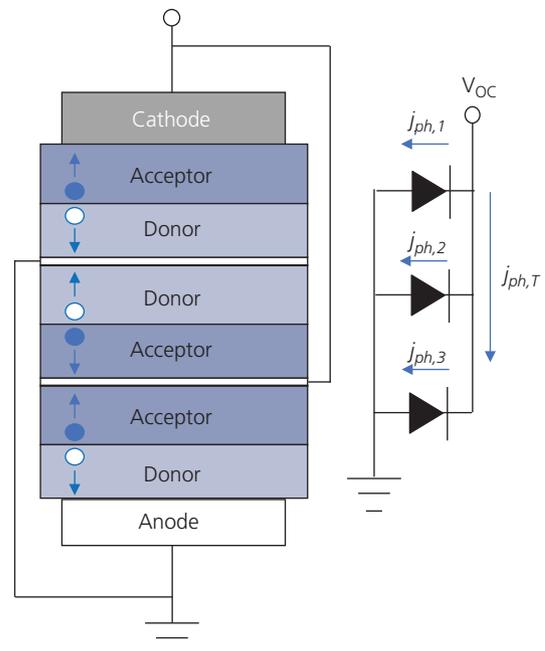

**Figure 7.11** Energy level diagrams of a tandem OPV cell in (a) equilibrium and (b) under illumination. For simplicity, the presence of dipoles at organic interfaces is ignored. Electrons are shown as closed circles, and holes as open circles.

interface. However, interdigitated, mixed, and bulk HJs all share the same energetics as illustrated here, since the donor and acceptor components in these mixed morphologies still contact the anode and cathode, respectively (see Section 7.1.2.3).

Finally, it is worth mentioning that the series connected stack, while being the most frequently implemented, is not the only possible architecture. The requirement for balanced charge generation in all the subcells can be removed by connecting the subcells in parallel, as shown in Fig. 7.12. The disadvantages of this device are twofold. First, parallel connection requires contact to the transparent, low resistance electrodes between each subcell in the stack. The electrodes no longer serve as recombination zones since charges of similar sign are incident on both electrode surfaces. In practice, it is difficult to simultaneously achieve very low resistance and optically lossless contacts in a thin film between the active organics. Fabricating devices with transparent electrodes on separate substrates and then mechanically sandwiching the devices together is one route to obtain contacts to interior electrodes. In addition, the two different substrates can form the base and lid of a package if the entire unit is sealed around its periphery.

The second disadvantage of the parallel configuration is that the voltage at the output is equal to

**Figure 7.12** Schematic illustration and equivalent circuit of a parallel connected stacked photodiode or photovoltaic cell. Electrons are closed circles, holes are open circles. The total photocurrent,  $j_{ph,T}$ , is the sum of the separate photocurrents,  $j_{ph,i}$ , generated in the several subcells.

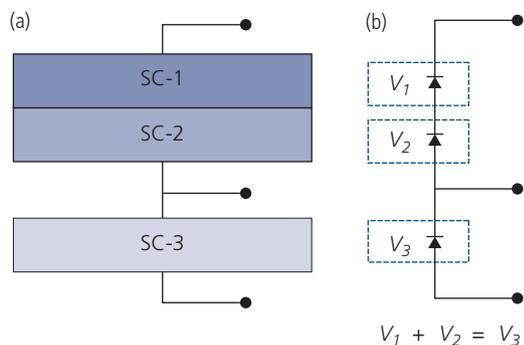

the minimum of all the voltages of the constituent subcells, and the photocurrent is the sum of the photocurrents from each of the cells (see the equivalent circuit in Fig. 7.12) following

$$j_{ph,T} = \sum_{i=1}^N j_{ph,i}. \quad (7.50)$$

As a result, the cell is a high current/low voltage element. This combination is susceptible to efficiency loss due to its internal series resistance—an effect that is minimized in the series stack in Fig. 7.9.

Hybrid combinations of series and parallel cells may ultimately provide the highest efficiency along with a reduced need for perfect current or voltage balance. For example, two low  $V_{OC}$  (i.e. long wavelength) cells can be stacked in series, and then connected in parallel to a high  $V_{OC}$  cell that absorbs at shorter wavelengths (see Fig. 7.13a). If the sum of the two low voltage cells is approximately equal to that of the high voltage cell, the voltage loss, which is the difference between the voltage generated by the single junction and the series double junction cell, can be minimized as shown by the equivalent circuit in Fig. 7.13b.

The series tandem can be fabricated on one transparent substrate (e.g. glass) in a conventional bottom illuminated, transparent top contact configuration, while the short wavelength device is fabricated in a top-illuminated configuration on a second substrate, which can either be transparent or opaque. The contacts from both are brought to the substrate edges and separately accessed after the substrates are bonded to form a sealed package. An illustration of the assembly procedure of the two substrates and their associated OPVs into a single, sealed package is shown in Fig. 7.14.

**Figure 7.13** (a) Series-parallel OPV schematic structure and (b) equivalent circuit.

### 7.1.2.2 $j$ - $V$ characteristics in the dark and under illumination

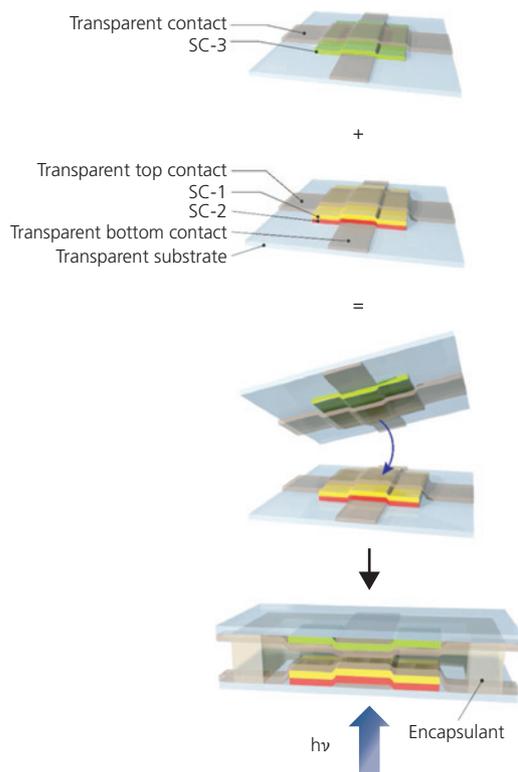

In Section 4.7.2, we used a theory based on PP production mediated by excitons to derive the current in an organic HJ in the absence of traps (Giebink et al., 2010b). This analysis showed that the  $j$ - $V$  characteristics were similar, but not identical to the Shockley ideal diode equation, viz. (see Eq. 4.282)

$$j = j_{0s} \left[ \exp\left(\frac{q(V_a - jAR_{ser})}{k_B T}\right) - \frac{k_{PPd}}{k_{PPd,eq}} \right] - j_{ph}, \quad (7.51)$$

where

$$j_{0s} = qa_0 k_{rec} N_{HOMO} N_{LUMO} (1 - \eta_{PPd}) \exp(-\Delta E_{HL}/k_B T) \quad (7.52)$$

is the saturation current density,  $a_0$  is the PP radius calculated using the Bohr model of the hydrogen atom and the dielectric constants of the contacting D and A materials,  $N_{HOMO}$  and  $N_{LUMO}$  are the densities of states of the corresponding frontier orbitals,

**Figure 7.14** Illustration of the assembly of OPVs on separate substrates into a single, packaged device. From top: The single and double junction cells are separately fabricated, assembled face to face and then encapsulated to seal the devices from the environment.

and  $k_{PPd}$  and  $k_{PPd,eq}$  are the PP dissociation rates at voltages  $V_a$  and 0, respectively. These rates are analogous to  $k_{diss}$  for the photoconductor in Fig. 7.2 (cf. Fig. 4.103). Also included is the series resistance,  $R_{ser}$ , which combines contact and internal layer resistances into a single quantity. The voltage drop across this resistance is  $V_{ser} = jAR_{ser}$ . Finally,

$$\eta_{PPd} = \frac{k_{PPd}}{k_{PPd} + k_{PPr}} \quad (7.53)$$

is the PP dissociation efficiency, where  $k_{PPr}$  is the rate of recombination of PPs. Hence, the photocurrent is  $j_{ph} = q\eta_{PPd}j_X$ , again analogous to the process in Fig. 7.2. In the more common situation where traps are present, we have shown that (Eq. 4.314):

$$j = j_{0D} \left[ \exp(q(V_a - jAR_{ser})/n_D k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right] + j_{0A} \left[ \exp(q(V_a - jAR_{ser})/n_A k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right] - j_{ph}, \quad (7.54)$$

where  $j_{0D}$  and  $j_{0A}$  are the saturation current densities due to traps on the donor and acceptor sides of the HJ, respectively (and hence depend on the respective trapped charge densities, among other factors found in Eq. 7.52), and  $n_D$  and  $n_A$  are the ideality factors, that define the voltage division between the donor and acceptor sides of the HJ. For  $n_D, n_A \sim 1$ , diffusion in the absence of traps is the dominant recombination process, and when  $n_D, n_A \geq 2$ , recombination via traps on the donor or acceptor side of the HJ is present.

For simplicity, we can assume that the HJ is approximately symmetrical, in that the density of trap states is equal on both the donor and acceptor sides, and that  $N_S = \sqrt{N_{LUMO}N_{HOMO}}$  is the joint density of states. It is straightforward to show for this case that there is only a single ideality factor,  $n_S = n_A = n_D$ . Then Eqs. 7.51 and 7.54 reduce to (Giebinski et al., 2010b)

$$j = j_0 \left[ \exp(q(V_a - jAR_{ser})/n_S k_B T) - \frac{k_{PPd}}{k_{PPd,eq}} \right] - j_{ph} \quad (7.55)$$

and the saturation current becomes

$$j_0 = qa_0 k_{rec} N_S^2 (1 - \eta_{PPd}) \exp(-\Delta E_{HL}/k_B T). \quad (7.56)$$

In addition to the series resistance, shunts across the junction must be included. The leakage through the shunt adds to  $j_0$ , and is accounted for by adding

a parallel resistance,  $R_{shunt}$ . The equivalent circuit for an OPD or OPV containing all the circuit elements that serve as proxies to describe numerous complex physical phenomena is shown in Fig. 7.15. Including  $R_{shunt}$  into the “master equation” Eq. 7.55 then gives

$$j = j_0 \left[ \exp(q(V_a - jAR_{ser})/n_S k_B T) - \frac{k_{PPd}}{k_{PPd,eq}} \right] + \frac{V_a - jAR_{ser}}{R_{shunt}} - j_{ph} \quad (7.57)$$

The  $j$ - $V$  characteristics of an archetype photodiode are shown in Fig. 7.16, which are similar to those shown on a semi-log scale in Fig. 4.113. The linear scale is helpful in revealing several parameters useful to understanding photodetector operation. The photodetector and photovoltaic modes correspond to the characteristics in the third and fourth quadrants, respectively. A photodetector used in the photovoltaic mode at  $V_a = 0$  V yields the detector short circuit current,  $j_{SC}$ . Solar cells, however, are operated at the

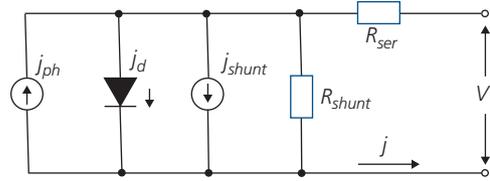

Figure 7.15 Equivalent circuit for an organic photodiode.

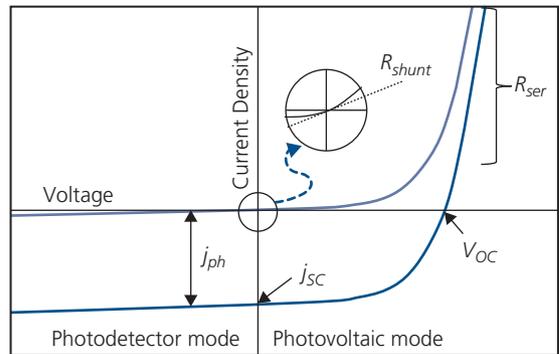

Figure 7.16 Current-voltage characteristics of an organic HJ diode in the dark (light blue line) and under illumination (dark blue line), generating a photocurrent density,  $j_{ph}$ .  $R_{shunt}$  is the shunt resistance determined by the slope of the  $j$ - $V$  curve at  $V_a = 0$  V, which is magnified in the inset. Also shown are the open circuit voltage ( $V_{OC}$ ) and the short circuit current density ( $j_{SC}$ ). The region dominated by series resistance is in the first quadrant. The photodetector and photovoltaic modes of operation are indicated.

maximum power generation point, which is intermediate between  $V_a = 0\text{V}$  and  $V_{OC}$ .

At low forward bias, the current increases exponentially with  $V_a$  with exponential slope equal to  $q/n_S k_B T$ . While Eq. 7.54 predicts two slopes since in general,  $n_A \neq n_D$ , it is also true that only one trapping process will dominate at, and be observable in a linear plot such as Fig. 7.16. As forward bias is increased,  $V_{ser}$ , the voltage drop across the series resistance, becomes significant and the slope of the  $j$ - $V$  characteristic is linear, following Ohm's law determined by  $R_{ser}$ .

Under reverse bias, the dark current increases slowly with  $V_a$  due to increased PP ionization where,  $k_{ppd}(V_a) > k_{ppd}(0) = k_{ppd0}$  as approximated by Onsager-Braun theory (Eq. 4.305). As we will find in Sec. 7.2, other factors such as generation-recombination of charge and photoconductivity can also contribute to the slope in reverse bias. At large reverse bias, the slope increases at a greater rate than shown in Fig. 7.16. This is the region of *junction breakdown*. Breakdown can have several sources, including *tunneling* of charge at high fields across the HJ, *avalanche breakdown* due to *impact ionization* of high energy carriers with valence electrons on the molecules in the layers, *microplasmas*, and *thermal runaway* (Sze, 1981). Whereas tunneling and avalanche breakdown may be reversible (i.e. the  $j$ - $V$  characteristic at lower voltage is recovered without hysteresis), microplasmas and thermal effects permanently damage the junction. Furthermore, due to the low charge mobilities, it is unlikely that impact ionization leading to carrier multiplication (and hence photocurrent gain) can occur in OPDs. Hence, the most prevalent causes of breakdown under reverse bias are thermal effects or shorting via microplasmas. Tunneling breakdown may also occur in some situations, although it is rare given the relatively small extent of the electron wavefunctions in molecular solids. Tunneling breakdown is characterized by an approximately exponential increase in dark current with voltage, and only a minor dependence on temperature (Sze, 1981).

The slope of the  $j$ - $V$  characteristic at  $V_a = 0$  gives the shunt resistance:

$$R_{shunt} = \left. \frac{1}{A} \frac{dV_a}{dj} \right|_{V_a=0}, \quad (7.58)$$

illustrated by the diagonal line in the inset. The shunt resistance is a function of charge leakage around the junction, and is important in devices that are operated near 0 V. For the trap free D-A HJ (corresponding to  $n_S = 1$ ), and ignoring the small voltage dependence of  $k_{ppd}$  as  $V_a \rightarrow 0$  (Braun, 1984, Peumans and Forrest, 2004, Giebink et al., 2010b), then from Eq. 7.55,

$$R_{shunt} = R_{ser} + \frac{k_B T}{qA} \left( \frac{1}{j + j_0 + j_{ph}} \right). \quad (7.59)$$

That is, at  $V_a = 0$  and in the dark, the shunt resistance is simply equal to the series plus the *thermal resistance*,  $R_{th} = k_B T / (qA j_0)$ . This latter term is due to recombination across the HJ. For a one-sided junction (i.e. where either  $j_{0D}$  or  $j_{0A}$  dominates), the thermal resistance is increased by the ideality factor,  $n_D$  or  $n_A$ . Under illumination, the shunt resistance increases to  $R_{th} = k_B T / qA(j_0 + j_{ph})$ . There are often parasitic resistances that can contribute to  $R_{shunt}$ . For example, defects at the rectifying HJ can result in leakage that is not accounted for by the ideal expressions for  $j$  vs.  $V$ . The shunt resistance in this case is found by combining the current through the parasitic resistance,  $R_p$ , in parallel with the expression in Eq. 7.55. Indeed, in such situations, it is not uncommon for  $R_p \ll R_{ser} + R_{th}$ . Thus,  $R_{shunt}$  and its deviation from the ideal Eq. 7.59 is used to diagnose the quality of the rectifying junction.

Under illumination, the  $j$ - $V$  characteristics undergo a nearly rigid shift by an amount equal to  $-j_{ph}$ . The curve crosses the  $j = 0$  axis at the open circuit voltage,  $V_{OC}$ , and at  $V_a = 0$  the short circuit current is  $j_{SC} = j_{ph}$ . According to Eq. 7.6,  $j_{ph} = j_T - j_0$  (here we replace  $j_D$  with  $j_0$  from the diode equation). The photocurrent contribution to the  $j$ - $V$  characteristics is indicated in Fig. 7.16. We show below that application of reverse bias can result in an increase in  $j_{ph}$  that is larger than the increase in  $j_0$  due to contributions from  $\eta_{CC}(V)$ , since a large applied voltage can efficiently sweep out photo-generated electrons and holes before they recombine.

### 7.1.2.3 Active region morphologies

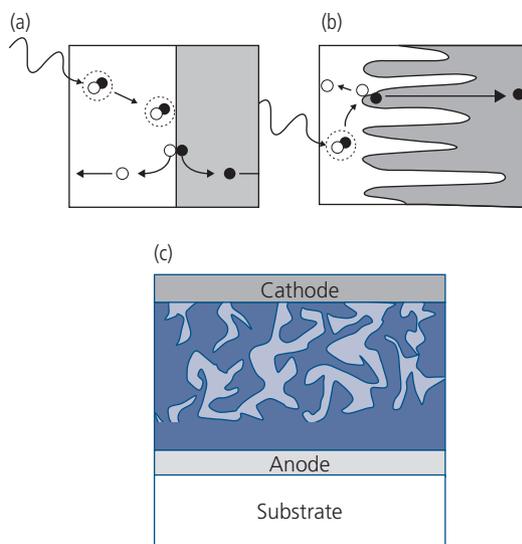

Up until this point, we considered only a simple photoactive region consisting of the donor layer in contact with the acceptor to form a planar interface. However, in both OPDs and OPVs, considerably higher efficiencies are achieved using irregular or interdigitated interfaces presenting a large area for exciton dissociation.

Photogeneration occurs in both the acceptor and donor regions, within a depletion region of width  $w_T$ , and in the undepleted regions lying remote from the HJ. However, we have shown in Chapter 4 that unless they are intentionally doped, organic materials have few background charges, in which case the active region is fully depleted. There are three principal morphologies employed in organic detectors that maximize efficiency and bandwidth. They are the planar heterojunction that was discussed in reference to Fig. 7.6, the random *bulk heterojunction* (BHJ), and the more ordered *controlled BHJ*. An illustrative

comparison between the planar and BHJ architectures is shown in Fig. 7.17.

In the planar junction, light may be absorbed at distances much larger than  $L_D$  from the point of dissociation. This leads to a trade-off between  $\eta_{ED}$  and  $\eta_A$  in Eq. 7.48 since  $a \ll 1/L_D$ . Therefore, efficient detectors employ a morphology where the D and A regions form an interdigitated junction with a large surface area that completely fills the active region volume (Halls et al., 1995, Yu et al., 1995). This is the BHJ architecture in Figs. 7.17b and c that was originally inspired by the large area junction of a *dye sensitized solar cell* (DSSC). In a DSSC, a rough  $\text{TiO}_2$  surface is coated with a sensitizing dye, and the entire structure is immersed in an electrolyte (O'Regan and Grätzel, 1991). The large area of the  $\text{TiO}_2$  surface enables the efficient harvesting of photons without creating resistive bottlenecks to charge generated at the sensitizer/ $\text{TiO}_2$  interface.

The idealized BHJ in Fig. 7.17b shows a perfectly ordered, interdigitated network of A and D materials. The network optimizes the photodetector by orthogonalizing the directions for light absorption and exciton diffusion. That is, light is absorbed along the direction parallel to the interdigitation which can extend for distances  $\gg 1/a$ . However, the width of the fingers should be  $\leq L_D$  to assure that excitons reach a

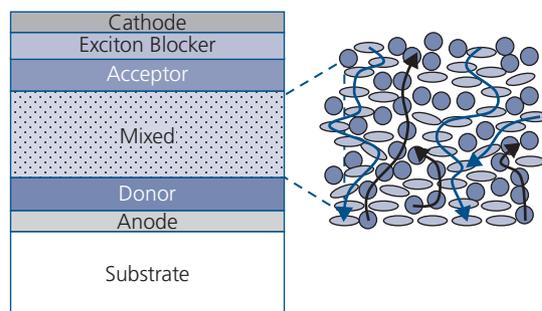

**Figure 7.17** Illustration of photodetection in an idealized (a) planar and (b) bulk heterojunction (BHJ) diode. The acceptor regions are shaded. Holes are represented by open circles, electrons by filled circles, excitons are shown by dotted circles, and the D-A junction is the boundary with the shaded region. (c) A BHJ diode with blended donor and acceptor regions forming a random network. The acceptor regions are in light blue. The neat, donor region (dark blue) adjacent to the anode prevents shorting of the acceptor from cathode to anode.

heterointerface where they dissociate prior to their recombination. This geometric optimization breaks the fundamental trade-off between  $\eta_{ED}$  and  $\eta_A$ , allowing both to simultaneously approach unity.

Achieving the ideal, interdigitated BHJ with the appropriate dimensions requires nanometer control of the morphology. In Section 5.4.2, we showed that management of strain via organic vapor phase deposition (OVPD) of a CuPc/PTCBI HJ achieved this precisely controlled structure (Yang et al., 2005a). The resulting solar cell comprised 35 nm long by 30 nm wide nanocrystalline pillars of CuPc covered by blanket deposition of the PTCBI acceptor. These dimensions are close to the exciton diffusion length in the CuPc. The growth of the BHJ with this precise geometric and morphological control led to an approximately 2.5-fold increase in the OPV cell quantum efficiency compared to that of an analogous planar HJ made from these same materials.

Conventionally, BHJ structures are obtained by blending two, partially miscible polymers in a solution (Yu et al., 1995). This forms a thermodynamically driven, random D-A network shown in Fig. 7.17c. While the blend provides a large surface area junction, it contains numerous defects such as islands of one material, or *cul de sacs* that prevent charge extraction to the electrodes. A layer of the unblended donor (next to the anode) or acceptor (adjacent to the cathode) is required to prevent shorting by direct bridging by one or both of these materials across the entire active volume of the device. The BHJ shown in Fig. 7.17c features a zone of neat acceptor near to the anode.

Many variations on the BHJ morphology have been demonstrated in both polymer and small molecular weight materials systems. A notable and successful variant is the mixed HJ, or the *planar-mixed HJ* (PM-HJ) shown schematically in Fig. 7.18 (Uchida et al.,

**Figure 7.18** Illustration of the planar-mixed HJ (PM-HJ) structure. The mixed region is shown in detail on the right, where the acceptor molecules are dark, shaded circles and the donor molecules are light, open ellipses. Percolating pathways for electrons (black lines) and holes (blue lines) are shown.

2004, Xue et al., 2005). This small-molecule-based device comprises a region with a blend of donor and acceptor molecules deposited via co-deposition in vacuum or OVPD. The mixed layer is sandwiched between neat, planar layers of donor molecules adjacent to the anode, and a neat acceptor adjacent to a transparent and electron conducting/exciton blocking layer (see Section 7.4.1). A structural variant employs one or sometimes even no neat layers. Excitons in the mixed layer are generated on either a donor or acceptor molecule. The exciton rapidly dissociates into a PP since acceptor and donor molecules are in contact everywhere within the mixture. This is an improvement over the BHJ since there is neither need, nor opportunity for exciton diffusion over even short distances. This leads to  $\eta_{ED} = 1$  for the PM-HJ.

While exciton dissociation occurs with unity efficiency in the mixed region, there remains two losses that must be overcome. The first is due to absorption in the neat, planar layers. The excitons generated in the donor and acceptor slabs surrounding the blend must diffuse to the mixed region to undergo dissociation. While the neat layers increase the optical path length and hence the number of excitons generated, as well as preventing shorts from forming between the cathode and anode by the mixed layer, they should be kept at thicknesses  $< L_D$  to minimize exciton recombination. The second requirement is that percolating pathways for electron and hole conduction on the acceptor and donor molecules, respectively, must exist within the mixed layer to ensure that the charges do not recombine prior to collection. If conducting paths from the excitonic point of origin to a charge-collecting electrode are incomplete, charge will build up until the potential within the mixed layer that opposes the external bias is sufficiently large to shut off further charge collection. This is controlled by the morphology the blend, and the ratio of the particular donor and acceptor molecules used. Further, their steric and electrostatic characteristics must be considered in choosing the deposition and other processes used in their fabrication to ensure that *bicontinuous*, low resistance pathways for charge conduction are formed.

The disruption of the conductive pathways, and the disorder induced by the close proximity of donor and acceptor molecules, results in a reduced charge mobility compared with that in neat layers of the same materials. To quantify the conductive properties of the blend, we define the *carrier drift length*,  $l = \mu\tau F$  as the distance a charge can travel before recombination. Here,  $\tau$  is the carrier lifetime. A high charge collection

efficiency,  $\eta_{CC}$ , requires that  $l$  be comparable to, or less than the mixed-layer thickness. Charge transport in the homogeneous layers is considered to be lossless since photogenerated holes and electrons are spatially separated, except when  $V_a$  approaches the built-in junction potential. The collection efficiency can therefore be written (Xue et al., 2005)

$$\eta_{CC} = \frac{L_C}{x_M} (1 - \exp(-x_M/L_C)), \quad (7.60)$$

where the charge collection length,  $L_C$ , is the sum of the hole and electron drift lengths prior to recombination, and  $x_M$  is the thickness of the mixed layer (Crandall, 1983). From this expression we find that  $\eta_{CC} = 1$  for  $x_M \ll L_C$ , and  $\eta_{CC} = L_C/x_M$  for  $x_M \gg L_C$ , suggesting that the mixed layer should be thinner than the collection length to obtain a high efficiency. Furthermore,  $\eta_{CC}$  is a function of the applied voltage through the field dependence of  $L_C$ :

$$L_C = \left( \tau_{Dp}\mu_p + \tau_{Dn}\mu_n \right) (V_a - V_{bi})/x_T, \quad (7.61)$$

where  $\tau_{Dp}$  and  $\tau_{Dn}$  are the hole and electron lifetimes within the mixed layer, and  $x_T$  is the thickness of all layers between the anode and cathode contacts. Hence,  $\eta_{CC}$  increases with the applied voltage, which efficiently separates charges immediately upon their photogeneration. To take full advantage of the mixed molecular HJ structure, it is important to have high carrier mobilities in a thin mixed layer such that  $L_C$  is comparable to the optical absorption length.

It should be apparent that the morphologies of the absorbing regions of planar, BHJ and PM-HJ devices are determining factors in the detector efficiency. Ordered and interconnected regions lead to higher charge mobilities and longer diffusion lengths, increasing both  $\eta_{ED}$  and  $\eta_{CC}$ , and hence  $\eta_{ext}$  in the photodiode. For this reason, considerable effort has been directed towards controlling the film morphologies in organic photodetectors. This topic is discussed further below.

#### 7.1.2.4 Bandwidth

The energy level diagram of a generalized symmetric, p-intrinsic (i)-n excitonic HJ under reverse bias is shown in Fig. 7.19. Photons can be incident from either the right or the left, depending on which of the contacts is transparent. For the purpose of this discussion, we assume that light is incident via a transparent anode contact on the donor, and that the junction is at  $x = 0$ . Absorption occurs in both the donor and acceptor, generating carriers across the entire device active region, depending on the local flux density,

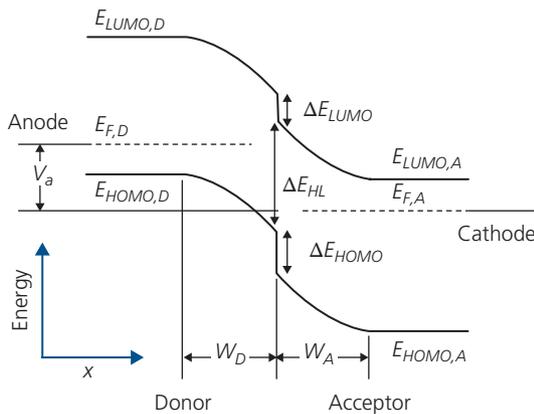

$\Phi(x, \lambda)$ . There is minimal charge recombination within the depletion region following exciton dissociation since electrons and holes are rapidly swept to the contacts by the applied and internal fields (resulting from  $V_a$  and the built-in voltage,  $V_{bi}$ , respectively). Hence, unlike a photoconductor, a photodiode has a gain,  $g = 1$ .

The response time of the photodiode is limited by four factors: (i) the time for exciton diffusion from the point of generation to the HJ,  $\tau_{ED}$ , (ii) charge drift time across the depletion region of total width  $w_T = w_D + w_A$ , (iii) charge diffusion time through the undepleted regions of the detector at  $w_A < x < -w_D$ , and (iv) the time required to charge the device capacitance,  $C_j$ .

Charges within the depletion region drift in the junction field resulting in a transit time,  $t_{tr} = t_{tr,n} + t_{tr,p}$ , where the electron and hole transit times ( $t_{tr,n}$  and  $t_{tr,p}$ , respectively) depend on the electric field and the charge mobilities in the acceptor and donor layers. These times are typically less than the diffusion time,  $\tau_{ED}$ . The rate at which charges diffuse through undepleted regions of the photodiode depends on their diffusion constants. The undepleted region transit time ( $t_{tr,un}$ ) also depends on whether or not there is a drift component to the transit time equal to

$$t_{tr,unp} = (x_D - w_D)^2 / (\mu_p \delta V_a) \quad (7.62)$$

for the example of hole drift in the donor. Here,  $\delta V_a$  is the residual voltage across the undepleted layer, and  $x_D$  is the total donor layer thickness. A similar expression obtains for electrons in the undepleted acceptor region. It is also apparent that the drift time depends on the total layer thicknesses,  $x_D$  or  $x_A$ . For very thick layers, with  $w_T \ll x_D + x_A$ , we would expect

**Figure 7.19** Energy level diagram of a D-A HJ detector under reverse bias ( $V_a$ ), defining energies and dimensions.

$t_{tr} < t_{tr,unp} + t_{tr,unr}$ , in which case the device will behave more like a photoconductor than a photodiode. It will exhibit photoconductive gain, whose bandwidth depends on the minority carrier lifetime. This device design is clearly undesirable, and hence will not be considered further. Hence, we assume there is little background charge as is typical of most OPDs, such that the undepleted regions are much thinner than  $w_T$ . Then, the time for charge transport across the undepleted zones of the detector is less than either  $t_{tr}$  or  $\tau_{ED}$ , and can be neglected.

Charging of the junction capacitance,  $C_j$ , places a further time constraint on detector response. Here,  $C_j$  is the series capacitance of the two depleted regions:

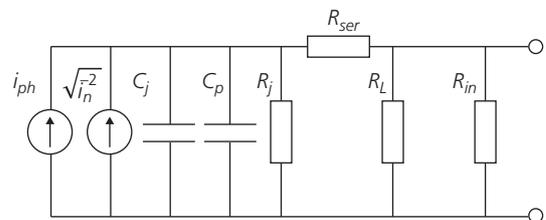

$$C_j = \frac{C_D C_A}{C_D + C_A} = \epsilon_0 A \frac{\epsilon_D \epsilon_A}{(w_A \epsilon_D + w_D \epsilon_A)}. \quad (7.63)$$

This is in addition to the parasitic capacitances from the contact and other peripheral contributing capacitances,  $C_p$ , to give the total device capacitance of  $C_T = C_j + C_p$ . Since achieving a short response time requires thin layers, and  $w_T \rightarrow x_D + x_A$ , then in most situations  $C_T \approx C_j$ . The total resistance,  $R_T$ , that determines the RC-limited response time of  $\tau_{RC} = R_T C_T$  is inferred from the small signal equivalent diode circuit in Fig. 7.20 to include capacitance and external loads. The photocurrent and noise current sources are in parallel with all circuit elements except the device series resistance. Thus,  $R_T = (R_{ser} + R_j) \parallel (R_L \parallel R_{in})$  where  $R_L$  is the load resistance of the detection circuit, and  $R_{in}$  is the effective input resistance of the following current amplifier. For a very low dark current device, it is reasonable to expect that the junction resistance as determined by the diode equation,  $R_j = i_T / V_a \gg R_{ser}$ , except at high reverse voltages where the device undergoes reverse breakdown. Similarly, it follows that  $R_j \gg R_L, R_{in}$ , thus giving

$$\tau_{RC} = (R_L \parallel R_{in}) C_T. \quad (7.64)$$

The foregoing discussion provides the bandwidth for an organic HJ detector of:

$$\Delta f = \frac{1}{2\pi} \left( \frac{1}{t_{tr}} + \frac{1}{\tau_{ED}} + \frac{1}{\tau_{RC}} \right) \quad (7.65)$$

**Figure 7.20** Small signal equivalent circuit of a photodiode.

and, since the gain of the OPD is  $g = 1$ , we have a gain-bandwidth product of

$$g\Delta f = \Delta f \quad (7.66)$$

(cf. Eq. 7.10). We assume that the transit time through undepleted regions is small compared to the other terms in Eq. 7.65. In many detectors, however, the three terms in Eq. 7.65 are comparable. We will find in Section 7.2 that diode designs have been devised to maximize detector bandwidth that eliminate one or more of the time constants, resulting in bandwidths approaching 1 GHz (Peumans et al., 2000b).

### 7.1.2.5 Noise and dynamic range

Since  $n, p \rightarrow 0$  in the depletion region in reverse-biased photodiodes, the probability of trapping and detrapping of carriers is negligible. Hence  $1/f$  noise is not a dominant source of noise. In contrast, noise from charge *generation* can be significant, leading to shot noise given by

$$\langle i_{sh}^2 \rangle = 2q(i_D + i_{ph})\Delta f = 2qi_T\Delta f, \quad (7.67)$$

which differs from the expression for photoconductors (Eq. 7.37) by a factor of 2 since, in the absence of charge in the depletion region, recombination is minimal. Also, for OPDs,  $g = 1$ . The other source of noise is the thermal, or Johnson noise, which from Eq. 7.34,

$$\langle i_{th}^2 \rangle = \frac{4k_B T \Delta f}{(R_{ser} + R_j) \parallel (R_L \parallel R_{in})} \approx \frac{4k_B T \Delta f}{R_L \parallel R_{in}}. \quad (7.68)$$

Due to the high junction resistance, the thermal noise is generally dominated by the impedance of the external circuit.

The total noise of a photodiode is typically much smaller than for a photoconductor due to the low dark resistance (and hence high  $i_D$ ) of the latter. Further, the Johnson noise of the photoconductor cannot be smaller than that of a photodiode since, even for the best case of a very high dark resistance, a photoconductor still must be used at the input of a detection circuit whose load and input resistances are, in principle, equal to those used for a photodiode.

The  $S/N$ ,  $NEP$ , and  $D^*$  then follow directly from our treatment for photoconductors in Sec. 7.1.1. The specific detectivity is:

$$D^* = q\eta_{ext}(\lambda/hc) \sqrt{\frac{A}{2qi_T + 4k_B T/R_L \parallel R_{in}}}. \quad (7.69)$$

From the foregoing, we infer that  $D^*$  is much larger for a photodiode due to its lower noise compared to the photoconductor. Similarly, from Eq. 7.47 we infer

that the  $DR$  of the photodiode is also larger due to its reduced  $NEP$ . Series resistance from contacts limits the maximum photocurrent, although undepleted donor and acceptor regions in OPDs can also contribute to  $R_{ser}$  placing further limits on  $i_{ph}$ , and hence  $DR$ .

### 7.1.3 Comparison of photoconductors and photodiodes

The simplicity of photoconductors led to their early demonstration and development, long preceding the demonstration of a HJ OPD that showed an asymmetric, rectifying  $j$ - $V$  characteristic (Tang, 1986). However, as we have found in this section, the bandwidth and noise performance of reverse-biased photodiodes far exceeds that of photoconductors. For these reasons, photodiodes are preferred for almost all sensitive detection applications. While photoconductors can source photocurrent, they are incapable of providing power to an external load. In contrast, photodiodes operating in the fourth quadrant of the  $j$ - $V$  characteristics (where  $V > 0$  and  $j < 0$ , and vice versa) in the so-called photovoltaic mode are useful as a power generating solar cell. Due to the potential low cost and ability to deploy such devices on large, flexible substrates, OPVs have been the subject of considerable research by the organic electronics community, and hence will be discussed at length in subsequent sections. We summarize the foregoing discussion by comparing the characteristics of photoconductors and OPDs operated in the detection (in contrast to the photovoltaic) mode in Table 7.2.

### 7.1.4 Modeling efficiency: optical and charge generation in OPDs and OPVs

According to Eq. 7.48, the product of the efficiencies of four processes leading to charge generation determines the quantum efficiency. Two of the processes, namely absorption ( $\eta_A$ ) and exciton diffusion ( $\eta_{ED}$ ), are coupled since the diffusion efficiency depends on the distance that the exciton is generated from a D-A junction, and this in turn depends on the distribution of the optical field within the device. In describing the optical field of a photoconductor, we used the simple model of an exponentially decaying flux density with distance (the Beer-Lambert law) within the absorbing semiconductor. Such a treatment is valid only in the case of a single layer structure, whereas multilayered OPDs form weak microcavities. Indeed, in Chapter 6 we showed that the optical field distribution in multilayer OLEDs was more complex than predicted

**Table 7.2** Comparison of operating parameters of photoconductors and photodiodes

Parameter	Photoconductor	Photodiode
Operating voltage	Near equilibrium ( $V_a \rightarrow 0$ )	Reverse bias
Photocurrent gain ( $g$ )	$\tau/t_r (1-10^6)$	1
$\eta_{int}$	$k_{diss}/(k_{diss} + k_D)$	$k_{ppd}/(k_{ppd} + k_{ppr})$
$\eta_{ext}$	$\frac{j_{ph}A}{qg(P_{inc}\lambda/hc)}$	$\frac{j_{ph}A}{q(P_{inc}\lambda/hc)}$
Responsivity	$qg\eta_{ext}(\lambda/hc)$	$q\eta_{ext}(\lambda/hc)$
Bandwidth ( $\Delta f$ )	$1/2\pi\tau_D$	$1/2\pi t_r$
Gain-bandwidth product ( $g\Delta f$ )	$1/2\pi t_r$	$1/2\pi t_r$
$\bar{i}_n^2/\Delta f$	$(4k_B T)/R_{PC} + \kappa/f^\alpha$	$2qi_T + 4k_B T/R_L \parallel R_{in}$
Specific detectivity ( $D^*$ )	$q\eta_{ext}(\lambda/hc)\sqrt{\frac{A}{(4k_B T)/R_{PC} + \kappa/f^\alpha}}$	$q\eta_{ext}(\lambda/hc)\sqrt{\frac{A}{2qi_T + 4k_B T/R_L \parallel R_{in}}}$

by such a simple considerations, and thus optical out-coupling of emitted radiation could only be understood and ultimately controlled by a detailed knowledge of the complex indices of refraction of all the layers comprising the device. This problem is even more complex in OPDs (and by extension, OPVs) since the product of  $\eta_A\eta_{ED}$  ultimately determines  $\eta_{int}$ .

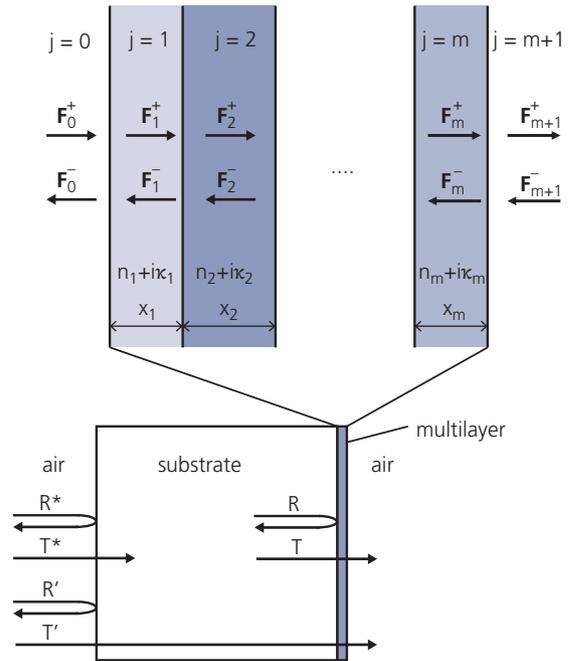

The absorption and exciton diffusion efficiencies in the photodetector are functions of the optical properties of the materials employed, excitation wavelength  $\lambda$ , layer thicknesses, and the layer order. To evaluate  $\eta_A\eta_{ED}$ , the optical electric field amplitude  $F(x)$  is calculated as a function of position in the generalized multilayer structure in Fig. 7.21 following the treatment of Heavens (1991) and later adapted to solve the specific situation of organic detectors (Pettersson et al., 1999, Peumans et al., 2003b). Generally, we assume that the materials comprising the device are homogeneous and isotropic, and the  $j$ th layer of a stack consisting of  $m$  layers between a semi-infinite substrate (layer  $j = 0$ ) and air ( $j = m+1$ ) is thus described by a complex index of refraction, viz.

$$\tilde{n}_j = n_j + i\kappa_j, \quad (7.70)$$

where  $n_j$  and  $\kappa_j$  are the real and imaginary parts of the refractive index, respectively. In the harmonic field approximation at frequency  $\omega$ , we can write

$$\mathbf{F}_j(x, t) = \mathbf{F}_{0j}\exp(-\xi_j x - \omega t)\hat{\mathbf{z}}, \quad (7.71)$$

where  $\xi_j = (2\pi/\lambda)\tilde{n}_j$  is the complex propagation constant. Since we are only concerned with the spatial distribution of the field, we can omit the time dependence of  $\mathbf{F}$ . Furthermore, since we assume that the

**Figure 7.21** Schematic of a multilayer stack with light incident in the  $+x$  direction from the left. Superscripts  $+$  and  $-$  refer to propagation in the  $+x$  and  $-x$  directions, respectively.

structure is semi-infinite in the plane normal to the propagation direction,  $x$ , we do not need to distinguish between the polarization directions of the field. In the following treatment, we use the convention that a  $+$  ( $-$ ) superscript represents propagation in the  $+x$  ( $-x$ ) direction. The thickness of the  $j$ th layer is  $x_j$ , and light is incident on the substrate in the  $+x$  direction. The interfaces between layers are assumed flat on the scale of the wavelength.

In the *transfer matrix formalism*, propagation of light is described by  $2 \times 2$  matrices subject to the continuity of the tangential component of the electric field at an interface. At the interface between layers  $j$  and  $k$ , the optical field is described by the interface matrix  $I_{jk}$ :

$$\begin{bmatrix} \mathbf{F}_j^+ \\ \mathbf{F}_j^- \end{bmatrix} = I_{jk} \begin{bmatrix} \mathbf{F}_k^+ \\ \mathbf{F}_k^- \end{bmatrix} = \frac{1}{t_{jk}} \begin{bmatrix} 1 & r_{jk} \\ r_{jk} & 1 \end{bmatrix} \begin{bmatrix} \mathbf{F}_k^+ \\ \mathbf{F}_k^- \end{bmatrix}, \quad (7.72)$$

where  $r_{jk}$  and  $t_{jk}$  are the complex Fresnel reflection and transmission coefficients, respectively, given by

$$r_{jk} = \frac{(\tilde{n}_j - \tilde{n}_k)}{(\tilde{n}_j + \tilde{n}_k)} \quad (7.73a)$$

and

$$t_{jk} = \frac{2\tilde{n}_j}{(\tilde{n}_j + \tilde{n}_k)}. \quad (7.73b)$$

The treatment thus far has considered reflection and transmission at each interface. We also need to account for the phase shift accumulated as the field propagates through a layer of thickness  $x_j$ . This is expressed in terms of the phase matrix given by

$$L_j = \begin{bmatrix} e^{-i\xi_j x_j} & 0 \\ 0 & e^{i\xi_j x_j} \end{bmatrix}, \quad (7.74)$$

where  $\xi_j x_j$  is the phase shift.

Thus, the field incident on the layer stack from the substrate,  $j = 0$ , is related to the transmitted field at  $j = m+1$  by the scattering matrix,  $\mathbf{S}$ :

$$\begin{bmatrix} \mathbf{F}_{m+1}^+ \\ \mathbf{F}_0^- \end{bmatrix} = \mathbf{S} \begin{bmatrix} \mathbf{F}_0^+ \\ \mathbf{F}_0^- \end{bmatrix} = \prod_{l=1}^m I_{(l-1)l} L_l \begin{bmatrix} \mathbf{F}_0^+ \\ \mathbf{F}_0^- \end{bmatrix}. \quad (7.75)$$

Here,  $\mathbf{F}_{m+1}^- = 0$  implies that there is no reflected wave at the end of the multilayer stack. The convenience of the transfer matrix method is that the field exiting from an arbitrary layer system is found simply by calculating the Fresnel coefficients at each interface and the phase change within each layer, and then taking the products of their respective  $2 \times 2$  matrices with the incident field. Then, with

$$\mathbf{S} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix}, \quad (7.76)$$

we obtain the total reflection ( $r$ ) and transmission ( $t$ ) coefficients of the stack:

$$r = \frac{\mathbf{F}_0^-}{\mathbf{F}_0^+} = \frac{S_{21}}{S_{11}} \quad (7.77a)$$

and

$$t = \frac{\mathbf{F}_{m+1}^+}{\mathbf{F}_0^+} = \frac{1}{S_{11}}. \quad (7.77b)$$

The absorption efficiency of the multilayer structure is equal to the fraction of the light neither transmitted nor reflected, which is given by

$$\eta_A = 1 - T - R = 1 - \frac{|t|^2 \tilde{n}_{m+1}}{\tilde{n}_0} - |r|^2, \quad (7.78)$$

where  $T$  and  $R$  are the transmissivity and reflectivity, respectively. Thus far, we have assumed that the substrate is infinitely thick. In fact it is only optically thick, that is,  $x_{sub} \gg \lambda$ , and is typically  $\sim 0.1$ – $1$  mm. Hence, the effect of the substrate is included by correcting  $T$  and  $R$  for reflections at the air/substrate and substrate/multilayer interfaces rather than by including it directly in the transfer matrix calculation. This gives substrate reflectivities and transmissivities for light incident from air with  $\tilde{n} = 1$  of (cf. Eq. 7.26):

$$R_{sub} = \frac{(1 - n_{sub})^2}{(1 + n_{sub})^2} \quad (7.79a)$$

and

$$T_{sub} = \frac{4}{(1 + n_{sub})^2}, \quad (7.79b)$$

where we have made the reasonable assumption that the substrate is non-absorbing (i.e.  $\tilde{n}_{sub} = n_{sub}$ ). This gives a total reflectivity and transmissivity of the multilayer structure, including the substrate, of

$$R' = \frac{R_{sub} + R}{1 + R_{sub}R} \quad (7.80a)$$

and

$$T' = \frac{T_{sub}T}{1 + R_{sub}R}, \quad (7.80b)$$

yielding the total absorption efficiency of  $\eta_A = 1 - T' - R'$ .

Since we are ultimately only interested in absorption within the active region (presuming that other layers do not generate excitons that can reach a D-A interface, and hence cannot contribute to the photocurrent), we need to calculate the *local* electric field within the layers comprising the dielectric stack. Let us assume that we are interested in the field within layer,  $j$ . Then we can separate the system into three parts: those layers in the regions  $0 < x < x'$ , the layer  $j$  itself, and those at  $x > x' + x_j$ , where  $x'$  is the sum of the thicknesses of the layers  $x_0$  to  $x_{j-1}$ . Then the scattering matrix of the entire structure is given by

$$\mathbf{S} = \mathbf{S}_j^- L_j \mathbf{S}_j^+, \quad (7.81)$$

with

$$\mathbf{S}_j^- = \left( \prod_{l=1}^{j-1} I_{(l-1)l} L_l \right) I_{(j-1)j} \quad (7.82a)$$

and

$$\mathbf{S}_j^+ = \left( \prod_{l=j+1}^m I_{(l-1)l} L_l \right) I_{m(m+1)}. \quad (7.82b)$$

The electric field propagating in the positive direction in layer  $j$  at the left interface is related to the incident plane wave via

$$t_j^+ = \frac{\mathbf{F}_j^+}{\mathbf{F}_0^+} = \frac{S_{j11}^+}{S_{j11}^+ S_{j11}^- e^{-i\xi_j x_j} + S_{j21}^+ S_{j12}^- e^{i\xi_j x_j}}, \quad (7.83)$$

and similarly for the electric field propagating in the negative direction at the left interface:

$$t_j^- = \frac{\mathbf{F}_j^-}{\mathbf{F}_0^+} = t_j^+ \frac{S_{j21}^+}{S_{j11}^+} e^{2i\xi_j x_j}. \quad (7.84)$$

Finally, we arrive at the total electric field at an arbitrary position inside layer  $j$  as the linear superposition of the fields propagating in opposite directions, and whose intensities are modified by the phase at  $x$ :

$$\frac{\mathbf{F}_j(x)}{\mathbf{F}_0^+} = t_j^+(x) + t_j^-(x) = t_j^+ e^{i\xi_j x} + t_j^- e^{-i\xi_j x}. \quad (7.85)$$

The time-averaged *Poynting vector* gives the power as a function of position, which for the harmonic field in Eq. 7.71 yields the local generation rate:

$$G_j(x) = \frac{2\pi\epsilon_0\kappa_j n_j}{h} |\mathbf{F}_j(x)|^2, \quad (7.86)$$

which is related to  $\eta_A P_{inc}$  via Eq. 7.3. This differs from the simple model of absorption calculated using the Beer–Lambert relationship since it considers reflection and absorption within each layer of the dielectric stack in the OPD.

To calculate  $\eta_{ext}$  we must also consider exciton diffusion, that is, we need to calculate the probability,  $\eta_{ED}$ , that an exciton generated at  $x$  will diffuse to a D-A junction where charge transfer followed by carrier generation can occur. The continuum steady state exciton diffusion equation for the  $j$ th layer is, therefore,

$$L_{Dj}^2 \frac{\partial^2 N_j(x)}{\partial x^2} - N_j(x) + \tau_{Dj} G_j(x) = 0, \quad (7.87)$$

where  $\tau_{Dj} = L_{Dj}^2/D_j$  is the exciton diffusion lifetime in layer  $j$ ,  $D_j$  is its diffusion coefficient, and  $N_j(x)$  is the exciton density.

Equation 7.87 is solved using two possible boundary conditions: (i) ideal non-quenching interfaces, and (ii) quenching interfaces with an infinite surface recombination velocity. The first boundary condition, corresponding to  $\partial N_j(x)/\partial x = 0$ , applies to excitons in a narrow energy gap organic semiconductor at a heterointerface whose LUMO and HOMO levels are nested within the LUMO and HOMO of the contacting material (type I HJ), prohibiting exciton dissociation by via charge transfer. This case is clearly undesirable for OPDs. The second boundary condition, corresponds to  $N_j(x) = 0$ , and applies to type II D-A HJs where all excitons dissociate by CT and contribute to the photocurrent, as well as to organic/metal contacts where excitons non-radiatively recombine without contributing to the photocurrent. The photocurrent can then be calculated from the exciton diffusion current evaluated at the D-A interface:

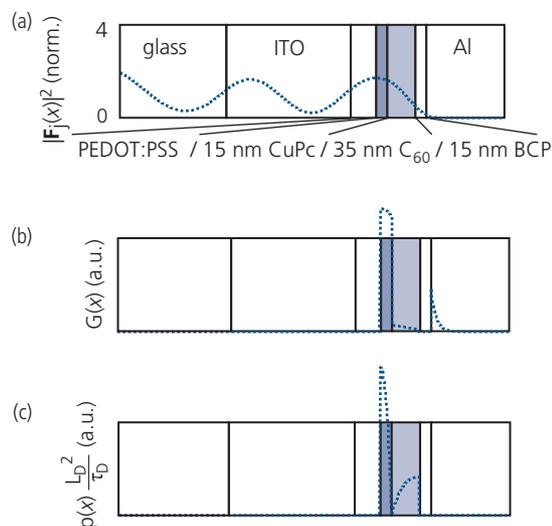

$$j_{ph,j} = qD_j \left| \frac{\partial N_j(x)}{\partial x} \right|_{x=x_{HJ}}, \quad (7.88)$$

where  $x_{HJ}$  is the position of the heterointerface. Then, the external efficiency from layer  $j$  leading to charge transfer is given by the ratio of the photocurrent to the incident photon flux:

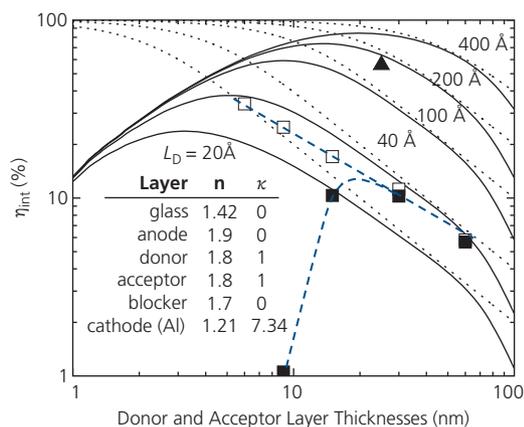

$$\eta_{ext,j} = 2h \frac{j_{ph,j}}{q\epsilon_0\lambda |\mathbf{F}_0^+|^2}, \quad (7.89)$$

where we have assumed that  $\eta_{CT}\eta_{CC} \approx 1$ , which is often the case for the most efficient D-A HJ photodetectors. Now, we have seen that  $G_j \propto |\mathbf{F}_0^+|^2$ , and thus  $j_{ph,j} \propto |\mathbf{F}_0^+|^2$ . Hence the external quantum efficiency is independent of the incident optical power in the linear range of OPD operation, that is, where series resistance or other second order effects such as charge annihilation are small.

The external quantum efficiency in stratified structures is determined by first calculating  $|\mathbf{F}_j(x)|^2$  throughout the multilayer as shown in Fig. 7.22a for the archetype device: ITO anode/32 nm PEDOT: PSS hole injection layer (HIL)/15 nm CuPc donor/35 nm C<sub>60</sub> acceptor/16 nm BCP exciton blocking layer (EBL)/100 nm Al cathode at  $\lambda = 600$  nm. Optical constants for each layer are provided in the table in Fig. 7.23. The local generation rate is calculated using the electric field and the optical properties of the active layers, as shown in Fig. 7.22b. Finally, using  $L_D$  determined from independent measurements such as spectrally resolved photoluminescent quenching (see Section 3.9, Lunt et al., 2009 and Bergemann and Forrest, 2011) the diffusion equation is solved to

**Figure 7.22** Steps used in calculating the external quantum efficiency of an archetype organic photodiode. (a) The OPD structure along with the normalized intensity distribution calculated using the optical constants for each layer provided in Fig. 7.23. (b) The optical absorption profile at  $\lambda = 600$  nm, and (c) the exciton profile calculated using the method described in text. All calculations are shown as dashed lines (Peumans et al., 2003b).

**Figure 7.23** Internal quantum efficiency vs. donor and acceptor layer thicknesses for a symmetric organic OPD whose materials parameters are provided in the table. The structure is on a glass substrate coated with a 150 nm thick anode, donor and acceptor layers, a 10 nm thick, transparent exciton blocking layer, and a 150 nm thick Al cathode. The solid lines are calculated for various  $L_D$ . The dotted lines assume no absorption at the metal cathode. The open and filled squares correspond to measurements of devices described in text, and the solid triangle is for a glass/ITO/PEDOT:PSS/CuPc/C<sub>60</sub>/BCP/Ag OPD (Peumans et al., 2003b).

obtain  $N(x)$  in Fig. 7.22c. Then, the photocurrent implied from Eq. 7.86 yields  $\eta_{ext}$  (Peumans et al., 2003b).

Extending the analysis for the specific structure in Fig. 7.22, we provide a guide in Fig. 7.23 for designing bilayer OPDs and OPV cells, where  $\eta_{int}$  is used as a

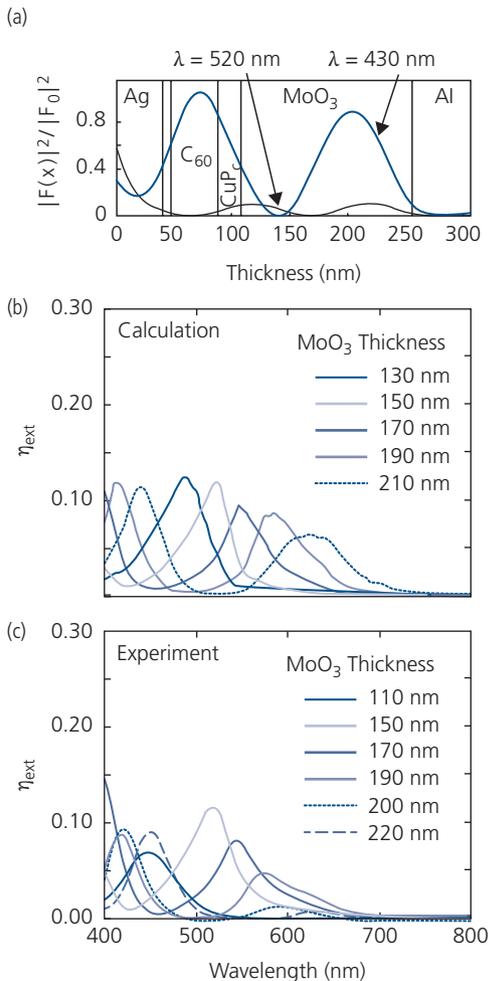

performance parameter, since it is a measure of the exciton harvesting efficiency. In these calculations, the wavelength is fixed at  $\lambda = 620$  nm. The symmetric device structure is: glass/150 nm anode/ $x$  nm donor/ $x$  nm acceptor/10 nm spacer/150 nm cathode. For the donor and acceptor layers,  $\kappa = 1.0$  was used, which corresponds to  $\alpha = 2\pi\kappa/\lambda = 1.0 \times 10^5$  cm<sup>-1</sup>, which is typical for  $\pi^* \leftarrow \pi$  transitions (see Table 7.1). Since this device is symmetrical, the same  $L_D$  was used for both the donor and acceptor layers. Of course, accurate modeling of a realistic detector requires precise knowledge of the layer thicknesses, the optical properties ( $n$  and  $\kappa$ ), and  $L_D$  of all materials used. The solid lines are model calculations of  $\eta_{int}$  vs. the donor and acceptor layer thicknesses assuming  $L_D = 2\text{--}40$  nm. The dotted lines represent a simple exciton diffusion model that does not account for interference or absorption in regions where  $x > L_D$ , or at metal contacts.

The maximum  $\eta_{int}$  is obtained for donor and acceptor layer thicknesses  $\sim L_D$ . Thicker layers suffer from absorption in regions far away from the D-A interface. For layers thinner than  $L_D$ , absorption in the metal cathode decreases  $\eta_{int}$ , causing a large deviation from the simple model (dotted lines). This latter effect poses a limit to the achievable  $\eta_{int}$  for a given  $L_D$ . The data points in the figure show measurements of devices. The solid squares correspond to glass/ITO/CuPc/PTCBI/Ag, and the open squares are for a similar device except that it contains a transparent BCP exciton blocking layer between the cathode and the acceptor. Also shown (triangle) is the result for a device that replaces the acceptor, PTCBI, with C<sub>60</sub>. The fits to the PTCBI device indicate that its diffusion length is approximately 3 nm. However, we note that the efficiency decreases dramatically for an acceptor layer thickness  $< 10$  nm for the device lacking the EBL. This is due to exciton quenching at the cathode when the thickness is less than  $\sim 2L_D$ . In contrast, the device with the EBL shows an increasing  $\eta_{int}$  as  $x_A \rightarrow L_D$ . Also, the longer diffusion length of C<sub>60</sub> results in a concomitant increase in the internal efficiency. In all cases, the optical model yields an accurate value for the device efficiency.

The transfer matrix approach has been used in devices with intentionally strong microcavities that allow for tuning the absorption spectra to enable wavelength-selective detection. Such a spectrally selective OPD has been demonstrated with the following structure (see Fig. 7.24a, An et al., 2009): Al anode (50 nm)/MoO<sub>3</sub> transparent optical spacer (110–220 nm)/CuPc or  $\alpha$ -NPD donor (20 nm)/C<sub>60</sub> acceptor (40 nm)/BCP EBL (7 nm)/Ag cathode

(40 nm). The strong microcavity results from the dielectric layers sandwiched between the reflective Al anode and the semitransparent, reflective Ag cathode through which the illumination is incident. The MoO<sub>3</sub> anode buffer layer thickness is adjusted from 110 nm to 220 nm to tune the cavity to the desired wavelength (An et al., 2009).

Figure 7.24a shows the calculated optical intensity distribution for  $\lambda = 520$  nm and 430 nm. The peak intensity within the CuPc/C<sub>60</sub> active region is at 520 nm, whereas the intensity is weaker at 430 nm. Hence, it is expected that the OPD will have a greater sensitivity at the longer wavelengths. The transfer matrix formalism coupled to the exciton diffusion

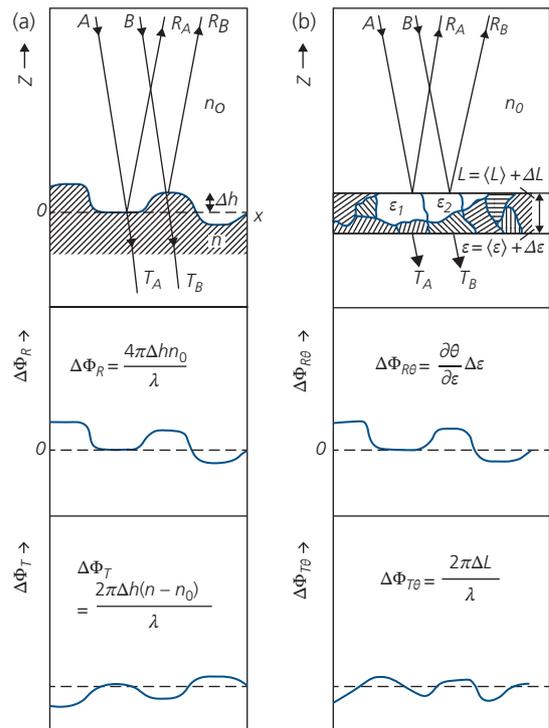

**Figure 7.24** (a) Sample OPD structure with a MoO<sub>3</sub> optical spacer/ anode buffer layer thickness of 150 nm, and the optical field distribution at two wavelengths of 520 nm (in resonance with the CuPc/C<sub>60</sub> active region) and 430 nm (off resonance). (b) Simulated and (c) measured external quantum efficiency spectra for devices in (a) for varying MoO<sub>3</sub> spacer thicknesses. Devices with 200 nm and 220 nm thick MoO<sub>3</sub> thicknesses use CuPc instead of  $\alpha$ -NPD (An et al., 2009).

equation using measured optical constants and  $L_D$  has been applied to devices with different MoO<sub>3</sub> thicknesses. Atomic force microscope (AFM) images of the films showed an rms roughness of 14.5 nm for Al and 7.3 nm for Ag. Hence, it is reasonable to expect that films deposited onto the Al surface will replicate at least some fraction of the roughness of the base layer. The calculations, therefore, were modified from those in the foregoing discussion to account for rough interfaces that were generated during layer deposition.

Rough surfaces are a common feature of many multilayer organic thin films, and hence it is worthwhile to consider this situation in some detail. The reflection and transmission of a plane wave from a rough surface can be understood from Fig. 7.25a. Rays of wavelength,  $\lambda_0$ , incident from a medium with index of refraction  $n_0$  at angle  $\beta$  are reflected from surface irregularities of height,  $\Delta h$ . The reflected light undergoes a position-dependent phase shift of

$$\Delta\Phi_R = \frac{4\pi\Delta hn_0}{\lambda_0} \cos\beta. \quad (7.90)$$

**Figure 7.25** (a) Reflection and transmission of a pair of rays, A, B, that are incident at angle  $\beta$  to the surface normal. The middle and lower panels show variations in phase vs. position for the reflected (R) and transmitted (T) waves. (b) As in (a) for a heterogeneous medium with domains of different dielectric constants,  $\epsilon_1$  and  $\epsilon_2$  (Filiński, 1972).

For a surface with a Gaussian distribution of surface roughness, the reflection coefficient is thus modified (Filiński, 1972):

$$R'(\beta) = R_s(\beta) \exp(-\Delta\Phi_R^2) = R_s(\beta) \exp\left[-\left(\frac{4\pi\sigma n_0}{\lambda_0} \cos\beta\right)^2\right], \quad (7.91)$$

where the rms surface roughness is given by

$$\sigma = \left(\sum \Delta h^2\right)^{1/2}. \quad (7.92)$$

Here,  $R_s$  is the reflection coefficient obtained for a specularly smooth surface. Using similar reasoning for a transmitted wave (see Fig. 7.25a), we have a phase shift of

$$\Delta\Phi_T = \frac{2\pi\Delta h}{\lambda_0} (n - n_0) \cos\beta \quad (7.93)$$

to yield a modified transmission coefficient of

$$\begin{aligned} T'(\beta) &= T_s(\beta) \exp(-\Delta\Phi_T^2) \\ &= (1 - R_s(\beta)) \exp\left[-\left(\frac{2\pi\sigma(n - n_0)}{\lambda_0} \cos\beta\right)^2\right]. \end{aligned} \quad (7.94)$$

Film composition heterogeneity, that is, where the composition of the medium is spatially variant such as in a D-A blend or BHJ, can also be present. Spatial variations in dielectric properties due to domains with different crystal orientation, densities, or even from a high, spatially varying impurity concentration may exist. This introduces a heterogeneous dielectric medium that comprises domains of differing dielectric constants,  $\epsilon_1, \epsilon_2, \dots$ , as shown in Fig. 7.25b. Rays traveling through different regions of the film will therefore undergo phase shifts similar to that experienced from a rough surface. Then,  $\Delta\Phi_\theta$  is the rms fluctuation in phase due to a distribution of dielectric constants, viz.

$$\Delta\Phi_\theta = \frac{2\pi L}{\lambda} \left[ \sum \left(\frac{\Delta n}{n^2}\right)^2 \right]^{1/2}, \quad (7.95)$$

where  $L$  is the total layer thickness in Fig. 7.25b. In absorptive media, the phase shift due to variations in both the real and imaginary indexes of refraction ( $\Delta n$ ) are included. Then in analogy to our treatment for roughness, we modify the reflection coefficient by:

$$R'_\theta = R_s \exp(-\Delta\Phi_\theta^2). \quad (7.96)$$

A similar expression can be derived for the transmission coefficient,  $T'_\theta$ . Finally, both surface roughness and material inhomogeneities are incorporated into the expressions used in the transfer matrices by

adding their respective contributions to the phase shifts encountered in propagating through the  $i$ th layer.

Returning to Fig. 7.24b, the external quantum efficiency is calculated for devices with various MoO<sub>3</sub> buffer layer thicknesses, incorporating the effects of surface roughness imparted by the Al anode. The strong microcavity arising from the active semiconductor layers sandwiched between two reflective metal contacts results in narrow peaks, each at a different wavelength depending on the buffer layer thickness. For the thickest buffer layers, there are two maxima, one at short and the other at longer wavelength. These dual peaks correspond to two intensity maxima, one at  $\lambda/4n$  and the second at  $3\lambda/4n$  lying within the D-A layers. The experimental results in Fig. 7.24c are reasonably close to predictions, although there are some notable differences, particularly at long wavelengths. This difference is due to inaccuracies in the layer refractive indexes which were taken from literature values rather than being directly measured (An et al., 2009). Note that the devices with MoO<sub>3</sub> thicknesses of 200 nm and 220 nm (dashed lines) used  $\alpha$ -NPD in place of CuPc as the donor to enhance the short wavelength absorption.

One feature of microcavities discussed in Chapter 6 is their sensitivity to light incidence angle and polarization. This is indeed the case for the devices in Fig. 7.24, where wavelength peak shifts as large as 40–50 nm are observed as the angle is varied from 0° (normal incidence) to 60° (An et al., 2009). This effect is undesirable if the incidence angle is not fixed, whereas it can be used to detect the incidence angle if the source wavelength is known.

### 7.1.5 Modeling efficiency: dependence on film morphology

Thus far we have considered only charge generation and the optical fields in planar, bilayer heterojunctions (PHJs). However, we have shown that efficient detectors use BHJs or mixed HJs. The characteristics of such entangled structures (cf. Fig. 7.17) must be accurately modeled to optimize materials and architectures for improved performance. Developing morphological models is more straightforward for small molecules deposited from the vapor phase than for solution processed films. In the former case, the dynamics of domain formation is based only on the intermolecular interaction energies at the substrate surface, along with the particular kinetics of the growth process that involves non-interacting particles in the vapor phase. More

complex solution phase interactions along with undefined molecular shapes govern polymer morphologies. Achieving a desired morphology is ultimately an experimental process with a good degree of trial and error. A few such processes and the resulting morphologies achieved for films deposited from solution are described in Section 7.4.2. Here we focus on the less complicated problem of modeling mixtures deposited from the vapor phase (i.e. by either VTE or OVPD). This treatment provides a generalized methodology for understanding how the foregoing discussion of PHJs informs the more complex treatment of blends.

The basic elements for “constructing” a given small molecule morphology is to assume that the blends consist of solids predominantly bonded by van der Waals forces. Then the structure can be modeled using the atom–atom potential model developed in Section 2.5. In the following, we describe a general *dynamic Monte Carlo* (DMC) energy-based simulation method introduced by Adams et al. (1993) and then adapted to the specific problem of mixed small molecule HJ domain formation during growth (Watkins et al., 2005, Yang and Forrest, 2008). Variations on this *molecular dynamics simulation* procedure have been used to understand morphologies in OPVs, OLEDs, transistors, and numerous other thin film structures.

We start by assuming the organic molecules are arranged on a cubic (Watkins et al., 2005, Yang and Forrest, 2008) or a face-centered cubic lattice to account for molecular asymmetries, allowing extended molecules to occupy two lattice sites (Ding et al., 2018). The lattice constant is  $a$ , which is on the order of a molecular diameter (typically  $\sim 1$  nm). The lattice sizes discussed below are  $(100a)^2$  in the substrate ( $x$ – $y$ ) plane, with varying depth in the substrate normal ( $z$ ) direction. Periodic boundary conditions are applied. The bottom and top of the lattice are assumed to contact the anode and the exciton blocking layer, respectively.

Phase separation from a *homogeneously* mixed active region is generated using an entropy-driven site spin-exchange Ising model (Adams et al., 1993) whose parameters are adjusted to reproduce the observed grain size and distribution for binary blends. Lattice sites are allowed to exchange their spins between all 26 proximate neighbors (6 in the  $\langle 100 \rangle$  direction, 12 in the  $\langle 110 \rangle$  direction, and 8 in the  $\langle 111 \rangle$  direction). Since the van der Waals interaction between like molecules is generally larger than the interaction between different molecules, the change in system energy that ensues from the exchange of

two neighboring molecules (spins) is represented using the Ising Hamiltonian for the energy of site,  $i$ :

$$\varepsilon_i = -\frac{J}{2} \sum_j \left( \delta_{s_i, s_j} - 1 \right), \quad (7.97)$$

where  $\delta_{s_i, s_j}$  is the Kronecker delta for spins occupying sites  $i$  and  $j$ . The coupling between sites is given by  $J$ , which is arbitrarily set to +1. The summation is over first and second nearest neighbor sites, with the energetic contribution decreased by  $\sqrt{2}$  for the latter. Exchange attempts between sites  $i$  and  $j$  are accepted with the probability  $P(\Delta\varepsilon)$ . This is thermally activated according to (Kawasaki, 1972)

$$P(\Delta\varepsilon) = \frac{\exp(-\Delta\varepsilon/k_B T)}{1 + \exp(-\Delta\varepsilon/k_B T)}, \quad (7.98)$$

where the energy difference between sites  $i, j$  is  $\Delta\varepsilon$ . Here,  $T$  is in units of  $J/k_B$ . This procedure leads to large-scale phase separation occurring in a system with limited miscibility. The accepted spin exchanges tend to form aggregates of like molecules by lowering the total system energy, while the grain size is controlled by the number of executed spin exchanges.

The growth of more complex D-A nanocrystalline networks is modeled assuming growth by alternate deposition of ultrathin layers of D and A molecules (Yang et al., 2005b, Ding et al., 2018), taking into account gas phase transport, surface diffusion, and evaporation back into the gas phase. The structural morphology is simulated based on the atom–atom potential method. Recall from Section 2.5 that the total bond potential between neighboring molecules  $i, j$  is  $U(R_{ij}) = \frac{1}{2} \sum_{m,n} \phi_{m,n}(R_{ij})$ . Here,  $R_{ij} = |\mathbf{R}_i - \mathbf{R}_j|$  is

the relative molecular positions and  $\phi_{m,n}(R_{ij})$  is the potential between the  $m$ th and  $n$ th atoms in different molecules,  $i$  and  $j$ . Both the London and Buckingham potentials are convenient for large-scale atom–atom modeling of organics. The energy of molecule  $i$ , is then obtained by summing over all neighboring molecules  $j$ .

It is assumed that the organic molecules are randomly generated in the gas phase at a distance far from the substrate. Once incident on the solid surface, they diffuse from site  $i$  to unoccupied site  $j$ , at a rate:

$$w_{i \rightarrow j} = w_0 f(\Delta\Phi), \quad (7.99)$$

where  $w_0$  is the hopping attempt frequency, and  $\Delta\Phi = \Phi_j - \Phi_i$  is the difference in energy of the molecule occupying site  $i$  or  $j$ . Then,

$$f(\Delta\Phi) = \begin{cases} \exp(-\Delta\Phi/k_B T) & \text{for } \Delta\Phi \geq 0 \\ 1 & \text{for } \Delta\Phi < 0 \end{cases} \quad (7.100)$$

A molecule on the surface can also re-evaporate back into the gas phase where the destination site,  $j$ , is above the solid surface, with  $\Phi_j = 0$ . The dominance of bond energies between like molecules over those between dissimilar molecules results in the formation of large, homogeneous domains.

Morphologies are “constructed” by assuming that the first homogeneous layer consists of D molecules. Following that, a thin A layer is deposited, forming aggregates that do not provide full coverage of the underlying D layer. A second, thin D layer is then deposited to partially cover the A layer, but it also directly contacts the first, continuous D layer. Several such thin, discontinuous D-A layer pairs are sequentially deposited, followed by a thick and continuous capping layer.

To connect the morphology to the charge generation efficiency, exciton and carrier transport within the simulated morphology must also be modeled. We found in Chapter 4 that short-range hopping between localized states provides a reasonable picture of the transport in disordered organic systems. For this purpose, the *first reaction method* (FRM) using the DMC algorithm is applied. In FRM, the probability of an allowed process (e.g. exciton site hopping) is calculated following the first time the exciton or charge appears, and is updated following exciton dissociation, quenching, bimolecular recombination or charge collection. Compared to a full DMC calculation in which the probability is recalculated after each change of system configuration, FRM significantly reduces computation time (Watkins et al., 2005). The FRM calculation is reasonably accurate as long as the particle densities are small, where interparticle interactions can be neglected. This is generally the case for detectors and solar cells under modest illumination intensities. The FRM simulation generates excitons at rates consistent with the incident light intensity and spectrum, and tracks their diffusion to the D-A HJ where they dissociate into free carriers.

Förster energy transfer governs exciton diffusion in materials commonly used for detection. Hence, the hopping time,  $\tau_{EX}$ , depends on  $R_{ij}^6$  and the difference in site energies,  $\Delta E_{ij}$ , viz. (Scheidler et al., 1996, Yang and Forrest, 2008)

$$\tau_{EX} = \tau_D \left( \frac{R_{ij}}{a} \right)^6 \frac{\log(X)}{f(\Delta E_{ij})}. \quad (7.101)$$

Here,  $\tau_D$  is the exciton lifetime, and  $0 < X < 1$  is a random number. The hopping probability is based on the Miller–Abrahams model in Section 4.3.2:

$$f(\Delta E_{ij}) = \begin{cases} \exp(-\Delta E_{ij}/k_B T) & \text{for } \Delta E_{ij} \geq 0 \\ 1 & \text{for } \Delta E_{ij} < 0 \end{cases}. \quad (7.102)$$

Onsager–Braun theory (Braun, 1984) is used to describe exciton dissociation, where the generated carrier gains energy equal to the difference between the D-A energy offset and the exciton binding energy.

Finally, electron transport is calculated based on effective-medium theory (cf. Fishchuck et al., 2002 and Section 4.3.2). This yields the carrier hopping time:

$$\tau_{ch} = \frac{qa^2 \exp(4a[R_{ij} - a])}{6k_B T \mu_{n(p)}} \frac{1}{f(\Delta E_{ij})}, \quad (7.103)$$

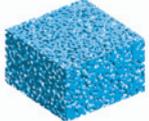

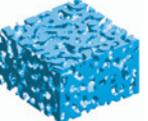

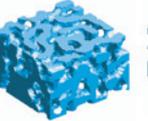

where  $\mu_{n(p)}$  is the electron (hole) mobility.

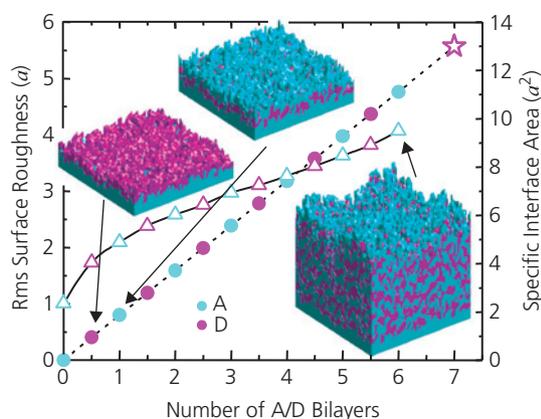

This analysis has been used to understand photo-generation in CuPc/C<sub>60</sub> D-A HJs with six different morphologies: a bilayer, planar HJ (PHJ), a homogeneous D-A mixture, a PM-HJ, an ordered BHJ consisting of pillars with diameters greater than  $L_D$ , arranged in a chessboard pattern bounded on top and bottom with a D and A layer, and a random nanocrystalline network. The PHJ cell consists of two homogeneous layers separately comprised of D and A molecules. The PM-HJ cell is comprised of a D-A mixed layer sandwiched between top and bottom continuous homogeneous layers (Yang and Forrest, 2008).

The morphological evolution of an initially homogeneously mixed, 60 nm thick CuPc:C<sub>60</sub> film that is subsequently annealed by calculating the structure after a specified number of DMC steps (i.e. “spin exchanges”) is provided in Table 7.3. The average domain size is expressed in units of lattice constants,  $[a]$ , and the specific interface area in units of  $[a^2]$ . The specific interface area is the ratio of the total calculated D-A interface area to its projection onto the substrate plane. The homogeneous mixture has a domain size of  $a$ , equal to the volume occupied by a single molecule, and a specific interface area  $>60a^2$ . As annealing proceeds to 100 steps, the domain volume grows by segregation of the components, finally leading to a domain size of  $10a$  and a much smaller projected area of  $6a^2$ .

When the top surface is unconstrained (i.e. it is free to develop 3D structure), the simulations predict roughening during annealing that increases with layer thickness, consistent with phenomena observed for thermally annealed CuPc/PTCBI mixed junctions (Peumans et al., 2003a). Roughening is shown in Fig. 7.26 for the simulated growth of a sample consisting of a stack of alternating CuPc

**Table 7.3** Average domain sizes, specific interface areas and cell efficiencies of mixed films before and after annealing for different numbers of DMC steps for a  $100 \times 100 \times 60 \text{ nm}^3$  lattice. The shaded areas are one of the two components (D or A), and the “empty” areas are occupied by the opposite component (Yang and Forrest, 2008)

DMC steps	0	1	10	50	100
Morphology					
Domain size [a]	1.0	2.0	4.9	7.9	10.3
Specific interface area [a <sup>2</sup> ]	61.2	29.7	12.2	7.6	6.0
$\eta_{CC}$	0.31	0.34	0.40	0.44	0.43
$\eta_{ED}$	1.00	1.0	0.97	0.93	0.87
$\eta_{int}$	0.31	0.34	0.39	0.41	0.37

**Figure 7.26** Simulation of the growth of alternating D-A stacks with the structure  $\text{CuPc}(10a)/[\text{C}_{60}(3a)/\text{CuPc}(3a)]_n/\text{C}_{60}(30a)$ , where D = CuPc and A =  $\text{C}_{60}$  indicating the (a) root mean square surface roughness (open triangles in units of [a]) and (b) the specific interface area (circles in units of [a<sup>2</sup>]) (Yang and Forrest, 2008).

and  $\text{C}_{60}$  layers as follows:  $\text{CuPc}(10a)/[\text{C}_{60}(3a)/\text{CuPc}(3a)]_n/\text{C}_{60}(30a)$ , where  $n$  is the number of bilayers. Surface roughening is a general property of nanocrystalline growth, although its magnitude depends on the particular materials systems and growth dynamics involved.

By combining the results of morphological simulations with the charge and excitonic dynamics of Eqs. 7.101–7.103, we can determine the internal efficiency of the mixed or BHJ device. Moreover, the external efficiency of the detector is found by including the physical dimensions of the device with the optical constants ( $n$ ,  $\kappa$ ) of the layer stack. In Table 7.3, for example, we use the exciton diffusion and charge collection efficiencies to arrive at the internal quantum efficiency (recall  $\eta_{int} = \eta_{ED}\eta_{CT}\eta_{CC}$ ) as a

function of morphology obtained through mixed HJ annealing. In these calculations, it has been assumed that the charge transfer efficiency,  $\eta_{CT}$ , is unity. As we have seen in this and previous chapters, however, this is not generally true, particularly for junctions where  $\Delta E_{HL}$  is small. Nevertheless, it is straightforward to include this factor into the calculation of  $\eta_{int}$  based on discussions from Chapter 4 and Section 7.4.

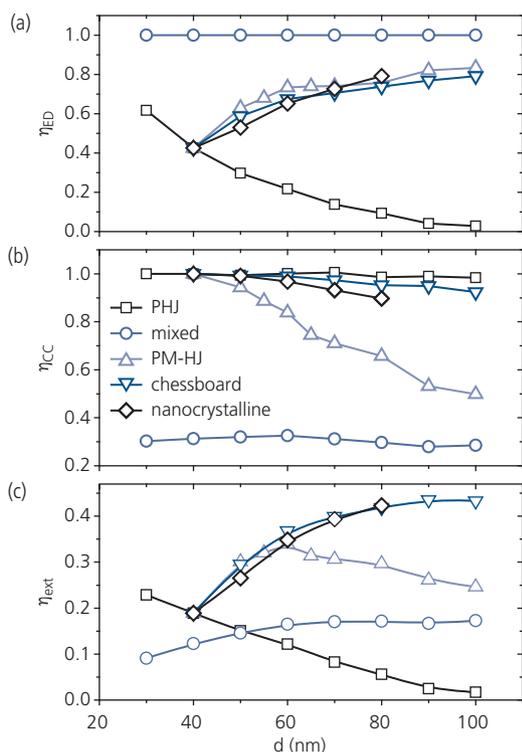

Simulated efficiencies of five  $\text{CuPc}/\text{C}_{60}$  morphologies are shown in Fig. 7.27. For these calculations the following materials parameters were employed for CuPc and  $\text{C}_{60}$ , respectively:  $L_D = 15 \text{ nm}$ ,  $40 \text{ nm}$ ;  $\tau_D = 10 \text{ ns}$ ,  $1 \mu\text{s}$ , and  $\mu_p = 7 \times 10^{-4} \text{ cm}^2/\text{V s}$  and  $\mu_n = 5 \times 10^{-2} \text{ cm}^2/\text{V s}$ . As expected, the exciton diffusion efficiency of the planar HJ decreases exponentially with  $d$ , although its charge collection efficiency is always close to 100%. The opposite holds true for the homogenous mixture, where charge collection is impeded by the lack of percolating conductive paths, yet every photogenerated exciton has a neighboring counter molecule that results in  $\eta_{ED} = 1$ . The planar mixed device shares properties of both of these extremes. Unsurprisingly, the external quantum efficiency (and hence  $j_{ph}$ ) is maximized for an ideal chessboard morphology, or for a nanocrystalline network. We have shown in Section 5.4.2 that a chessboard structure can approximately be achieved by the strained growth of CuPc nanopillars on ITO using OVPD (Yang et al., 2005a). Nanocrystalline networks, although more random than chessboards are more readily achieved during growth and yet deliver nearly equivalent performance. Finally, the analysis provides information on the optimal active layer thicknesses for a given materials system. It is apparent that the efficiency saturates at thicknesses between 60 nm and 80 nm, which indeed is close to that used in OPVs comprising small molecule active regions.

It is encouraging that experimental results summarized in Table 7.4 are in agreement with the simulations. In particular, the agreement between the transfer matrix calculations of the optical field intensity, and the exciton diffusion theory has proven this analysis to be invaluable in accurately predicting the design and performance of a wide range of highly

complex planar, bulk HJ, mixed HJ, and multi-element stacked organic detectors.

## 7.2 Organic photoconductors and photodiodes: properties and examples

Having considered the theoretical underpinnings of organic photodetection, in this section we give examples of how this property is implemented in devices. We also introduce several examples of photo-detector applications that benefit from the unique attributes of organic semiconductors, particularly their flexibility and conformability. We will show that very high sensitivity (i.e. low noise) and bandwidth can be achieved using OPDs demonstrated to span the electromagnetic spectrum from X-rays to the NIR. We begin in Section 7.2.1 with a brief discussion of photoconductive detectors, and then in Section 7.2.2 we move to descriptions of the many and varied implementations of OPDs. The discussion of an organic device that is a hybrid between a detector and a transistor is the organic phototransistor, or OPT. A discussion of OPTs is found in Section 8.5.

**Figure 7.27** Simulations of five CuPc/C<sub>60</sub> HJ morphologies yielding the (a) exciton diffusion, (b) charge collection and (c) external quantum efficiencies as functions of the active layer thickness,  $d$ . The PHJ cell has the structure of CuPc( $d_0$  nm)/C<sub>60</sub>( $d_0 + 20$  nm), where  $2d_0 + 20$  nm =  $d$ . The PM-HJ, chessboard structures comprises a 10 nm thick bottom CuPc layer and a 30 nm thick top C<sub>60</sub> layer. The nanocrystalline structure is CuPc(10 nm)/[C<sub>60</sub>(3 nm)/CuPc(3 nm)] <sub>$n$</sub> /C<sub>60</sub>(30 nm), where  $n = 0, 2, 4, 6,$  and  $8$ . The square pillar width in the chessboard structure is 5 nm (Yang and Forrest, 2008).

### 7.2.1 Photoconductors

We have found in Chapter 4 that a wealth of knowledge about charge transport and photogeneration in organic semiconductors has been acquired via the study of their photoconductive properties (Borsenberger et al., 1978, Karl et al., 1991, Bäessler, 1993). However, there are far fewer examples of organic photoconductors used in device applications. A notable exception is their early application in *electrophotography* (also known as *xerography*). In its most elementary embodiment, the electrophotographic process requires a large photoconductive sheet mounted on a roller with a contact on its surface. The sheet is charged by the application of voltage to the roller electrode. When illuminated, charges are generated and subsequently separated

**Table 7.4** Comparison between simulated and observed  $\eta_{ext}$  for various CuPc/C<sub>60</sub> solar cells under 1 sun intensity, AM1.5G illumination

HJ structure	Simulated $\eta_{ext}$	Measured $\eta_{ext}$	Ref.
PHJ:	0.13	0.14	(Yang et al., 2007)
CuPc(20nm)/C <sub>60</sub> (40nm)		0.15	(Peumans and Forrest, 2001, Fujishima et al., 2009)
Mixed HJ:	0.16	0.16	(Sullivan et al., 2004)
CuPc:C <sub>60</sub> (1:1, 60 nm)			
Nanocrystalline network HJ:	0.42	0.43	(Yang et al., 2007)
CuPc(10 nm)/[C <sub>60</sub> (3 nm)/CuPc(3 nm)] <sub>6</sub> /C <sub>60</sub> (30 nm)			

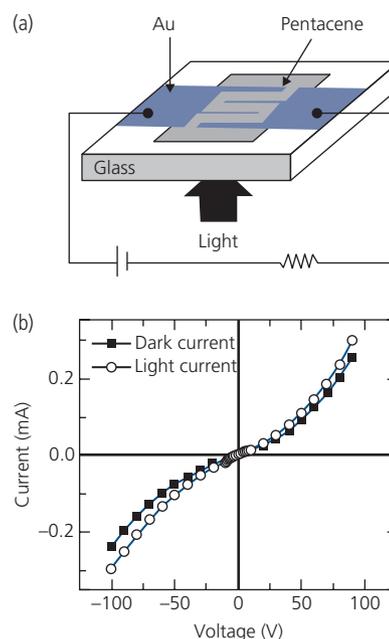

by the resulting field. Charges migrate to the surface of the sheet, neutralizing the photogenerated charge in the illuminated areas. Thus, the sheet carries an electrostatic, latent image that is subsequently decorated by colored particles charged opposite to the latent charge on the surface. This converts the electrostatic image to a permanent image once the particles are “fixed” to the surface (i.e. via heating). For a comprehensive description of organic photoconductors used in electrophotography, the reader is referred to reviews by Law (1993) and Weiss and Abkowitz (2010). It is worth noting that electrophotography provided the materials, and in many ways inspired early successful demonstrations of efficient OLEDs and OPVs at Kodak in the 1980s (Tang, 1986, Tang and VanSlyke, 1987), and that ultimately led to our current “organic electronic revolution.”

The electrophotographic configuration differs from that of the discrete organic photoconductive (OPC) device that converts light to a photocurrent. Due to their inferior performance (i.e. low bandwidth and high noise) compared to photodiodes, there are few reports of OPCs developed for sensitive detection purposes. However, these deficiencies are partially counterbalanced by photocurrent gain, and the relative simplicity of the OPC.

There is considerable confusion that leads to misidentification of photoconductors as photodiodes (Aihara et al., 2003, Campbell and Crone, 2007, 2009, Hokuto et al., 2011). It is therefore important to once more articulate their distinct attributes. (i) A photoconductor does not have a junction. This results in symmetrical, Ohmic characteristics under an applied voltage of both polarities. That is,  $j \propto V$  over the full range of normal operation. A diode-like, rectifying characteristic indicates the presence of a junction arising from the presence of two different semiconductors (i.e. a HJ), or at the contacts (a Schottky barrier). Indeed, asymmetrical rectifying characteristics are an unmistakable feature of an OPD. (ii) Photocurrent gain is observed in an OPC but not in an OPD. In Section 7.1, we noted that the unambiguous identification of gain can be problematic, given that the photocurrent is proportional to  $g\eta_{ext}$ . If  $\eta_{ext}$  is small, the product  $g\eta_{ext}$  may be less than unity. Hence, to ensure that there is photoconductive gain, a comparison of the device response with a calibrated detection standard with a known efficiency must yield  $g\eta_{ext} > 1$ . Otherwise it is possible to assume that the external efficiency is very small, resulting in a gain that is mistakenly inferred to be large, and still arrive at  $g\eta_{ext} < 1$ . (iii) The photocurrent is proportional to  $V_a$  in the OPC, whereas in an OPD,  $j_{ph}$  is independent, or at best weakly dependent on voltage. Recall from Eq. 7.7

that the OPC photocurrent gain follows  $g \propto V_a$ . Hence,  $j_{ph} \propto g\eta_{ext} \propto V_a$ . In contrast,  $g = 1$  at all voltages for an OPD. (iv) Lacking a rectifying junction, an OPC does not exhibit a photovoltaic effect (cf. Fig. 7.17). That is, its  $j$ - $V$  characteristics intercept the origin both in the dark and under illumination. Thus, an OPC cannot be used as a photovoltaic power source. By meeting all four of these performance criteria, an OPC can be clearly distinguished from a photodiode.

A device with all of the attributes of a photoconductor is the interdigitated structure in Fig. 7.28a. The OPC uses a conventional lateral geometry where the semiconductor (a 200 nm thick pentacene layer) is deposited by VTE onto the surface of a  $3 \times 3 \text{ mm}^2$  interdigitated Cr/Au electrode pattern, with an electrode “finger” width of 10  $\mu\text{m}$  separated by 20  $\mu\text{m}$  long photoconductive channels. Light is incident onto the electrodes via the glass substrate. The  $I$ - $V$  characteristics in the dark and under illumination are shown in Fig. 7.28b. The characteristics are symmetrical, since both electrodes are comprised of the same metal (and hence the same work function). The small nonlinearity in the curves is an indication of a residual extrinsic injection from the contacts. However, this small deviation from Ohm’s law is insufficient to significantly affect the photoconductive nature of the device. Under illumination, the increase

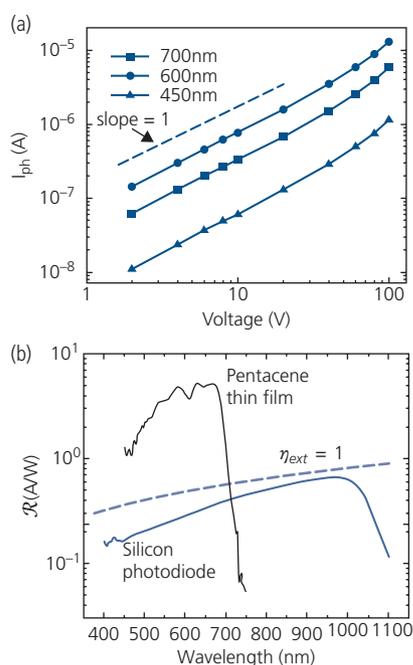

**Figure 7.28** (a) Schematic illustration of a pentacene OPC and its test circuit. (b) Current–voltage characteristics of the OPC in the dark and under 0.5 mW illumination at  $\lambda = 632 \text{ nm}$  (Gao and Hegmann, 2008).

in current is due to the addition of a photoconductive current,  $i_{ph}$ . Note that even in the presence of a photocurrent, the  $I$ - $V$  curve still intercepts the origin, indicating a lack of a photovoltaic effect, which is consistent with the absence of a rectifying junction.

The operating characteristics of the pentacene OPC are shown in Fig. 7.29. The photocurrent is linear in voltage to  $V_a \sim 60$  V (Fig. 7.29a). At higher voltages, the photocurrent increases superlinearly, possibly due to trap filling or heating. Nevertheless, the adherence to Ohm's law over a wide range of voltage is clear.

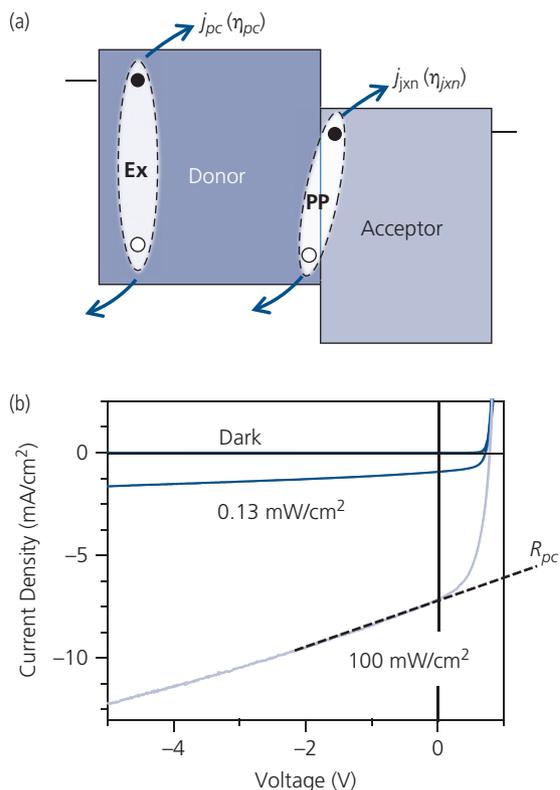

Figure 7.29b shows the responsivity of the OPC compared with a Si photodiode used to determine the OPC efficiency. Also shown is a line corresponding to a unity external efficiency. Due to the dependence of  $\mathcal{R}$  on incident wavelength, the external efficiency has a slope that increases with  $\lambda$ . Importantly, the OPC shows a responsivity that significantly exceeds that for  $\eta_{ext} = 1$ , providing unambiguous evidence for the presence of photocurrent gain. From the OPC responsivity and analysis of the photocurrent spectra with voltage, it is found that  $g = 16$ . The gain decreases with increasing optical input power, following a sublinear dependence of  $g = \tau_t \mu_e V_a / L^2 [1 + (P/P_0)^n]$ , where  $n = 0.65$ . This dependence is attributed to shallow electron traps, with a

**Figure 7.29** (a) Photocurrent–voltage characteristics of the OPC in Fig. 7.28 at three different wavelengths shown in the legend. The dashed line indicates a unity slope. (b) Responsivity vs. wavelength of the OPC, also showing that of a Si photodiode used to determine the OPC efficiency. Dashed line shows the response expected for a unity external quantum efficiency (Gao and Hegmann, 2008).

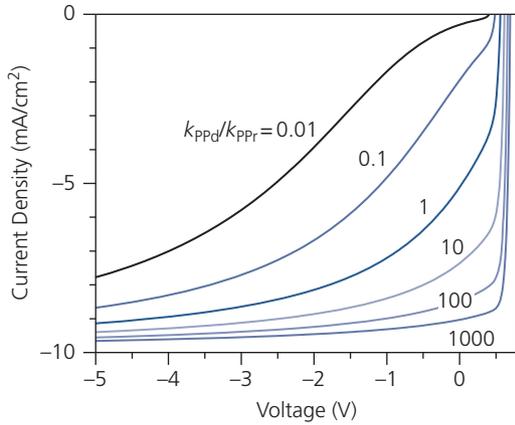

trap residence time,  $\tau_t$ . As power increases, the traps become saturated with charge, and the transit time decreases, resulting in the concomitant decrease in gain.

The presence of a rectifying junction does not rule out the possibility that photoconductivity may also contribute to the photoresponse of a photodiode. Indeed, photogeneration in regions beyond the depleted zones has been quantified for planar phthalocyanine donor/ $C_{60}$  acceptor HJ diodes (Jeong et al., 2012, Renshaw et al., 2012). This combination of effects complicates the analysis of the  $j$ - $V$  characteristics beyond that used to describe the ideal situation where all the charge is generated by excitons arriving and dissociating at the D-A HJ. The effect of photoconductivity on the photocurrent characteristics of the D-A HJ photodiode are illustrated in Fig. 7.30a for a device with structure: ITO/SubPc (13 nm)/ $C_{60}$

**Figure 7.30** (a) Energy level diagram of a HJ photodiode showing two sources of photocurrent: polaron pair (PP) dissociation at the HJ leading to a slope in the reverse-biased photocurrent,  $j_{jxn}$ , and exciton (Ex) dissociation in the bulk of the donor or acceptor layer leading to a photoconductive current,  $j_{pc}$ . (b) Bipolar  $j$ - $V$  characteristics of a SubPc (donor)/ $C_{60}$  (acceptor) planar HJ photodiode in the dark and under white light illumination at two different incident powers. The slope of the dashed line extrapolation from the linear reverse characteristics gives the photoresistance,  $R_{pc}$ . Data from Renshaw et al. (2012).

(40 nm)/BCP (8 nm)/Ag (100 nm). The two sources of photocurrent are direct exciton dissociation in the bulk with efficiency,  $\eta_{pc}$ , and exciton migration to the D-A junction with efficiency,  $\eta_{jxn}$ . The photoconductive contribution, according to Eq. 7.4, should scale linearly with voltage. In Fig. 7.30b, we show the bipolar  $j$ - $V$  characteristics in the dark and under white light illumination. Over a wide range of reverse bias, the current under illumination linearly increases, along with a current contribution due to a photoconductance,  $R_{pc}^{-1}$ .

We have found in Section 4.7.2 (cf. Eq. 4.303 and 4.305) that the voltage dependence of the junction current under reverse bias is due to field-induced PP dissociation; an effect observed for both planar and bulk HJs (Mihailetchi et al., 2004, Giebink et al., 2010a, Giebink et al., 2010b, Limpinsel et al., 2010). Contrary to the simple linear dependence on voltage predicted for photoconductivity, field-induced PP dissociation increases approximately exponentially, and can be mistaken for photoconductivity (Braun, 1984). In Fig. 7.31, the reverse  $j$ - $V$  characteristics are plotted for an ideal HJ diode in the absence of photocurrent, but for varying ratios of  $k_{PPd}$  to  $k_{PPr}$ . Over this extended range of reverse bias, there is no region where the curves are linear as in Fig. 7.30 due to the dominance of Onsager–Braun (O-B) dissociation, with its approximately exponential voltage dependence.

PP dissociation via O-B resulting in  $j$ - $V$  characteristics similar to those predicted in Fig. 7.31 has been

**Figure 7.32** Current–voltage characteristics of P3HT:PC<sub>61</sub>BM BHJ photodiode under 1 sun intensity illumination from a white emitting LED.  $V_{POS}$  is the voltage at the symmetry point in the  $j$ - $V$  characteristics. Data are points for Ag (circles) and Ca/Al (squares) cathodes, and lines are fits to the data assuming O-B and Sokel–Hughes processes. Inset: Experimental  $j$ - $V$  characteristics on a log-log scale of the Ca/Al BHJ, as well as fits to O-B (dotted line), S-H (dashed line), and their combination (solid line). Axis on the right is the O-B dissociation probability (Limpinsel et al., 2010).

observed in PC<sub>61</sub>BM acceptor-based BHJ diodes in Fig. 7.32. The characteristics are symmetric about voltage,  $V_{POS}$ , between 0.52 and 0.64 V. This is the built-in potential along with a contribution from differences in the contact work functions (either Ca/Al or Ag cathodes, and an ITO anode). The field at the contacts partially depletes the semiconductor, and hence reduces the internal electric field to  $F = |V_a - V_{POS}|/d$ , where  $d$  is the BHJ film thickness. The photogeneration process is due to two processes in these diodes: excitons can either migrate to a P3HT (D)-PC<sub>61</sub>BM (A) HJ where they form a PP. Alternatively, the large work function/LUMO offsets can separate the PPs at the cathode, yielding a constant photocurrent offset of  $j_{cont}$ .

In the bulk, the field-assisted PP dissociation efficiency determined from O-B theory is given by:

$$P_{O-B}(F) = \eta_{ppd}(F) = \frac{k_{PPd}(F)}{k_{PPd}(F) + k_{PPr}} \quad (7.104)$$

Dissociation is followed by charge collection, whose efficiency,  $\eta_{CC}$ , is also dependent on the electric field. That is, the charges can recombine due to collisions with counter charges (e.g. photogenerated electrons with holes) in the entangled BHJ regions where high densities of charges find themselves in close proximity under intense illumination. Charge recombination

in insulators prior to collection leads to a collection efficiency of (Sokol and Hughes, 1982)

$$\eta_{CC}(V) = \frac{\exp(qV/k_B T) + 1}{\exp(qV/k_B T) - 1} - \left( \frac{2k_B T}{qV} \right) \quad (7.105)$$

The voltage dependences of both PP dissociation via O-B in Eq. 4.305 and collection via Eq. 7.105 lead to a photocurrent in both the forward and reverse directions that is described by combining Eqs. 7.104 and 7.105 to obtain (Limpinsel et al., 2010)

$$\begin{aligned} j_{ph} &= qGdP_{O-B}(F)\eta_{CC}(V_a - V_{POS}) + j_{cont} \\ &= qGd\eta_{PPd}(F)\eta_{CC}(V_a - V_{POS}) + j_{cont}. \end{aligned} \quad (7.106)$$

As previously,  $G$  is the exciton generation rate.

Results of fitting Eq. 7.106 to the  $j$ - $V$  data of the P3HT:PC<sub>61</sub>BM cell are shown by the solid lines in Fig. 7.32. The photocurrent offset due to photogeneration at the contacts leads to a higher  $j_{cont}$  for the device with a Ag compared to a Ca/Al cathode. The various contributions to the photocurrent from field-dependent PP dissociation, and from recombination in the bulk, are plotted in the inset for the Ca/Al cathode. Note that near  $V_{POS}$ , the  $j$ - $V$  response is linear and is indistinguishable from photoconductivity.

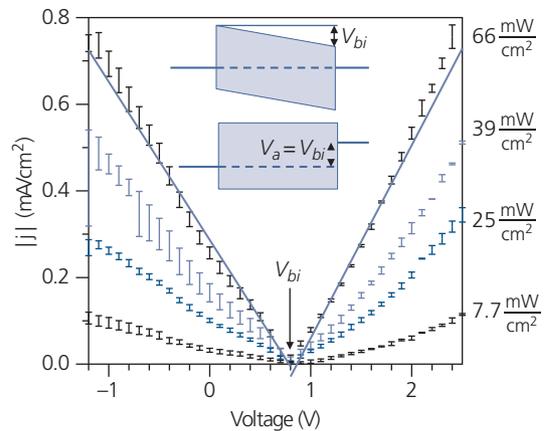

Photoconductivity can, indeed, dominate the current in reverse bias (e.g. Fig. 7.30). In this case, we can extend the analysis for an ideal HJ in the presence of traps to obtain

$$\begin{aligned} j &= j_{OD} \left[ \exp(q(V_a - jR_{ser})/n_D k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right] \\ &+ j_{OA} \left[ \exp(q(V_a - jR_{ser})/n_A k_B T) - \frac{k_{PPd}}{k_{PPd0}} \right] \\ &- j_{xn} + j_{pc} \end{aligned} \quad (7.107)$$

where, using Eq. 7.4, we obtain the photoconductive contribution to the current in terms of its charge generation efficiency,  $\eta_{pc}$  (Renshaw et al., 2012):

$$\begin{aligned} j_{pc} &= S_{pc}(V_a - jR_{ser} - V_{bi}) \\ &= q\eta_{pc}G(\tau_e\mu_e + \tau_h\mu_h)(V_a - jR_{ser} - V_{bi})/d. \end{aligned} \quad (7.108)$$

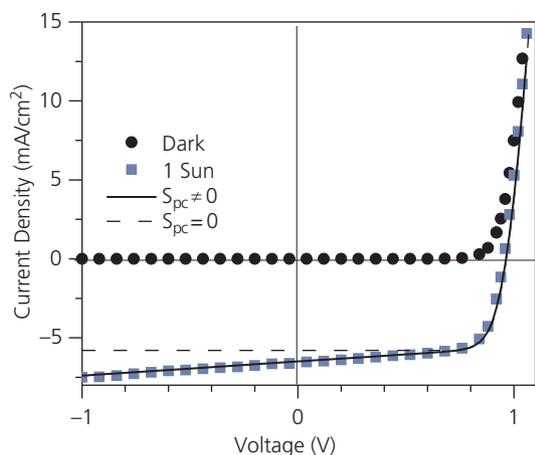

The  $j$ - $V$  characteristics can be fit by Eq. 7.107, provided that an independent measurement of the photoconductance,  $S_{pc} = 1/R_{pc}$ , is separately obtained for the D and A layers of the HJ. This is found by measuring the photoconductivities of single layer devices comprising either the D or A layer sandwiched between ohmic electrodes. Figure 7.33 shows one such measurement for an ITO (150 nm)/SubPc (60 nm)/Ag (100 nm) OPC at several different simulated solar illumination intensities. The symmetric characteristics increase linearly for both positive and

**Figure 7.33** Response of an ITO/SubPc/Ag photoconductor to different intensities of simulated solar illumination. The solid line is a linear fit to the data. Inset: Energy level diagrams of the PC at (top) equilibrium and (bottom) flat band. Adapted from Renshaw et al. (2012).

negative  $V_a$ , as expected for a photoconductor in the absence of space charge effects or energy level bending. The photocurrent is zero at  $V_a = V_{bi} = 0.8$  eV, which is equal to the work function differences of the cathode and anode contacts. Unlike the BHJ in Fig. 7.32, there is no evidence for energy level bending at the contacts. The energy level diagrams for this device at both equilibrium and at flat band, where the absence of an electric field results in  $j_{pc} = 0$ , are shown in the inset. From these and similar data obtained from a C<sub>60</sub> OPC, it is found that  $S_{pc} = 0.40$  mA/V cm<sup>2</sup> at a light intensity of 66 mW/cm<sup>2</sup> for SubPc and  $S_{pc} = 0.82$  mA/V cm<sup>2</sup> at 100 mW/cm<sup>2</sup> for C<sub>60</sub>.

Photoconductivity measurements were used to fit the planar SubPc/C<sub>60</sub> HJ characteristics in Fig. 7.30, using  $S_{pc} = 0.90$  mA/V cm<sup>2</sup> at 1 sun (100 mW/cm<sup>2</sup>) intensity, white light illumination. The fits also assume  $j_{OA} = 1.0$  pA/cm<sup>2</sup>,  $j_{OD} = 47$  nA/cm<sup>2</sup>,  $R_{ser} = 3.7$  Ω cm<sup>2</sup>, and ideality factors of  $n_A = 1.6$ , and  $n_D = 5.9$ . These parameters, along with  $V_{bi} = 0.8$  V then provide a simulation of the illuminated  $j$ - $V$  data shown by the solid line in Fig. 7.34. The dashed line only includes effects of  $k_{PPd}(V_a)$  from Onsager–Braun dissociation that does not account for the observed reverse-biased voltage dependence. By including the additional current due to photoconductivity, the simulation and the device data are in agreement over the entire range of measurement, indicating efficient PP dissociation and the importance of photoconductivity in these archetype OPV structures. The presence of photoconductance results in an increase in  $j_{sc}$  by 15% in the SubPc/C<sub>60</sub> devices. Hence, in

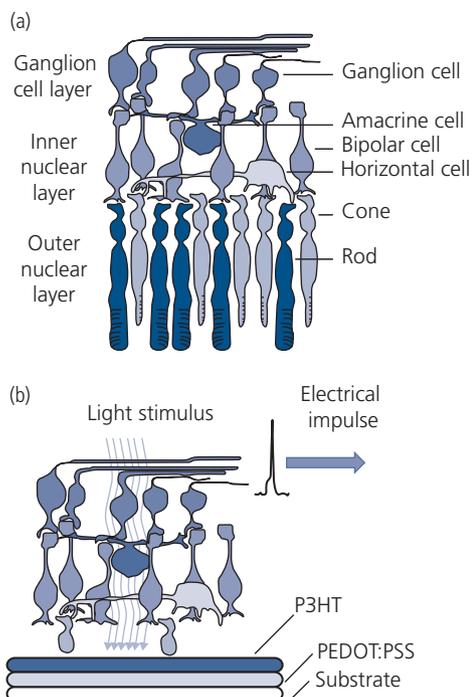

**Figure 7.34** Current–voltage characteristics in the dark (circles) and under 1 sun intensity, simulated solar illumination (squares) of the D-A HJ in Fig. 7.30. The dashed line is a fit to Eq. 7.55 in the absence of photocurrent ( $S_{pc} = 0$ ), and the solid line includes  $S_{pc}$  as independently measured for SubPc and  $C_{60}$  photoconductors in Fig. 7.33 (Renshaw et al., 2012).

planar HJs, this effect cannot be ignored, although in bulk and mixed HJs where there are no undepleted photoactive regions, the contributions of photoconductivity are insignificant.

Photoconductors have seen few photonic device applications. One notable exception is the use of P3HT photoconductors as photoreceptors in retinal implants. The polymer is deposited on an aqueous PEDOT:PSS electrode on a 30  $\mu\text{m}$  thick silk fibroin substrate, illustrated in Fig. 7.35. The unit was implanted into a rat retina whose photoreceptive rod and cone cells had degenerated from retinitis pigmentosa (Ghezzi et al., 2013). The ionic, aqueous environment within the retina creates the second contact that interfaces with the inner nuclear layer. When illuminated, photogenerated electrons stimulate the nerve cells that contact the photoconductor, sending an electrical impulse to the brain via the ganglion network. Thus, retinal photosensitivity was restored (Maya-Vetencourt et al., 2017). The biocompatibility, flexibility, and functionality of organic electronics make this technology attractive for such medical prosthetics.

## 7.2.2 Photodiodes

An optimized photodetector should be designed to have a high bandwidth, low dark current (and hence low noise), and most importantly, high external quantum efficiency. This combination of attributes requires that the materials, layering scheme and

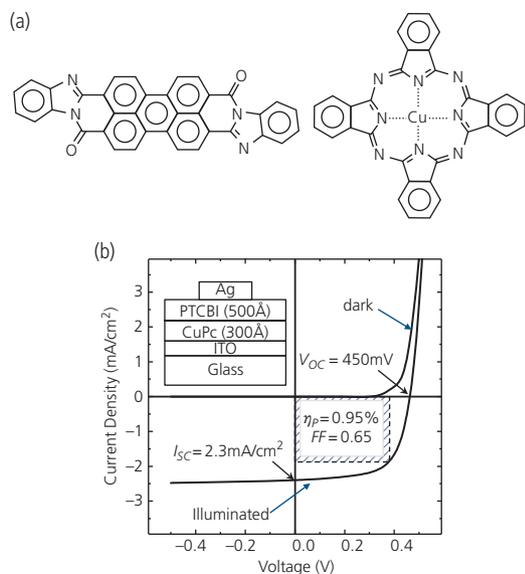

**Figure 7.35** (a) Normal retina structure showing light-receptive rod and cone cells connected to the ganglion cell layer that delivers electrical impulses to the brain when activated by light. (b) A degenerated retinal structure where the photoreceptive cells are replaced by a P3HT photoconductor. Illumination of the OPC generates charges that stimulate the nerve network, analogous to direct stimulation of the rods and cones. Adapted from Ghezzi et al. (2013).

layer morphology be selected and controlled to achieve the required performance goals. In this section, we will primarily focus on photodiodes for signal detection, and leave the discussion of solar cells to Section 7.3. However, since many of the attributes of OPDs are shared with OPVs, it is not possible to completely separate the discussion of devices that are optimized for both applications. Hence, to fully understand the operation of an OPV, we must first take a close look at detectors used as optical sensors.

### 7.2.2.1 Photodiode materials

The first bilayer OPD with a high rectification ratio (i.e. the ratio of current in the forward to that in the reverse biased direction at the same  $|V_a|$ ) comprised the donor, CuPc, and the acceptor, PTCBI. The  $j$ - $V$  characteristics obtained in the dark and under 75  $\text{mW}/\text{cm}^2$ , AM2 simulated solar illumination (see Section 7.3) are shown in Fig. 7.36. The device area as determined by the Ag cathode was 0.1  $\text{cm}^2$ . The donor, acceptor, and cathode layers were deposited by VTE. The HJ formed between the D and

**Figure 7.36** (a) Molecular structural formulae of the acceptor, PTCBI (left), and the donor, CuPc (right). (b) Current–voltage characteristics of the OPV under AM2 white light illumination of  $75 \text{ mW/cm}^2$ . The short circuit current ( $I_{SC}$ ) and open circuit voltage ( $V_{OC}$ ) are shown, along with the power conversion efficiency ( $\eta_p$ ) and fill factor ( $FF$ ) at the maximum power point. Inset: Device structure. Adapted from Tang (1986).

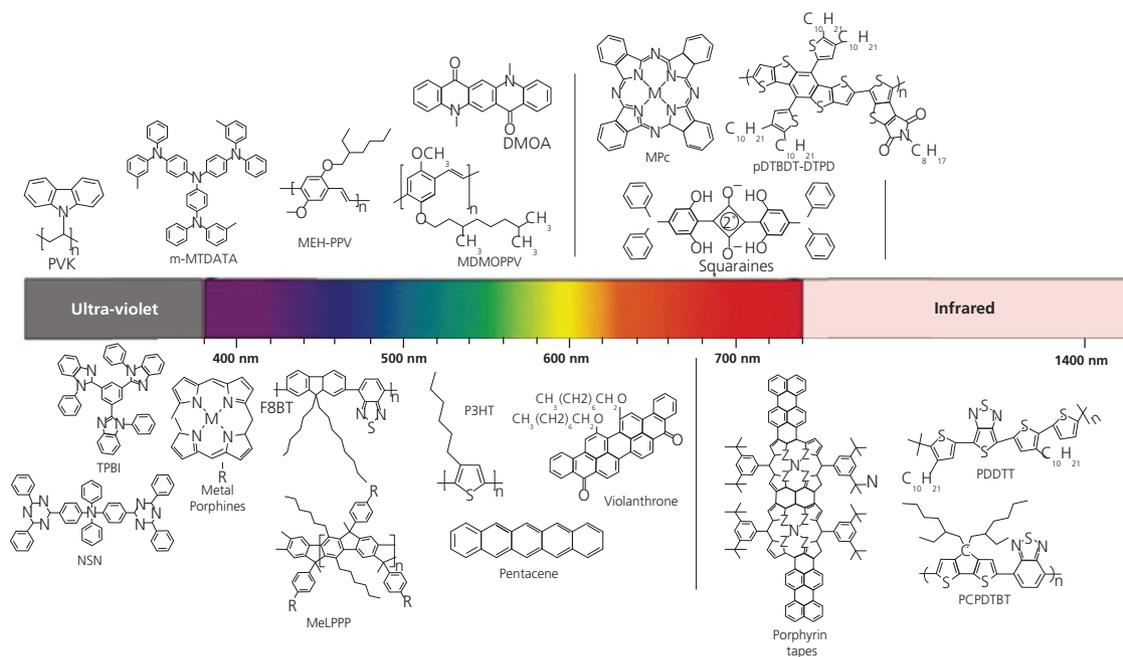

A molecule produces an apparently exponential turn-on in the forward direction, and a low dark current of  $5\text{--}10 \text{ nA/cm}^2$  under reverse bias. The ideality factor, determined from the forward-biased characteristics fit to the Shockley diode equation, is  $n = 1.5\text{--}1.7$  (Tang, 1986). The operation of this OPD is consistent with discussions both in Chapter 4 and Section 7.1, that is, excitons generated within the D and A layers drift to the HJ where they undergo dissociation. The liberated electrons flow in the acceptor to the cathode, and the holes transport through the donor to the anode.

Since this demonstration, many other donor and acceptor materials have been identified that have led to higher optical response and improved sensitivity. The donors are chosen to absorb in the wavelength range of interest while ensuring that the positions of the frontier HOMO and LUMO levels create a type II (staggered) HJ with the acceptor. The energy level offsets between the HOMO and LUMO levels of the D and A pair must be sufficiently large to promote efficient PP formation, followed by their dissociation into free charge. This requires HOMO and LUMO energy offsets of  $0.2\text{--}1 \text{ eV}$ .

There are several reviews of materials used in OPDs and OPCs (Dong et al., 2012, Baeg et al., 2013, Jansen-van Vuuren et al., 2016). We provide a few selected examples of donors and acceptors employed

in photodiodes for light sensing applications, with further example materials with particular applications to solar energy conversion discussed in Section 7.4.4. Figure 7.37 shows several example OPD donor materials and their respective absorption bands. Molecules that span the spectrum from the UV for solar blind detection, all the way to the SWIR band between  $0.9$  and  $1.7 \mu\text{m}$  wavelength, have been developed for use in high efficiency detectors. The most commonly employed donor is P3HT due to its compatibility in forming bulk HJs with PCBM. With an energy gap of  $1.9 \text{ eV}$ , it absorbs from the light blue into the red. Similarly, MEH-PPV is a soluble, red-to-green absorbing material that can be paired with an appropriate acceptor to access the middle of the visible spectrum (Halls et al., 1995, Yu et al., 1995). Several polymers used in OPDs that absorb farther into the red and NIR have also been demonstrated, such as PDDTT (Gong et al., 2009) and PCPDTBT (Peet et al., 2007) in Fig. 7.37 that have long wavelength absorption cut-offs at  $1300 \text{ nm}$  and  $950 \text{ nm}$ , respectively.

There are numerous donors based on small molecules that span the spectrum from the UV into the SWIR region. One particularly broad class of molecules is the metal phthalocyanines, MPcs. Their high thermal stability, ease of vacuum thermal sublimation, reasonably good hole mobilities, and diversity of optical absorption spectra resulting from the large choice of metal centers (most notably Zn, Cu, Sn, and Pb) makes them attractive for detection. Metal Pcs have been used in detectors sensitive from the green into the NIR (Tang, 1986, Peumans and Forrest, 2001, Bailey-Salzman et al., 2006, Pfuetzner et al., 2009). Porphyrins, whose properties are closely related to the Pcs, have also been employed for optical sensing. A notable example is porphyrin tapes, where two or more porphyrin rings are fused to increase the electron conjugation length, thus pushing absorption to wavelengths as long as  $1400 \text{ nm}$  (Zimmerman et al., 2010a). The linear polyacene, pentacene, and polyacene derivatives such as rubrene have also been used due to their high hole mobilities (and hence high operating bandwidths when employed in OPDs) and absorption in the visible (Tsai et al., 2009, Yang et al., 2013). Many of the donors used for detection in the blue and UV have their origins as hole conducting hosts and transport layers. Hosts require large energy gaps to effectively transfer excited states to lower energy dopant molecules. Furthermore, the high mobilities required for hole transport make them suitable as donors. Two examples in Fig. 7.37 are m-MTDATA with a long wavelength cutoff of  $375 \text{ nm}$ , NSN with a cutoff of

**Figure 7.37** Example donor molecules employed in OPDs are shown, along with the spectral range of their absorption from the ultraviolet into the short wavelength infrared (SWIR).

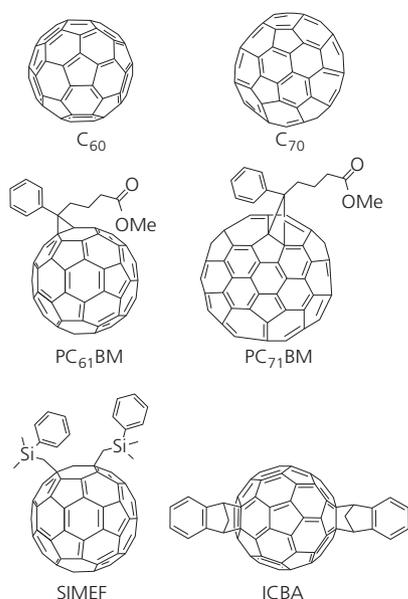

310 nm, and TPBi (cutoff of  $\sim 400$  nm) (Yan et al., 2009). When combined with a UV absorbing acceptor such as the polymer, PVK, the detectors are useful in environments with large background solar irradiation. This allows for so-called *solar-blind detection*, which is used to detect deep UV light that is emitted, for example, by the flame from a missile or jet engine. This emission must often be detectable in bright sunlight, or when viewed while backlit by the sun (Li et al., 2011).

In contrast to donors, comparatively few acceptors have been developed. An acceptor must have good electron conductivity along with appropriately positioned HOMO and LUMO levels relative to the donor for efficient exciton dissociation. In subsequent sections, we will find that the advancement of solar cell efficiency has primarily been paced by the identification of new, efficient acceptor molecules. The rectifier in Fig. 7.36 uses a perylene-based acceptor due its large LUMO energy. However, solar cell power conversion efficiencies employing thermally deposited perylenes has been limited to only  $\sim 1\%$ . In the 1990s, the fullerene,  $C_{60}$  (Yu et al., 1994) and its soluble derivative  $PC_{61}BM$  (Yu et al., 1995) were successfully used in efficient solution-based detectors, and this was extended to small molecule based OPDs and OPVs in 2001 (Peumans and Forrest, 2001). More recently,  $C_{70}$  and its analog,  $PC_{71}BM$ , have been favored due to their broader spectral absorption than their  $C_{60}$ -based analogs.

Functionalization with silyl groups in SIMEF raises the LUMO energy to  $-3.7$  eV compared to  $-3.8$  eV for  $PC_{61}BM$ , increasing  $\Delta E_{HL}$ , and hence the open circuit voltage of OPDs operated in the photovoltaic mode. In addition, its favorable packing morphology is helpful for promoting electron transport (Matsuo et al., 2009). The fullerene, ICBA, also has frontier orbital energies that can provide a slightly modified optical absorption and energy offsets from  $PC_{61}BM$ . It also has improved solubility that broadens applications accessible to the fullerene family. Several of example fullerenes are shown in Fig. 7.38.

Fullerene acceptors led to the first solution-processed BHJ (Yu et al., 1995) and mixed HJ structures (Xue et al., 2005). Their spherical symmetry leads to rapid and efficient PP production in planar as well as blended D-A films. The success of fullerene acceptors in achieving high OPD and OPV efficiencies was unmatched by other molecules until the middle of the second decade of the twenty-first century when a new class of non-fullerene, non-perylene acceptor molecules (called *non-fullerene acceptors*, NFAs) emerged, an advance that has led to a renewed burst of development of high efficiency OPDs (see Section 7.4.4).

A limitation of the fullerene family is apparent from the very few modifications that have been introduced to tailor their energetic and/or physical properties. Indeed, the molecules in Fig. 7.38 represent

**Figure 7.38** Fullerenes used in organic photodiodes. C<sub>60</sub> and C<sub>70</sub> are employed in small molecule devices. The remaining fullerenes are used in solution-based devices due to their solubility arising from attaching the pendant groups to the fullerene cores.

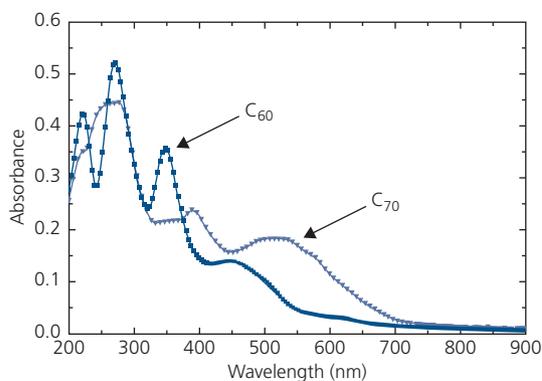

almost all examples that have been used in high efficiency detectors.

The absorbance spectra of C<sub>60</sub> and C<sub>70</sub> are given in Fig. 7.39. Absorbance is defined as the logarithm of the transmittance of a substance, that is,

$$A = -\log_{10} T = \int_0^d \alpha_{10}(x) dx, \quad (7.109)$$

where the film thickness is  $d$  and  $\alpha_{10}$  is the *decadic attenuation coefficient* given by  $\alpha_{10} = \alpha / \log_{10}$ . The higher order fullerene, C<sub>70</sub>, is preferable for most OPD and OPV applications due to its absorption into the NIR, whereas C<sub>60</sub> only absorbs weakly from the yellow to red due to low absorbance of the CT state between 550 and 650 nm.

The squaraines (SQs) are solution processed small molecules that can be functionalized by capping end groups that shift their absorption spectra from the visible to the NIR. For example, the modified SQs such as the diphenyl moiety in Fig. 7.37 absorbs out to 850 nm (Binda et al., 2009, Wei et al., 2011b). An example glycolic chain-substituted SQ (GlySQ) blended with PC<sub>61</sub>BM has demonstrated high efficiency as a photodetector due to its low dark current. The detector dark current was reduced by interposing a 30 nm thick layer of a cross-linked and insoluble, wide energy gap MEH-PPV anode buffer layer between

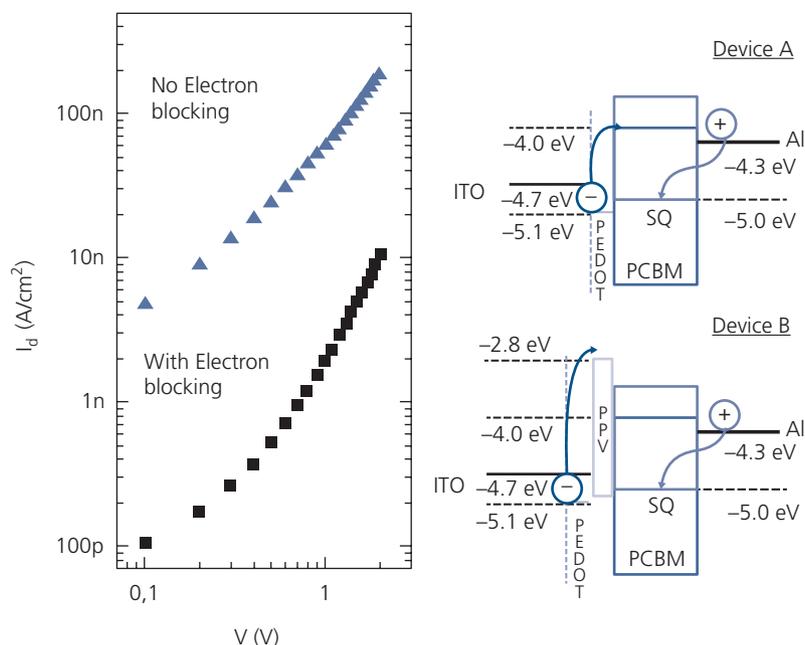

**Figure 7.39** Absorbance spectra of 20 nm thick C<sub>60</sub> and C<sub>70</sub> films (Pfuetzner et al., 2009).

the ITO anode and the BHJ active region to prevent electron injection under reverse bias, as shown in Fig. 7.40. Dark currents of 2 nA/cm<sup>2</sup> at 1 V reverse bias are indicative of the importance of anode buffer layers, to be discussed further in Section 7.4.1 in the context of OPVs. The specific detectivity at this voltage for a 4 mm<sup>2</sup> detector is  $D^* = 3.4 \times 10^{12}$  Jones vs.  $5.9 \times 10^{11}$  Jones for devices with and without the buffer, respectively. The 3 dB roll off frequency is 1 MHz, indicating that parasitic resistance from the electron-blocking layer does not degrade the detector dynamic response.

Demonstrating devices with high quantum efficiencies at wavelengths extending into the NIR and beyond is particularly difficult to achieve due to the energy gap law (see Section 3.6.1), which states that the rate of non-radiative exciton recombination increases as the energy gap is reduced. Hence, narrow energy gap materials needed for NIR detection are vulnerable to dissipative reactions that ultimately result in reduced diffusion lengths, and hence lower efficiencies. In addition, narrow energy gaps lead to increased dark currents due to thermal charge generation from HOMO to LUMO. In spite of these challenges, considerable success has been achieved in demonstrating efficient NIR photodetectors using optimized materials.

An efficient long wavelength organic detector is based on solution-processed small molecular weight porphyrin tapes comprising two Zn-metallated porphyrins, triply-linked at the meso-meso and both  $\beta$ - $\beta$  positions shown in Fig. 7.41. Long wavelengths are accessed by molecular linking to extend the electron conjugation length, thereby leading to a reduced energy gap compared to the core porphyrin molecule itself (Tsuda and Osuka, 2001, Duncan et al., 2006). The Zn porphyrins with 3,5-di-*tert*-butylphenyl

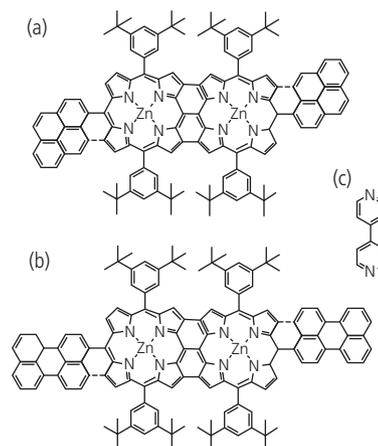

**Figure 7.40** Reverse dark current characteristics of a GlySQ:PC<sub>61</sub>BM OPD in presence and absence of an MEH-PPV electron blocking layer at the anode. Energy level diagrams for the devices are shown at right. Dashed lines give the energies of the corresponding organic and ITO layers (Binda et al., 2011).

side groups in Fig. 7.41 are functionalized by using three different terminations: Psub with singly bonded pyrene, Pfused with a doubly-bonded pyrene, and Ppery with a doubly fused perylene. The conjugation length is shortest for Psub, and longest for Ppery. Forming the additional bond to the pyrene end group reduces the energy gap of Psub by 0.20 eV. The absorption peaks are at 1150 nm (Psub), 1400 nm (Pfused), and 1485 nm (Ppery). The compounds absorb throughout the visible and into the NIR, with intense Q-band absorption peaks between  $\lambda = 1050$  nm and 1350 nm (Zimmerman et al., 2010a, 2011).

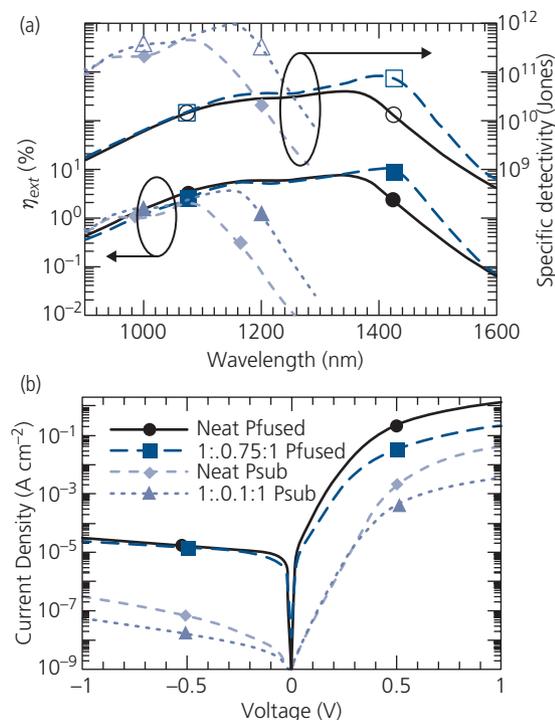

For Psub:PCBM:4,4'-bipyridyl (Bipy) additive (1:0.1:1), a maximum  $D^* = 8.8 \times 10^{11}$  Jones and  $\eta_{ext} = 3.6\%$  at  $\lambda = 1150$  nm was observed, whereas a Pfused:PCBM:Bipy (1:0.75:1) OPD had an order of magnitude lower  $D^*$ , but with  $\eta_{ext} = 10.5\%$  at  $\lambda = 1400$  nm. The  $j$ - $V$  characteristics, spectrally resolved external quantum efficiencies, and specific detectivities for Psub:PCBM:Bipy and Pfused:PCBM:Bipy devices are shown in Fig. 7.42. Devices using films of neat perylene-fused porphyrin dimers (not shown) achieved an  $\eta_{ext} = 9.1\%$  at  $\lambda = 1485$  nm (Zimmerman et al., 2011).

The detectivities achieved using the porphyrin tapes are significantly less than for other SWIR-sensitive detectors such as those based on InGaAs ( $\sim 10^{13}$  Jones), but are comparable to cooled PbS

**Figure 7.41** Fused Zn porphyrin donors with (a) singly (Psub) and doubly fused (Pfused) pyrene, and (b) a doubly fused perylene (Ppery). (c) 4,4'-Bipyridyl (Bipy) additive (Zimmerman et al., 2011).

detectors (Webster, 1999, Rogalski, 2002). The temporal response of the Psub-based OPDs to pulsed optical excitation using a 50  $\Omega$  load yielded a 3 dB roll-off frequency of 56 MHz at 0 V. The RC time constant-limited frequency of the OPD is  $\sim 200$  MHz, indicating that the response is limited by charge transit times or internal parasitic resistances (Zimmerman et al., 2010a).

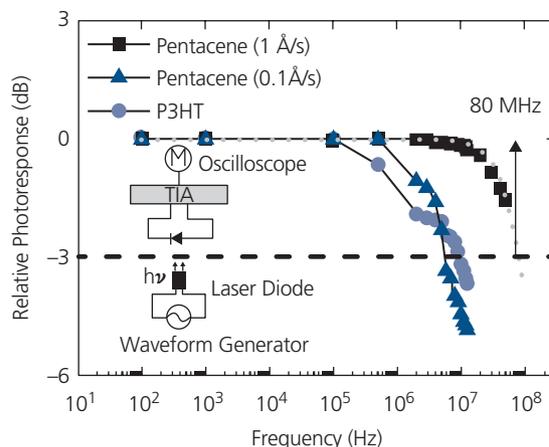

**Figure 7.42** (a) External quantum efficiency and specific detectivity spectra of devices fabricated from Psub and Pfused compounds in Fig. 7.41 with different additive concentrations. (b) The  $j$ - $V$  characteristics of the devices in (a). The molar ratios shown are for porphyrin:PC<sub>61</sub>BM: Bipy (Zimmerman et al., 2011).

There are other approaches to achieving long wavelength absorption such as employing the donor, BDN, that absorbs to  $\sim 1500$  nm (Dagleish et al., 2012), or ester functionalized PTT with absorption to 950 nm (Yao et al., 2007). However, the bandwidth and dark currents (and hence noise) of OPDs based on these thiol-based molecules do not achieve the high performance of OPDs employing porphyrin tapes.

### 7.2.2.2 High bandwidth OPDs

There have been numerous demonstrations of high bandwidth OPDs, ranging from several tens of MHz (Morimune et al., 2006, Tsai et al., 2009, Zimmerman et al., 2010a, Yang et al., 2013) to 430 MHz for multilayer OPDs absorbing across the visible spectrum (Peumans et al., 2000b, 2003b). As noted in Section 7.1.2, the bandwidth of a detector is limited by a combination of the exciton diffusion time, the charge extraction, or transit time in the depletion region, charge diffusion across undepleted regions, and the RC time constant due to detector series resistance and capacitance. The transit times, in turn, can be influenced by charge trapping at defects in both the depleted and undepleted regions of the OPD.

**Figure 7.43** Frequency response of donor/C<sub>60</sub> OPDs with the donors indicated in the legend. The dashed line follows  $P = P_0/(1 + f/f_{3dB})$  to obtain an extrapolated bandwidth of 80 MHz for the pentacene (1 Å/s) device. Inset: Test system used to measure bandwidth. TIA = transimpedance amplifier. The system bandwidth is 50 MHz, thus requiring the extrapolation to the  $-3$  dB intensity point of the highest bandwidth device. After Tsai et al. (2009).

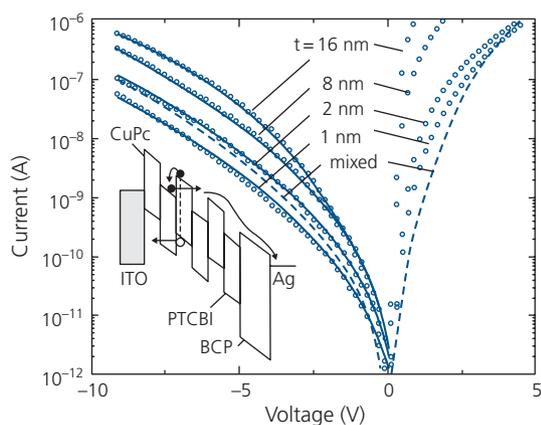

The bandwidth of a transit-time-limited device is determined by the hole mobility in the donor and the electron mobility in the acceptor. The mobilities, in turn, are affected by the presence of static disorder, see Section 4.3.2. The effects of disorder on detector bandwidth have been explored by comparing the bandwidths of C<sub>60</sub> devices comprising either a highly disordered P3HT donor layer, or with a pentacene donor thermally deposited in vacuum at various rates (Tsai et al., 2009). The responses of three, 4 mm<sup>2</sup> devices to a pulsed laser diode at a wavelength of 633 nm are shown in Fig. 7.43. The frontier energies of both P3HT and pentacene are nearly equal, thereby ensuring that differences in bandwidths between devices are due to morphology determined by the deposition rate rather than energetics that might affect the PP dissociation rate. The mobilities of the various layers, measured from their space charge limited  $j$ - $V$  characteristics were  $1.9 \times 10^{-3}$ ,  $6.0 \times 10^{-5}$ ,  $2.3 \times 10^{-5}$ , and  $2.8 \times 10^{-4}$  cm<sup>2</sup>/V s for C<sub>60</sub>, P3HT, and pentacene deposited at 0.1 Å/s and at 1 Å/s, respectively.

The high mobility sample (pentacene, 1 Å/s) has an eight-fold higher roll-off frequency of  $\Delta f = 80$  MHz compared to the other, more disordered devices. Here,  $\Delta f$  is measured at the frequency where they photoresponse drops by 3 dB from its value at low frequency. This difference is roughly equal to the corresponding differences in mobilities between the

donor films. All device responses are limited by the hole transit time across the donor layers.

A high bandwidth OPD with  $\Delta f = 430$  MHz is based on alternating D-A multilayer structure that places interfaces in close proximity to the points of exciton generation, resulting in  $\tau_{ED} \rightarrow 0$  (see the energy level diagram in the inset, Fig. 7.44). The device consists of a stack of ultrathin (ranging from 1 to 16 nm), alternating PTCBI acceptor and CuPc donor layers, sandwiched between an ITO anode and a BCP exciton blocking layer, and capped by a Ag cathode. To maintain sharp interfaces, the multilayer stack was deposited by the UHV process of organic molecular beam deposition (Section 5.4.2). The sharp interfaces require an external electric field to efficiently extract the photogenerated holes and electrons trapped by the energy barriers to electron and hole transport formed by the HOMO and LUMO energy offsets at each heterointerface.

The room temperature  $j$ - $V$  characteristics for devices with different individual layer thicknesses but with the same total thickness of 32 nm, are shown in Fig. 7.44. For comparison, data for a mixed-layer device (dashed line) is also shown. The differences between the mixed and the multilayer  $j$ - $V$  characteristics suggest different transport mechanisms; the multilayers are dominated by tunneling and the mixed HJ by charge diffusion (Peumans et al., 2003b). The dark current density at a fixed reverse voltage decreases by over an order of

**Figure 7.44** Current–voltage characteristics of 1 mm diameter OPDs comprising two, four, 16, and 32 layers (open circles) and mixed (dashed line) CuPc/PTCBI layers. The individual layer thicknesses are given by  $t$ . The number of layers is adjusted to reach a total absorption region thickness of 32 nm. Fits of the data to theory based on Frenkel–Poole emission are shown by solid lines. Inset: Schematic energy level diagram of the alternating donor–acceptor multilayer photodetector device under reverse bias. The process of exciton dissociation, followed by carrier separation via tunneling, is illustrated (Peumans et al., 2000b).

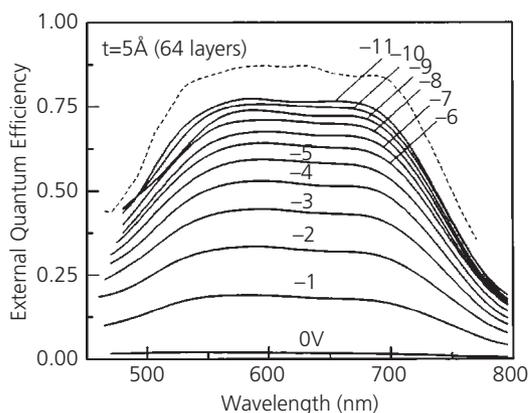

magnitude as the thickness of the individual layers is reduced from 16 to 0.5 nm.

The  $j$ - $V$  characteristics are understood by assuming that electrons and holes trapped in the acceptor and donor regions escape via *Frenkel–Poole emission* (see Section 4.3.2). This tunneling mechanism illustrated in Fig. 7.44 follows

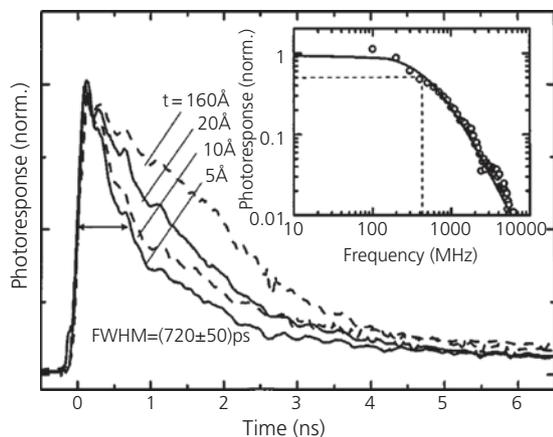

$$j(F) = AF \exp\left(\frac{q}{rk_B T} \sqrt{\frac{qF}{\pi\epsilon_r\epsilon_0}}\right), \quad (7.110)$$

where  $A$  is a constant and  $1 \leq r \leq 2$  is determined by the degree of impurity charge compensation ( $r = 2$  for a fully compensated semiconductor). The solid lines in Fig. 7.44 show fits to this expression using  $w_T$  inferred from capacitance–voltage data. The dark  $j$ - $V$  characteristics can be accurately fit over 5–6 orders of magnitude in  $j$  using Eq. 7.110. These data suggest that the PTCBI layers donate their electrons, and hence compensate all the charged acceptor levels in the adjacent CuPc layers up to a distance 10 nm from the heterointerface, thus fully depleting the multilayer stack.

The external quantum efficiency of a  $t = 5 \text{ \AA} \times 32$  alternating layer photodetector as a function of the applied bias is shown in Fig. 7.45. The absorption efficiency is also shown (dashed line). The similar spectral shapes of  $\eta_{ext}(\lambda)$  and  $\eta_A(\lambda)$  confirm that charge generation takes place via exciton dissociation. Under short circuit conditions, the peak  $\eta_{ext}(\lambda) = 1\%$ , increasing  $\eta_{ext}(\lambda) > 70\%$  between wavelengths of 540 nm to 700 nm at  $-10$  V. This indicates efficient exciton dissociation at the D-A interfaces followed by fast and complete charge separation and transport.

**Figure 7.45** External quantum (solid lines) and absorption efficiencies (dashed line) of a  $5 \text{ \AA} \times 32$  period PTCBI/CuPc OPD vs. wavelength and reverse bias (Peumans et al., 2003b).

**Figure 7.46** Temporal response of 0.1 mm diameter CuPc/PTCBI OPDs with varying individual layer thicknesses ( $t$ ) with a 320 Å total active layer thickness. Inset: Fourier transform of the temporal response of a 32-period device normalized to dc operation. The 3 dB bandwidth of the detector is  $\Delta f = 430$  MHz (Peumans et al., 2000b).

In spite of the many energy barriers present in the multilayer structures, carrier transport is rapid due to tunneling through the thin barriers. This is supported by measurements of the temporal response of 0.1 mm diameter devices under excitation with short ( $\sim 1$  ps) optical pulses at  $\lambda = 670$  nm and  $-9$  V, shown in Fig. 7.46. The response times decrease with increasing number of interfaces, which is contrary to expectations if charge percolation is by successive trapping and hopping, as typical for mixed junctions. Devices incorporating thinner layers exhibit a faster response due to a reduction in the exciton diffusion lifetime. The response time of the bilayer device ( $t = 160$  Å) is limited by the intrinsic exciton lifetime, which is 1.8 ns in a neat PTCBI. The highest bandwidth is achieved with the device with  $t = 5$  Å, which allows for rapid and efficient tunneling of electrons and holes throughout the device. This OPD exhibits a full width at half maximum (FWHM) response of 720 ps, corresponding to  $\Delta f = 430$  MHz. Interestingly, the combination of high quantum efficiency in conjunction with the high bandwidth makes the performance of this OPD comparable or even superior to Si p-i-n photodiodes, although the leakage currents, and hence the detectivity of the OPD is inferior to those latter PDs.

### 7.2.2.3 OPDs based on nanotubes and quantum dots

A means for extending OPD sensitivity into the NIR while avoiding rapid recombination in narrow energy gap organics is to combine long wavelength

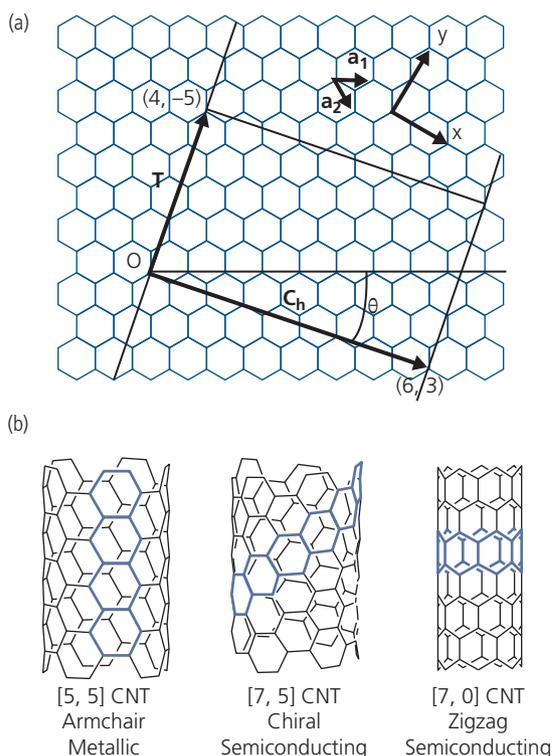

absorbing *inorganic* species in an organic matrix. Two inorganic materials that have been exploited for this purpose are semiconducting single-walled carbon nanotubes (SWNTs) and compound semiconducting quantum dots (QDs).

Carbon nanotubes (CNTs) can form very small energy gap semiconductor or metallic solids, depending on their diameters and chiralities. Provided that the metallic SWNTs are removed, light absorbed by the semiconducting nanotubes can generate low energy excitons that migrate to a type II HJ formed with an organic in a composite, or colloid, where they undergo charge transfer and generation similar to conventional organic D-A HJs.

We characterize the CNT structure by its *chirality* vector,  $C_h$ , shown in Fig. 7.47a. For a graphene sheet with unit vectors  $a_1$  and  $a_2$ :

$$C_h = na_1 + ma_2, \quad (7.111)$$

where  $n$  and  $m$  are integers. By wrapping the sheet into a cylinder about its axial vector,  $T$ , nanotubes of different chiralities are achieved. Examples of the *armchair*, *chiral*, and *zigzag* structures are shown

**Figure 7.47** (a) Carbon nanotube naming scheme based on graphene unit cell vectors,  $a_1$  and  $a_2$ .  $T$  denotes the tube axis. (b) Three example chiralities of SWNTs.

in Fig. 7.47b. The different chiralities result in strikingly different conductive properties. If  $n = m$ , the tube forms an armchair structure that is metallic. If  $n - m$  is a multiple of 3 with  $n \neq m$  and  $nm \neq 0$ , the band gap is very small, that is, the tube is quasimetallic, although semimetallic CNTs do not exist. Otherwise the tube is a semiconductor whose energy gap is varied both by its chirality and diameter.

Since an OPD requires that the composite be semiconducting, the metallic CNTs, as well as multiple walled tubes and bundles need to be removed from the source material stock. As discussed in Section 5.3.4, metallic and other undesired fractions can be separated using ultracentrifugation. This is a time consuming process, yet it has resulted in detectors with sensitivities deep into the IR.

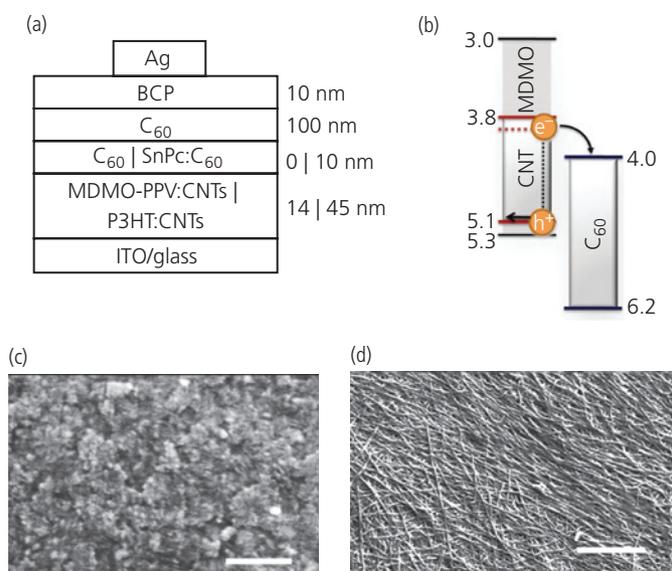

The first report of a composite detector employing a SWNT–polycarbonate blend was a photoconductor in the lateral geometry of Fig. 7.1. This device was sensitive in both the long wavelength IR and in the visible. It had a long recovery time constant ( $\sim 100$  s) after removal of the IR excitation, and showed only a few percent change in conductivity in the dark vs. under white illumination of  $0.7 \text{ mW/cm}^2$  (Pradhan et al., 2008).

This demonstration was followed by a CNT–polymer/organic semiconductor type II HJ OPD

with the structure shown in Fig. 7.48a. The SWNTs with diameters ranging from 0.7 to 1.1 nm were purified via ultracentrifugation, and then wrapped by immersion in a solution with a semiconducting polymer, either MDMO-PPV or P3HT. Polymer wrapping prevents the CNTs from contacting each other and forming bundles. The CNT solution was applied by doctor blade onto an ITO coated glass substrate, and then capped either with a neat  $C_{60}$  layer or a SnPc: $C_{60}$  (1:3) D-A blend that was employed to enhance the photodiode visible-NIR response. The layer was coated with a  $C_{60}$  layer, a BCP blocking layer and a Ag cathode.

The energy level diagram of the MDMO-PPV: CNT/ $C_{60}$  device in Fig. 7.48b is useful to understand the photogeneration mechanism. Photons absorbed directly in the CNT form excitons that subsequently migrate to the HJ with the  $C_{60}$  where they dissociate. When combined with  $C_{60}$ , the CNT acts as a donor. If the  $C_{60}$  is blended with SnPc, shorter wavelength photons not absorbed by the CNT are absorbed by the SnPc, which is also a donor. Including SnPc fills the hole in the spectrum from approximately 500 nm to 800 nm where the SWNTs are only weakly absorbing.

A scanning electron micrograph showing the morphology of the MDMO-PPV: CNT blend is

**Figure 7.48** (a) Layer scheme of a composite SWNT–polymer/organic HJ OPD. The diagram represents three different devices: in two of the devices, the semiconducting nanotubes were wrapped in the polymer MDMO-PPV, or P3HT. In one device, the composite was contacted directly by a  $C_{60}$  acceptor layer, and in another, it contacted a SnPc: $C_{60}$  blend. (b) Energy level scheme of the MDMO-PPV: CNT/ $C_{60}$  OPD. Scanning electron micrograph images of a film of (c) nanotube/MDMO-PPV composite and (d) bare nanotubes. The scale bars = 500 nm (Arnold et al., 2009).

Reprinted with permission from Arnold, M. S., Zimmerman, J. D., Renshaw, C. K., Xu, X., Lunt, R. R., Austin, C. M. & Forrest, S. R. 2009. Broad spectral response using carbon nanotube/organic semiconductor photodetectors. *Nano Letters*, 9, 3354. Copyright 2009 by the American Chemical Society.

provided in Fig. 7.48c. The film has an rms surface roughness of 4 nm, compared to the very irregular surface of a mat of bare CNTs in Fig. 7.48d, with a roughness of 20 nm. Hence, the polymer wrapping has the added effect of planarizing the film to prevent shorts from the CNT to the cathode.

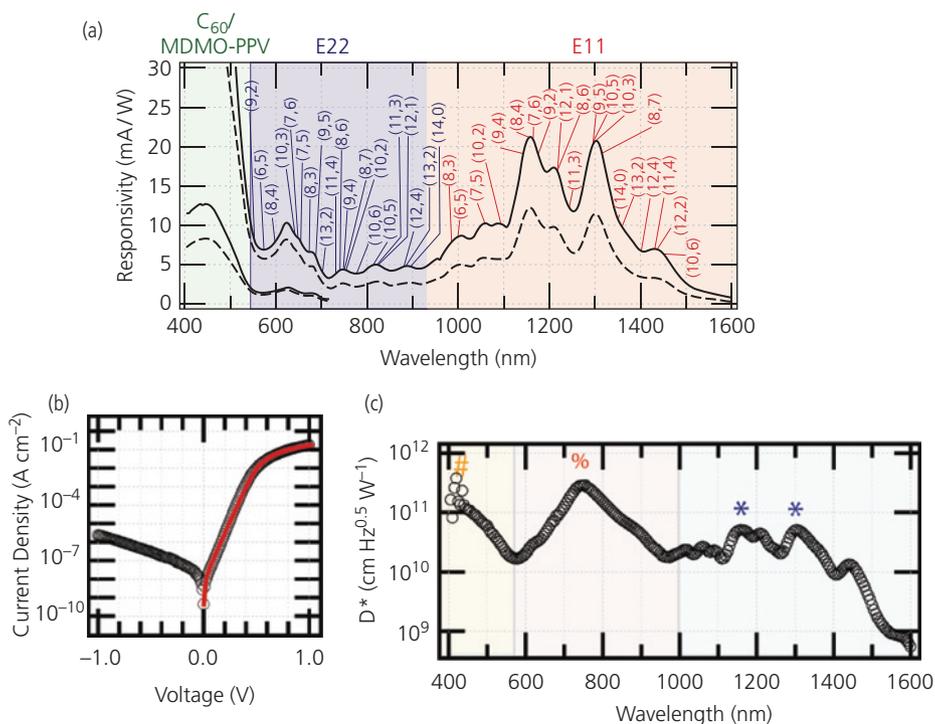

The performances of several CNT device structures are shown in Fig. 7.49. Absorption by the population of semiconducting CNTs having easily identifiable chiralities (indexed adjacent to each peak) results in a rich responsivity spectrum ranging from 550 nm (due to the E22 absorption), to >1500 nm by the E11 band. The responsivity at  $\lambda = 1155$  nm at  $-0.7$  V is 23 mA/W, corresponding to  $\eta_{ext} = 2.3\%$ . For MDMO-PPV/CNT layer thicknesses of 14 nm,  $\eta_{int} > 25\%$  between  $\lambda = 1000$  and 1400 nm. The responsivity significantly decreases at  $\lambda > 1450$  nm due to a lack of absorption since there are no CNTs with diameters  $> 1.1$  nm.

The temporal response of a 0.3 mm diameter MDMO-PPV:CNT device was measured at 0 V and  $\lambda = 847$  nm using a laser pulse width of  $\sim 1$  ns. The rise time, limited by the RC time constant of the diode was  $\tau_{RC} = 1.84$  ns. The OPD response had a time of

$\tau = 7.16$  ns limited by charge drift. This corresponds to a 3 dB detector bandwidth of 31 MHz.

The  $j$ - $V$  characteristics of a P3HT:CNT (1:3) OPD are shown in Fig. 7.49b, and its resulting specific detectivity is in Fig. 7.49c. A fit to the  $j$ - $V$  data (solid line, Fig. 7.49b) gives an ideality factor of 1.34. Based on these data, the CNT:P3HT/ $C_{60}$ :SnPc photodetector at 0 V exhibits  $D^* > 10^{10}$  Jones from  $\lambda < 400$  nm to  $\lambda = 1450$  nm, with a peak of  $\sim 3 \times 10^{11}$  Jones at 750 nm due to intense absorption by the SnPc, and  $7 \times 10^{10}$  Jones at 1200 nm and 1300 nm due to the SWNT blend (Arnold et al., 2009).

An analogous device employing poly(9,9-dichlorofluorene) wrapping to selectively disperse only CNTs with chiralities (7,5), (7,6), (8,6), (8,7), and (9,7) had response between 1000 nm and 1350 nm due to the narrower population of nanotubes (Bindl et al., 2010). This chiral selectivity all but eliminated the undesirable metallic CNTs, while permitting optimization of the overlap of the optical field with the device active region. As a result, the external quantum efficiency at 1200 nm reached 12.9%, corresponding to  $\eta_{int} = 91\%$ . However, the reverse dark

**Figure 7.49** (a) Responsivity of a 1:1 MDMO-PPV:CNT (14 nm)/ $C_{60}$  (100 nm) OPD at 0 V (dashed line) and  $-0.7$  V (solid line). The chiralities of CNTs leading to a given peak are indexed by integers ( $n$ ,  $m$ ). current was  $\sim 10$  mA/cm<sup>2</sup>, which is approximately 10<sup>5</sup> times higher than the P3HT-based device.

Colloids consisting of small bandgap compound semiconductor QDs are an alternative route to accessing the infrared. The exciton energy of a quantum-confined state within a nanoscale particle (or dot) depends on the particle diameter. The exciton energy in a sphere of radius,  $r_0$ , is found by solving Schrödinger's equation using the following Hamiltonian:

$$H = -\frac{\hbar^2}{2m_e^*} \nabla_e^2 - \frac{\hbar^2}{2m_h^*} \nabla_h^2 - \frac{q^2}{4\pi\epsilon_0\epsilon_{\text{QD}}|\mathbf{r}_e - \mathbf{r}_h|} + V(r_e, r_h), \quad (7.112)$$

where the boundary potential at the periphery is given by

$$V(r_e, r_h) = \begin{cases} 0 & \text{for } r_e, r_h < r_0 \\ \infty & \text{elsewhere} \end{cases}. \quad (7.113)$$

Here,  $\mathbf{r}_e$  and  $\mathbf{r}_h$  are the positions of the electron and hole, respectively, within the QD, and  $\epsilon_{\text{QD}}$  is its relative dielectric constant. The first two terms in Eq. 7.112 are the kinetic energies of the electron and hole, respectively, the third term is their binding energy, and  $V(r_e, r_h)$  is the potential that binds the charges to the QD.

Since QDs are nanocrystalline solids, they are often faceted, and hence the spherical dot approximation is not always valid, although it is sufficient to understand the factors determining the QD optical properties. The lowest lying (1s) Wannier–Mott exciton for a QD in a dielectric medium can be approximated by a hydrogenic state. Using time independent perturbation theory, the solutions to Eq. 7.112 yield (Brus, 1984)

$$E = \frac{\hbar^2 \pi^2}{2r_0^2 m_r^*} - \frac{1.8q^2}{4\pi\epsilon_0\epsilon_{\text{QD}}r_0}, \quad (7.114)$$

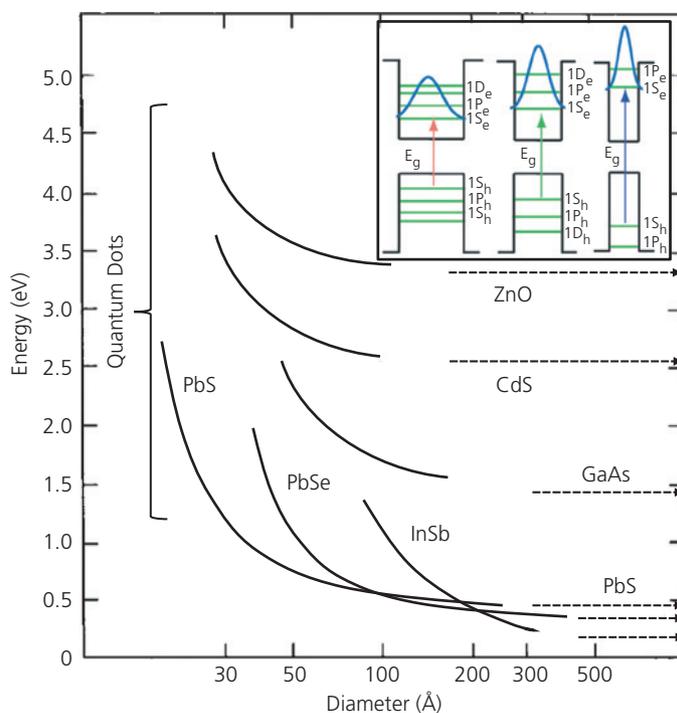

where  $1/m_r^* = 1/m_e^* + 1/m_h^*$  is the reduced effective mass. The first term is the kinetic energy of the quantum confined 1s state. For higher order (principal quantum number,  $n > 1$ ) excited states, this energy takes the familiar form for a particle in a box, viz.  $E_n = \hbar^2 \pi^2 n^2 / 2r_0^2 m_r^*$ . The second term is the Coulomb potential energy of the electron–hole pair.

An interesting analogy connects QD and doped donor–acceptor organic systems. Indeed, in Section 6.8 we showed that a fluorescent dopant molecule in a large energy gap host results in laser performance analogous to that of QD semiconductor lasers. The latter devices show weak temperature-dependent spectral and threshold characteristics due to the confinement of the luminescent state by the barriers formed by the wide energy gap semiconductor

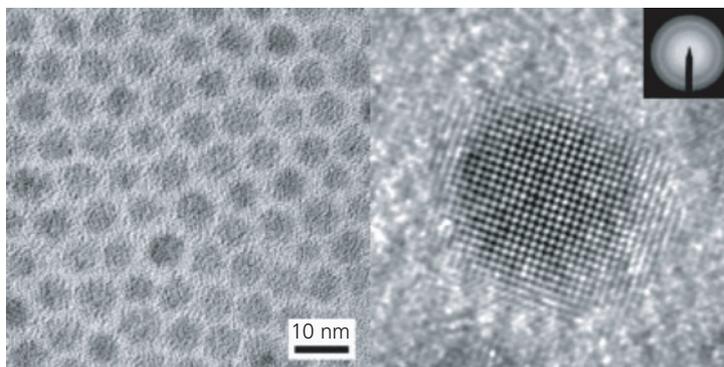

surrounding the narrow energy gap QD. The density of states of the dot is comparatively narrow relative to the bulk, leading to reduced thermal broadening of the electron and hole populations, and hence the reduced temperature dependence of the lasing threshold. Similarly, the excitons confined on isolated organic dopant molecules are also relatively immune from thermal broadening effects due to their spatial and energetic localization.

Equation 7.114 provides the dependence of  $E$  on particle radius and effective mass. Thus, the energy increases as  $r_0^2$  and  $m_r^*$  decrease. This dependence on diameter is shown for several inorganic QDs in Fig. 7.50. The lowest energy absorption transitions ( $1s_e \leftarrow 1s_h$  corresponding the 1s transitions from the hole to electron state, respectively) calculated in Eq. 7.114 are shown in the inset. Dots with a larger diameter have a lower energy than smaller dots (the latter are on the right). A composite incorporating narrow band gap QDs such as PbS, InSb and PbSe of the appropriate radii should, therefore result in absorption all the way into the mid-IR (the so-called *mid-wavelength IR*, MWIR, band from 3 to 5  $\mu\text{m}$ ).

Considerable advances have been made in achieving populations of QDs with a narrow distribution of diameters about a mean, target value. These so-called *monodisperse* populations can be achieved by ultracentrifugation and sedimentation of a relatively broad starting population of diameters (see Section 5.3.4). Alternatively, adding precise amounts of precursors during synthesis can also produce a monodisperse diameter population whose diameters are controlled by depletion of the precursors in solution which terminates dot growth. Micrographs of a synthetically generated, monodisperse population of PbS nanocrystals with an absorption peak at 1440 nm are shown in Fig. 7.51, with a high resolution image of a single dot showing its crystal structure, along with a selective area electron diffraction (SAED) pattern of the nanocrystals in the inset. The nanocrystals are synthesized by mixing a solution of PbO and oleic acid with TMS and octadecene in a 2:1 Pb/S ratio. The reaction runs to completion when all of the TMS is consumed. The resulting size dispersion is 10–15%, yielding narrow absorption peaks that can be tuned from  $\lambda = 800$  nm to 1800 nm. The dot lattice constant is 5.9 Å oriented along the [100] direction, which is the same as that observed for bulk PbS. The colloid in Fig. 7.51 shows that the dots are separated by the oleic acid ligands, thus preventing clustering and fusing of neighboring dots into larger particles with lower energy

**Figure 7.50** Lowest excited state energies of spherical semiconductor quantum dots of different compositions. The dashed lines show the band gap energies of the bulk semiconductors, which is approached at large diameters. Data from Brus (1984) and Kang and Wise (1997). Inset: Transitions between the  $1S_h$  and  $1S_e$  for three QDs of different diameters, increasing from left (lowest energy transition) to right (highest energy transition). Higher order  $1p$  and  $1d$  states are also shown.

transitions. Hence, the ligands serve two purposes: to control the growth of the dot population, and to form a solid colloidal dispersion that isolates individual dots.

The precision with which diameters and absorption spectra can be controlled is illustrated in Fig. 7.52a for populations of PbSe QDs. The radii are synthetically tuned from 3.3 nm to 8.1 nm.

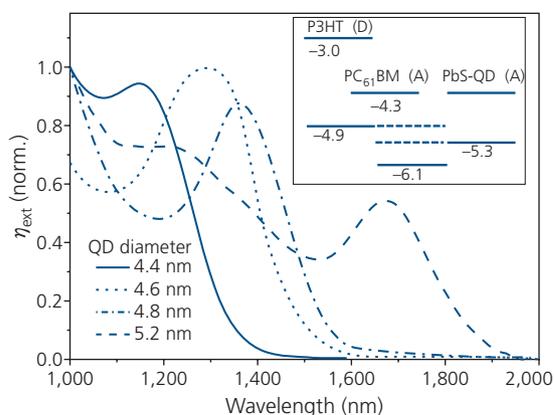

Evidence for the monodispersity of the populations is provided by the narrow spectral peaks corresponding to each diameter, tuned from approximately 1200 nm to 2100 nm. Interestingly, the spectra also exhibit higher order ( $n = 2, 3$ ) transitions at shorter wavelengths, providing further evidence for monodispersity. The dependence of the lowest transition energy vs. dot radius in Fig. 7.52b shows a fit

**Figure 7.52** (a) Absorption spectra of monodisperse populations of PbSe quantum dots showing the dot with its isolating ligand structure. The corresponding dot radius for each spectrum is shown. (b) Lowest energy absorption transition vs radius of PbSe QDs. The dashed line is a fit to the data using Eq. 7.114 (Semonin et al., 2012).

(dashed line) that is based on quantum confinement following Eq. 7.114.

Rectifying QD photodiode arrays with sensitivity to  $\lambda \leq 1900$  nm integrated with a CMOS passive pixel sensor (see Section 8.9.2) and a readout integrated circuit (ROIC) have been demonstrated. The external quantum efficiencies of the QD OPDs are shown in Fig. 7.53 (Rauch et al., 2009). The IR-imaging circuit comprised a  $256 \times 256$  focal plane array (FPA) with a pixel pitch of  $154 \mu\text{m}$ . The devices were a monodisperse population of PbS/oleic acid QDs

**Figure 7.53** Normalized external quantum efficiency vs. wavelength for P3HT:PC<sub>61</sub>BM:PbS-QD OPDs for different diameter QD populations. The curve for the 4.4 nm diameter dots corresponds to a maximum efficiency of ~15%. Inset: HOMO and LUMO energies (in eV) in the OPD active regions (Rauch et al., 2009).

blended in a P3HT donor and PC<sub>61</sub>BM acceptor BHJ active region. The 100–250 nm thick BHJ P3HT:PC<sub>61</sub>BM:PbS-QD (1:1:4) absorbing region was applied by a doctor blade onto the ITO/PEDOT:PSS bottom anode that made direct contact to the drain of the transistors in the address array, and was capped by an Al cathode.

The energy level diagram of the QD OPD is shown in Fig. 7.53, inset. Both the PbS QDs and PC<sub>61</sub>BM are acceptors, and P3HT is the donor. Current leakage from each of the constituents, and hence at longer wavelengths (i.e. larger radii dots), the dark current is prohibitively large for sensitive IR detection. Devices employing 4.5 nm diameter dots with a long wavelength cutoff at approximately 1450 nm had a dark current of  $10 \text{ nA/m}^2$  at  $-1 \text{ V}$ . Combined with a peak external quantum efficiency of 16.5% at 1220 nm, this corresponds to  $D^* = 2.3 \times 10^9$  Jones, which falls short of devices employing porphyrin tapes or CNTs. An unexpectedly large increase of  $\eta_{\text{ext}}$  with reverse bias is due to photoconductive gain in the blended active region. The imaging FPA had  $f_{3\text{dB}} = 2.5 \text{ kHz}$ , which was limited by the device capacitance. This bandwidth can be increased by reducing the pixel pitch or by modifying the device thickness and other architectural details.

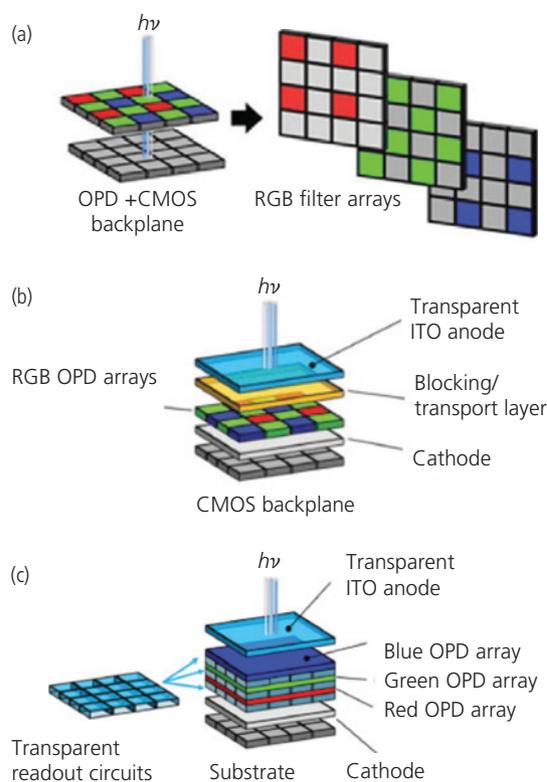

#### 7.2.2.4 Photodiode applications

Photodiodes have found an enormous range of applications for sensing, imaging, and communications. In this context, OPDs are a relatively new entrant into the photodetector family of devices, and hence the numbers of sensing applications that have been

demonstrated are few by comparison to those employing inorganic semiconductors. Nevertheless, the very broad wavelength range accessible to OPDs due to the variety of functional molecules that are synthetically accessible, make this class of detectors adaptable to detection from the UV to the MWIR. But “competing with silicon” is never a good idea unless there is a clear advantage to be gained by using a new technology. As we have already pointed out, organic electronic devices have features that are difficult and often impossible to access using their inorganic counterparts due to their inherent flexibility, stretchability, ultralight weight, narrow absorption spectral widths (leading to selective OPD transparency and detection), low temperature processing, and deposition that can lead to integration of devices on virtually any large area, flat substrate. In addition, one feature that we have not discussed up to now is the radiation hardness of organic thin films (Li and Yang, 2008, Kumar et al., 2011, Paternò et al., 2017, Barbé et al., 2018). The very small molecular weight atoms comprising organic devices make them relatively transparent to X-ray and gamma radiation. Hence, they may be useful for applications in space or in other high-energy radiation environments. In this regard, X-ray detection by combining scintillators with large area OPDs has been demonstrated, although this application domain remains in its infancy (Arca et al., 2013).

In this section, we consider only a few of the many sensing applications where OPDs have been employed. Our examples are chosen based on the unique materials and/or architectural features that organics provide. First, we describe OPDs used in full color imaging. Next, we show that the conformability of organics enables their application in hemispherical FPAs (HFPAs) that mimic the form, size, and several optical features of the human eye. This is followed by descriptions of position-sensitive detectors used for measuring both macroscopic and nanoscopic positions of illumination sources. We conclude with descriptions of an OPD integrated with an OLED to form an optoelectronic logical switching element and an organic charge coupled device imager. On occasion, OPDs have also been suggested for use in optical communications. We will not consider this application since there are many alternatives to OPDs that deliver considerably higher performance. This application space is adequately served by incumbent NIR detector technologies (e.g. based on Si and InGaAs), leaving only very specialized niches that may eventually be filled by OPDs.

Producing a full color image using an FPA is analogous to the challenge of providing a full color display

**Figure 7.54** Three different two-dimensional (2D) full color imaging array architectures. (a) An OPD array combined with an RGB filter array. (b) R, G, and B sensitive, narrow spectral bandwidth OPD pixel arrays integrated with a CMOS ROIC. (c) Stacked R, G, and B narrow spectral bandwidth OPD pixel arrays. After Jansen-van Vuuren et al. (2016).

© 2016 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

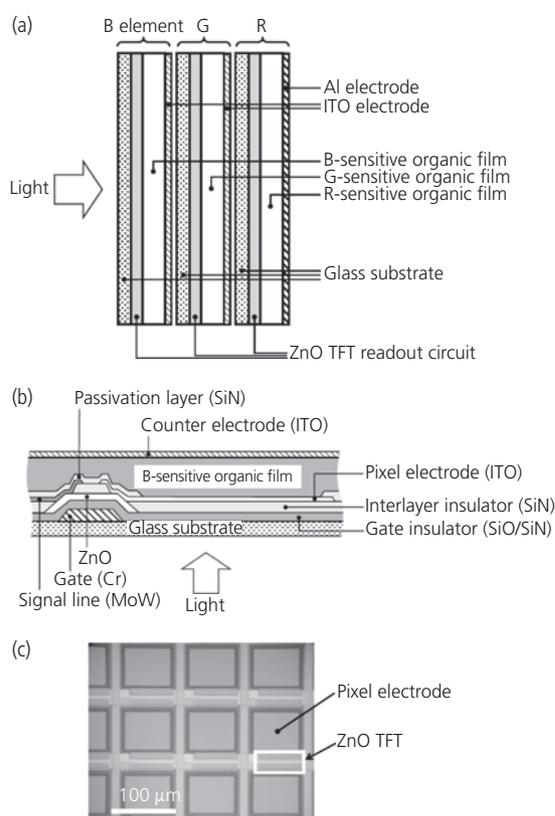

image, and hence the architectures used in both applications are similar. While there are numerous optical methods for producing full color images using dispersive elements such as lenses, gratings and prisms, here we discuss how images are formed by the planar integration of devices and filters in a thin film construction. Figure 7.54a shows a broad spectral bandwidth OPD array integrated onto a CMOS pixel sensor/ROIC backplane. Color separation is provided by placing a red-green-blue (RGB) color filter mask above the OPDs, thus limiting the spectral window of each detector. The rectangular close-packing of the filter indicates that one of the color triad (green in this example) will have two pixels per array “unit cell”, while the other two colors are each detected by only a single pixel. This inherently limits the imager resolution, requiring four detectors per full-color image pixel. Note that a similar duplication of the green pixel is often found in OLED displays (cf. Fig. 5.58). The filter architecture is analogous to OLED displays employing

white emitting pixels placed beneath RGB filter arrays, or blue OLEDs used to pump R and G fluorescent down-converting “color changing” layers (see Section 6.4.2).

A second design is to use narrowly spectrally sensitive OPD arrays, with one OPD that detects in the blue, another in the green and a third in the red. The architecture in Fig. 7.54b is analogous to RGB emitting OLED displays employed in mobile applications. The OPDs are deposited directly onto the CMOS backplane readout array. Finally, in Fig. 7.54c we show a stacked architecture, where the light is incident on vertically disposed and separated R, G and B OPD arrays (Hokuto et al., 2007, Hokuto et al., 2011). Each color detecting array is integrated with a transparent ROIC within the stack. Alternatively, a single ROIC backplane can be located beneath the stacked OPD arrays, which is then vertically connected using vias to their corresponding transistor address circuits. The array has at least three times the resolution of the laterally disposed pixels in Fig. 7.54a and b. This advantage must be weighed against the disadvantage of increased fabrication and interconnection complexity, as well as the demands placed on the lens system to achieve a high image-plane depth of field.

An early demonstration of a full color imager was a one-dimensional scanning array of BHJ OPDs (Yu et al., 1998, 2000). The broad spectral bandwidth linear array comprises 102, ITO/150–180 nm thick P3OT:PC<sub>61</sub>BM/Al OPDs on glass or flexible Mylar substrates. The array had a resolution of 40 dpi, with a total length of 64.8 mm. Images were obtained by sequentially interposing R, G, and B filters between the array and the object, and then scanning the image.

One-dimensional scanners capture images one line at a time, which is slow and only produces a blur-free image of fixed objects. These problems are eliminated with 2D CMOS FPAs commonly employed in digital cameras. A stacked, 2D imaging array is shown in Fig. 7.55a. Transparent ZnO thin film transistors (TFTs) are used as the address and readout electronics. The 128 × 96 arrays comprised small molecule-based OPDs with a 100 × 100 μm<sup>2</sup> pixel size, and with an image capture rate of 10 frames per second. The structure of the pixels is detailed in Fig. 7.55b. The ZnO transistors have a bottom gate, top source and drain configuration, comprising a SiO (50 nm)/SiN (100 nm) gate insulator, and a 45 nm thick ZnO channel. The OPDs are deposited onto the surface of an isolating, 200 nm thick SiN<sub>x</sub> interlayer, and are connected to the drain via ITO and a 100 nm thick MoW signal line. A second, transparent ITO counter electrode caps the device. Light is incident onto the OPD

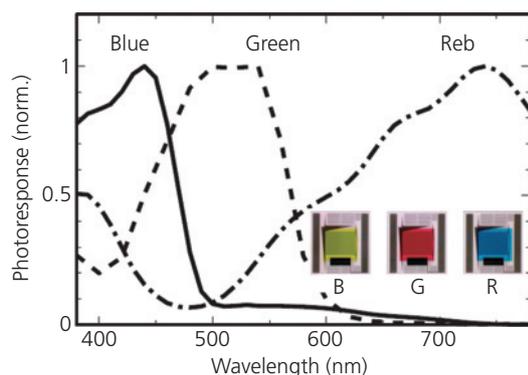

**Figure 7.55** (a) Schematic of an RGB imaging system where each color OPD along with its readout circuitry is fabricated on separate substrates and aligned in a sandwich structure. (b) Cross-section schematic of a blue-sensitive pixel in the array. (c) Micrograph of a section of the ZnO thin film transistor array (Hokuto et al., 2011).

via the substrate. A photomicrograph of a section of the ZnO TFT array is shown in Fig. 7.55c.

The detectors themselves consisted of the following photoactive regions: (i) B—coumarin 6 donor/C<sub>60</sub> acceptor, (ii) G—DMQA donor/Py-PTC acceptor, and (iii) ZnPc+TiOPc donor/Alq<sub>3</sub> acceptor. ITO was used for the B and G counter electrodes, whereas Al was used for the R-sensitive device. Images of the three devices are shown in Fig. 7.56, inset, whose colors are the complement of their absorption spectra. Thus, the blue element appears yellow, the green is magenta, and the red is cyan. The external quantum efficiencies of the three sub-pixels are 7.6% at 10 V reverse bias for blue, 7.0% at 3 V for green, and 18% at 15 V for red. Their dark currents ranged from approximately 10 nA/cm<sup>2</sup> for blue to 0.5 μA/cm<sup>2</sup> at 15 V for red. These device characteristics are adequate for producing a full color image, albeit with some defects (i.e. line-outs) present that presumably can be eliminated with improved process control.

A hybrid combination of a CMOS imager and a green sensitive OPD array has been demonstrated by stacking the FPA, filters, and detectors, forming a hybrid of all three architectures in Fig. 7.54. The 5 Mpx CMOS array employs two Si PDs with 50–60% efficiency spanning the visible spectrum (see

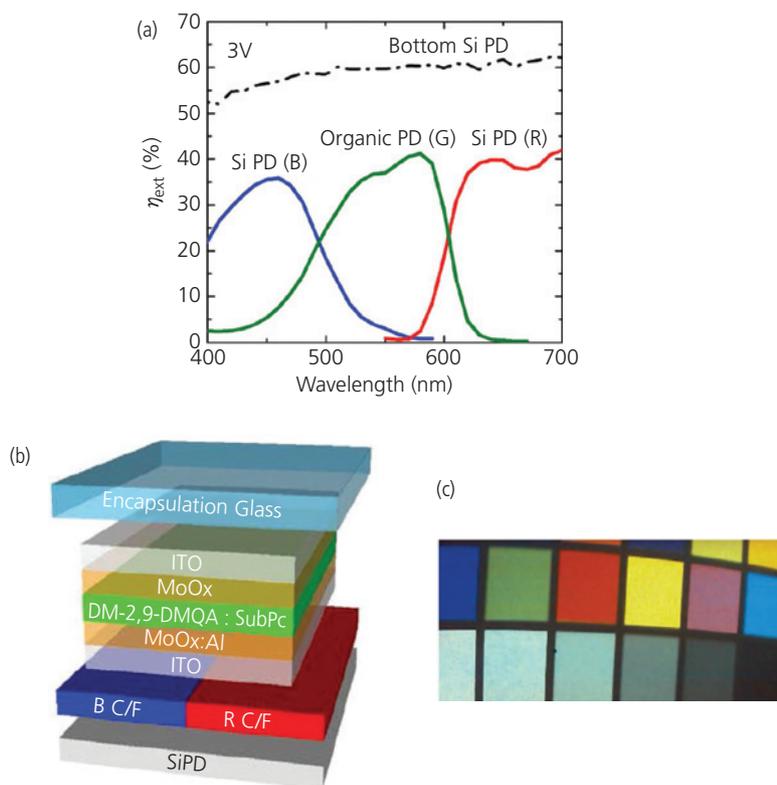

**Figure 7.56** Normalized spectral response of the three-color OPDs used in the arrays in Fig. 7.55. Inset: Photographs of the three pixels (Hokuto et al., 2011).

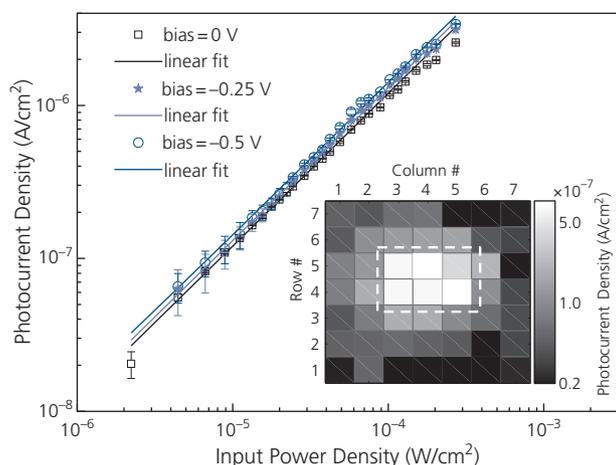

Fig. 7.57a). Blue and red color filters are deposited onto the pixelated Si PD and backplane surface. The Si electronics are planarized using chemomechanical polishing and covered with a semitransparent green-sensitive OPD. The flat surface is subsequently coated with sputter-deposited ITO that is connected to the underlying metal FPA circuit electrode. The OPD comprised a  $\text{MoO}_x:\text{Al}$  (5nm) cathode, DM-2,9-DMQA donor:SubPc acceptor (1:1, 90 nm) active region, and a  $\text{MoO}_x$  (10 nm)/ITO anode. A schematic illustration of the three-color pixel with a pitch of  $1.4 \mu\text{m}$  is shown in Fig. 7.57b (Lim et al., 2015).

The efficiencies of the two filtered Si PDs and the green OPD are approximately equal across the visible, as shown in Fig. 7.57a. The specific detectivity at the operating point of  $-3\text{V}$  reverse bias is  $2 \times 10^{12}$  Jones and the roll off frequency is  $\Delta f = 76.7 \text{ kHz}$ . A 5MPx image of a color sample panel obtained using this hybrid Si/organic PD FPA is shown in Fig. 7.57c. Good color balance is obtained due to the nearly equal quantum efficiencies of the three RGB sub-pixels.

Flat FPAs used in cameras do not present an optimal form factor for imaging systems since the focal planes of spherical lenses are themselves spherical.

**Figure 7.57** (a) Photoresponse of a hybrid Si/green OPD FPA showing the filtered and unfiltered Si PD responses. (b) Structure of the three-color-sensing pixel where the Si PDs are located beneath red and blue color filters (CF), and the green OPD covers the entire pixel surface. (c) Images of a color sample acquired with the 5 Mpx sensor array (Lim et al., 2015).

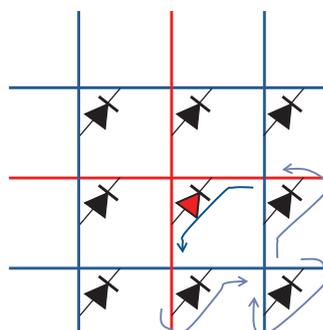

**Figure 7.58** Photocurrent density vs. input power density of a  $(200 \mu\text{m})^2$  photodetector in a  $20 \times 20$  array under various biases. Linear fits at each bias are shown as solid lines. The dynamic range, determined by the 1 dB compression point and minimum detectable power level, is approximately 20 dB, giving a 7-bit resolution. Inset: Grayscale image of a rectangular illuminated area (dashed line) on the hemispherical FPA, corresponding to a  $2 \times 3$  block of photodetectors. Photocurrents of pixels in the  $7 \times 7$  block containing the illuminated (at 633 nm) pixels show contrast with unilluminated pixels (Xu et al., 2008).

Thus, focusing an image onto a planar FPA requires a heavy, narrow field of view (FOV), high  $f$  number multi-element lens system to reduce image aberrations and chromatic dispersion. The planar form factor is a consequence of the limitations of photolithographic processing on inorganic semiconductor substrates. In contrast, the approximately spherical retina of the human eye provides a nearly ideal imaging system that employs a relatively simple, single element convex lens. Thus, the eye is compact, lightweight, has a very wide FOV nearly free of image distortion, and has a very low  $f$ /number.

In Section 5.6.4 we described the steps used in fabrication of a retina-like, HFPA that exploits the flexibility and conformability of organic electronics. The architectural challenges of mounting devices on the HFPA surface are met using arrays of OPDs on thermoformable substrates such as PET (Xu et al., 2008, 2009). The Au anode (10 nm)/CuPc (50 nm)/C<sub>60</sub> (50 nm)/BCP (10 nm)/Ag (20 nm) OPDs were formed into a  $100 \times 100$  passive matrix array of  $(40 \mu\text{m})^2$  OPDs on a 1 cm radius hemispherical surface. The external detector quantum efficiency had a maximum of 12.6% at  $\lambda = 640 \text{ nm}$ . This was limited primarily by absorption in the thin Au anode oriented toward the incident illumination, and was increased to 20.5% at 605 nm when the Au was replaced by ITO in a strain-free stamp transfer process (Xu et al., 2009).

A grayscale image produced by the pixel photocurrents due to placing a square aperture in the focal plane of a  $20 \times 20 \times (200 \mu\text{m})^2$  array is shown in the

**Figure 7.59** A passive matrix diode array showing the illuminated diode (red) and the selected row and column address lines. The photocurrent is shown by the black dashed line. Several parasitic sneak current paths are shown by blue dashed lines.

inset of Fig. 7.58. Apparently, several of the pixels lying beyond the aperture boundary (dashed line) also generate current that blurs the image. These are known as *sneak currents* in the passive matrix architecture arising from photocurrents within an illuminated row and column that add to the dark currents of the unilluminated detectors. This effect is illustrated in Fig. 7.59. The sneak currents can be reduced, but not eliminated by floating, rather than grounding the unaddressed row and column lines.

The photodetector specific detectivity is  $D^* = 1.25 \times 10^{11}$  Jones for the devices with the ITO anode. The detectivity in the array, and hence its dynamic range, is determined by shot noise from the sneak currents. Hence, the shot noise increases as  $\sqrt{N}$ , where  $N$  is the

number of diodes within a row that are addressed simultaneously during read out. The detectivity can be substantially increased if each photodiode is accompanied by a transistor address circuit that interrogates only one detector at a time while eliminating contributions from unilluminated pixels (see Chapter 8).

Position sensitive detectors (PSDs) are an important class of sensors that use the lateral photoeffect (Wallmark, 1957) to detect the location of an incident light beam. PSDs are commonly used in robotic vision, machine tool alignment, and guidance systems. The advantage of thin film PSDs over photodetector arrays is their ability to continuously track a signal with the resolution limited only by the light beam size, and not by detector size or pixel pitch. Furthermore, a thin film PSD requires only two outputs, whereas arrays require address lines to each detector. Since PSDs must track a beam over a large distance, the adaptability of organics to large, flexible substrates makes them well suited to this application (Rand et al., 2003, Kabra et al., 2004, Cabanillas-Gonzalez et al., 2011).

An example PSD comprises a long, transparent ITO strip deposited on a glass substrate used as both the anode for the photodetector and a resistive layer (see Fig. 7.60, upper inset). Light incident via the substrate generates a photocurrent,  $I_{ph}$ , that is collected at two, separated anodes. The total dark current for the device,  $I_D$ , is equally split between the two electrodes that are connected to an external circuit. The photocurrent contributions  $I_1$  and  $I_2$  are independently detected (see equivalent circuit, Fig. 7.60, lower inset) with magnitudes (Rand et al., 2003)

$$I_1 = \frac{I_D}{2} + I_{ph} \left( \frac{R_2}{R_1 + R_2} \right) \quad (7.115a)$$

and

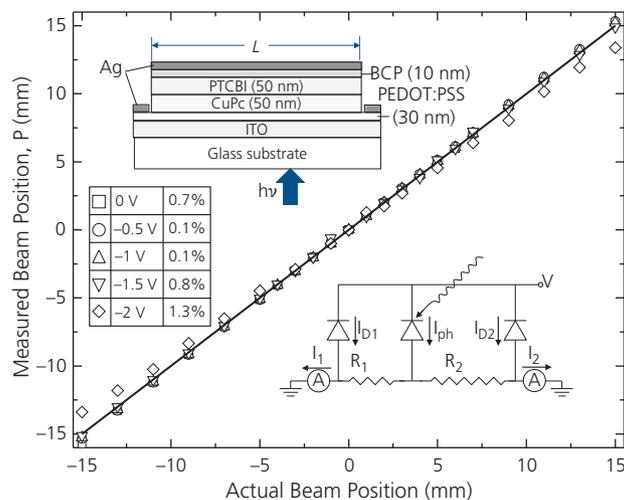

$$I_2 = \frac{I_D}{2} + I_{ph} \left( \frac{R_1}{R_1 + R_2} \right), \quad (7.115b)$$

where  $R_1$  and  $R_2$  are the resistances of the ITO strip from the position of the incident light beam to the adjacent electrode. The currents detected at the two electrodes give the location,  $x_L$ , of the incident beam

$$x_L = \frac{(I_1 - I_2)L}{2(I_1 + I_2)}, \quad (7.116)$$

where  $L$  is the length of the device active region. Ideally, the ratio of currents should be a linear function of the light beam position. In practice, however, nonlinearities are observed that are quantified using:  $\delta = 2\sigma/\Delta I_{FS}$  where  $\sigma$  is the rms deviation from a least squares fit to the current data, and  $\Delta I_{FS}$  is the total swing in current for a beam scanned across total distance,  $L$ . Another characteristic is the fractional error in measuring the beam position given by,  $\Delta l/L$ , where  $\Delta l$  is the difference between the actual and calculated positions.

The bilayer PSD structure in Fig. 7.60 employed a 3 cm  $\times$  1 mm resistive ITO anode strip. The device is sensitive to wavelengths from 450 nm to 750 nm, with a peak efficiency of 12% at  $-2$  V reverse bias. The data in Fig. 7.60 show the response of the PSD to a 180  $\mu$ m diameter beam for different reverse biases ranging from 0 to  $-2$  V. It is found that  $x_L$  is a linear function of beam position with a spatial resolution of 20  $\mu$ m, and an error of  $\Delta l/L = 0.05$  at  $-2$  V. All other voltages show an error less than 1%. The table in Fig. 7.60

**Figure 7.60** Measured vs. actual beam positions for the position sensitive OPD, shown in upper inset. Lower inset shows the equivalent circuit of the OPD. The table provides a legend and the positional error,  $\delta$ , of the beam over the OPD length,  $L$ . Adapted from Rand et al. (2003).

gives  $\delta$  vs. reverse bias as well as for different optical powers at  $-1$  V.

The tracking speed is one further criterion that characterizes the PSD. The capacitance of the PSD is  $15.3$  nF at  $-1$  V bias, resulting in  $\tau = RC = 9.2$   $\mu$ s for the ITO strip with a resistance of  $600$   $\Omega$ . Accurate and stable tracking can be obtained for a beam velocity ( $v_{max}$ ) less than the resolution divided by the response time. In this case,  $v_{max} = 20$   $\mu$ m/ $9.2$   $\mu$ s =  $2.2$  m/s.

A 2D PSD can be realized by placing pairs of contacts orthogonal to each other along the device periphery. As the device area increases to accommodate larger ranges of beam scans, the dark current also increases, reducing the sensitivity and scan rate.

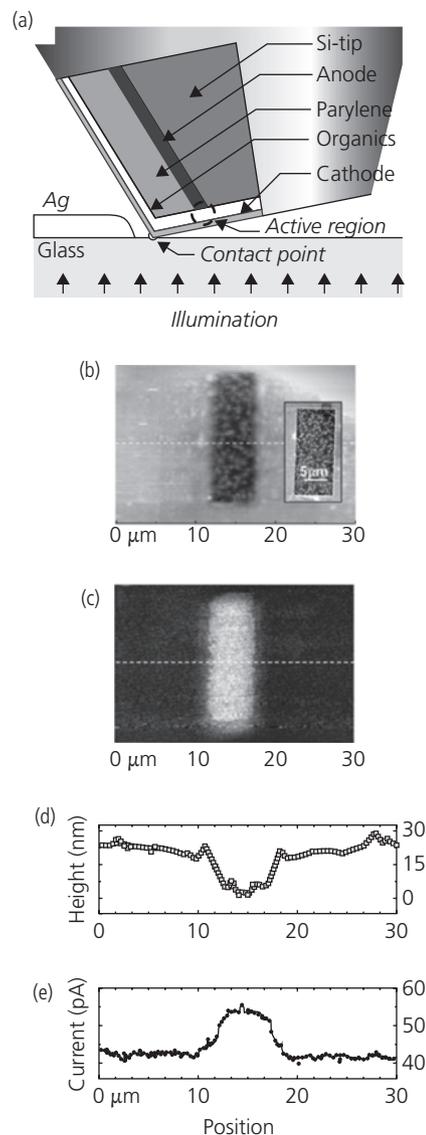

There are several alternative architectures that can be implemented to locate the beam position. For example, the absorption spectrum can be spatially varied by grading the donor and acceptor thicknesses between the contacts. The position is determined from the spectral response at  $x_L$  (Cabanillas-Gonzalez et al., 2011). This approach requires the use of a donor and acceptor with distinct absorption spectra, precise linear grading of the bilayer along the PSD length, the use of at least two wavelengths to obtain the relative absorption in the donor vs. the acceptor layer, and layers whose thicknesses are not significantly greater than the exciton diffusion length in each layer. This latter constraint ensures that excitons generated far from the D-A junction do not recombine before arriving at the HJ. While this architecture may be attractive for limited applications, it is not suited for general position sensitive detection.

The ability to deposit organics onto virtually any surface has enabled a high spatial resolution scanning probe PSD (An et al., 2008). The scanning PSD is located on the vertex of a conventional, Si AFM tip by forming a  $500$  nm diameter platform using focused ion beam (FIB) milling (see Fig. 7.61a). The OPD cathode comprising Al on a thin Ni adhesion layer was deposited onto the tip surface, making contact to the Si. The entire surface was coated with perylene, and the tip face was milled to open a  $500$  nm window that defined the detector active area. This was followed by the deposition of a  $C_{60}/\alpha$ -NPD bilayer active region coated by a blocking layer and anode metallization. External contact to the diode is made via the Si tip and the outer metal coating remote from the tip itself.

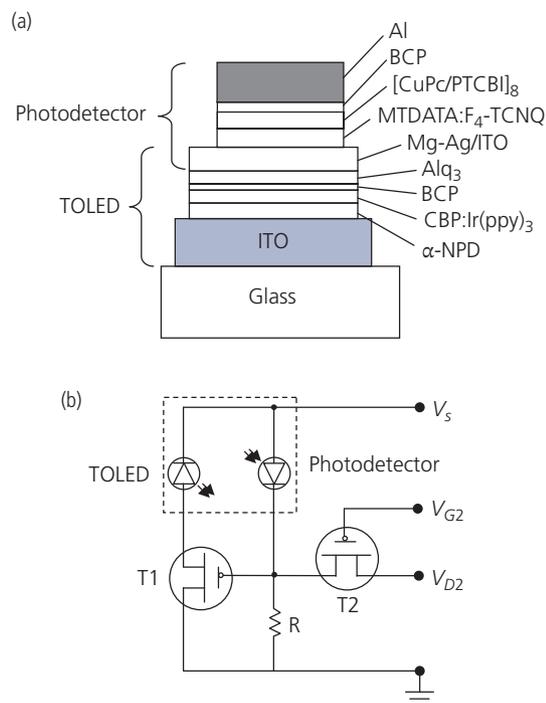

The tip is placed in contact with a metallized glass substrate with an  $8 \times 20$   $\mu$ m aperture illuminated from its reverse surface (Fig. 7.61a). A topographic scan of the aperture surface shown in Fig. 7.61b is acquired from the AFM as the tip is translated along the aperture surface. Simultaneously, an optical scan

is obtained by measuring the OPD current vs. position (Fig. 7.61c). Line scans with micron-scale resolution of the topography and the photocurrent along the dashed lines in Fig. 7.61b and c are shown in Fig. 7.61d and e, respectively (An et al., 2008).

Another application for an OPD is in the bistable optical latch shown schematically in Fig. 7.62a (Xue and Forrest, 2002). The green emitting PHOLED has a  $12$  nm thick semitransparent Mg-Ag/ITO cathode that serves as the anode of the eight-period, multilayer

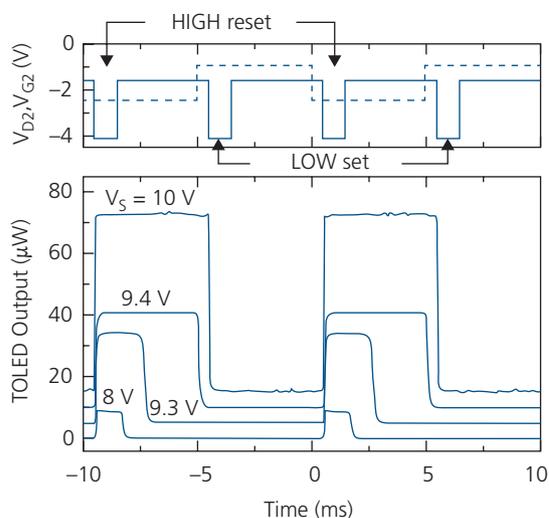

**Figure 7.61** (a) Schematic illustration of a microdetector at the end of a flattened AFM tip. (b) Topographic scan of an aperture in a Ag film on glass. Inset: Scanning electron micrograph of the  $8 \times 20$   $\mu$ m aperture. (c) Optical image of the aperture using the micro-OPD illuminated from the reverse side of the glass. (d) Topographic scan and (e) photocurrent scan of the aperture along the dashed lines in (b) and (c) (An et al., 2008).

**Figure 7.62** (a) Schematic cross-section of a transparent OLED integrated with an OPD in an optical bistable latch. (b) The integrated latch (dashed box) and external circuit used to create bistable operation (Xue and Forrest, 2002).

[CuPc/PTCBI]<sub>8</sub> OPD on its surface (cf. device in Fig. 7.44). When the PHOLED is energized, light is emitted through the substrate into the viewing direction. Light is also emitted from its top surface, and absorbed in the adjacent OPD. The resulting photocurrent provides positive feedback via an external load,  $R$ , at the drain of transistor, T1 (Fig. 7.62b). The circuit latches the transparent PHOLED in the emitting state until a blanking voltage,  $V_{G2}$ , is applied to the gate of T2. Thus there are two possible states of the circuit. In the LOW state, the PHOLED does not emit light, so that the current passing through the photodetector, is solely its dark current. By choosing an appropriate value of the load resistor,  $R$ , then  $V_{T1} < V_{G1}^L < 0$ , where  $V_{T1}$  is the threshold voltage of T1,  $V_{G1}^L = -|I_{PD}| \cdot R$  is the gate voltage of T1, and the superscript “L” represents the LOW state. Hence, T1 remains off to maintain the LOW state of the PHOLED. In the HIGH state, the PHOLED emits green light, generating a photocurrent. When the photodetector current is sufficiently high at  $V_{g1} < V_{T1} < 0$  ( $V_{g1}$  is the gate voltage of T1), T1 is turned on and the PHOLED continues to emit. Transistor, T2, therefore, toggles the switch between HIGH and LOW.

Optical bistability is shown in Fig. 7.63, where  $V_S$  is varied from 0 to  $-10$  V. The input of the drain and

**Figure 7.63** Operation of the TOLED/OPD bistable switch in Fig. 7.62. The upper panel shows the waveforms of the switching signals  $V_{D2}$  (dashed line) and  $V_{G2}$  (solid line). The lower panel shows the TOLED emission power vs.  $V_S$  (shifted vertically for clarity) (Xue and Forrest, 2002).

gate voltages,  $V_{D2}$  and  $V_{G2}$ , are shown in the upper panel. Here  $V_{G2}$  (solid line) is delayed from  $V_{D2}$  (dashed line) by 0.5 ms, and has a pulse width of 1 ms. During the pulse window of  $V_{G2}$ , T2 is turned on, setting  $V_{G1}$  to  $-0.95$  V or  $-2.45$  V, thereby switching the device to LOW, or reset to HIGH, respectively. The waveforms of the PHOLED bottom emission intensity at different  $V_S$  are shown in Fig. 7.63. At  $V_S = -8$  V, the PHOLED is on during the reset window. However, the HIGH state is not stable, and the PHOLED turns off when T2 is switched off. As  $V_S$  is increased, the PHOLED remains on for a brief period after T2 is switched off. The stable HIGH state is achieved for  $V_S = -10$  V, that is, the PHOLED is turned on at the onset of the reset window. It remains on until the onset of the set window, at which time it is turned off and remains off until the next reset pulse. The reset or set windows can be as narrow as 60 ns to make the device switch between the two stable states. The bandwidth of the circuit is  $\Delta f_{3dB} = 25$  kHz limited by the external components (Xue and Forrest, 2002).

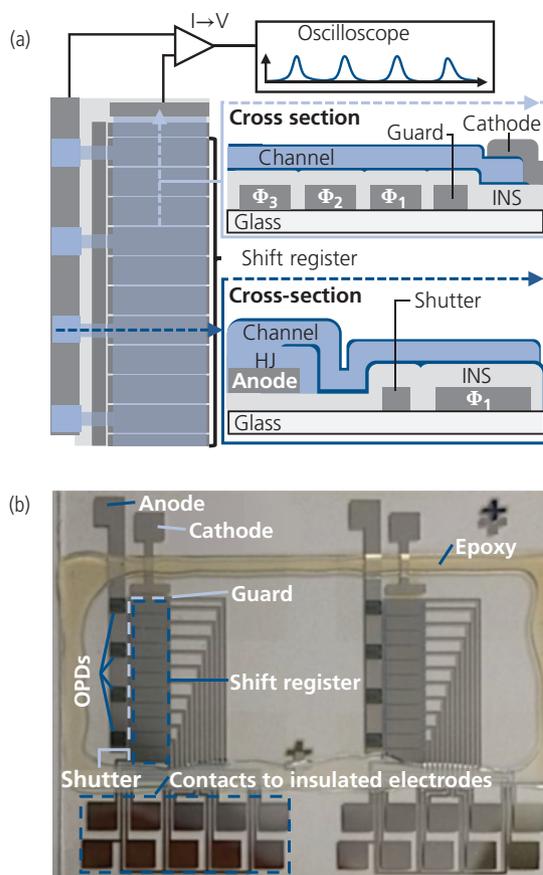

This integrated switch has potential applications in displays, where static image regions can be set, allowing for low bandwidth circuits that need to refresh only those pixels whose image content changes between frames. Also, it can simulate paper whereby an image can be generated and then maintained for long periods without need for refreshing the data. Finally, given its digital response to set and reset pulses, the switch is a building block for photonic logic circuits. Taken alone, the integrated PHOLED/photodetector can be used in

linear circuit applications such as in automatic display brightness control and sensing.

One last example application is an organic charge coupled device, or OCCD. Charge coupled devices transport charge packets near a semiconductor-insulator interface by sequentially passing them along between closely spaced electrodes in a voltage-controlled “bucket brigade” fashion. Since their introduction (Amelio et al., 1970, Boyle and Smith, 1970), CCDs have been successfully applied to high sensitivity optical imaging as a result of their favorable signal-to-noise ratio, high quantum efficiency, linearity, and speed (Janesick et al., 1987, Tiffenberg et al., 2017). In Section 4.5.5, we showed that charge transport can occur across distances of several centimeters in organic thin film heterostructures using energetic barriers to isolate electron and hole polarons (Burlingame et al., 2018). This striking phenomenon has led to the demonstration of an OCCD where electron packets delivered from an array of OPDs are transferred using a linear, three-phase shift register. Reaching the end of the register, the packets are read out, providing information about the intensity and spatial distribution of the incident light. In contrast to the operation of conventional CCDs that attract minority carriers to depletion regions at the semiconductor-insulator interface, the electrodes of the n-type organic semiconductor or shift register are negatively biased to block charge transport via repulsive potential barriers along its length (Coburn et al., 2019).

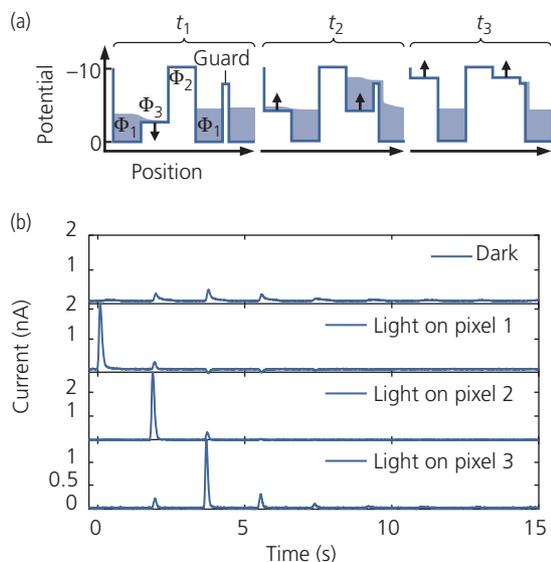

A four-pixel OCCD is shown schematically in Fig. 7.64a. The materials used in the OPD array and electron-transporting channel are identical to those shown in Fig. 4.77. Thirteen metal electrodes are photolithographically patterned on a glass substrate and coated with  $\text{Al}_2\text{O}_3$  – 11 electrodes separated by  $50\ \mu\text{m}$  define the shift register, and one each forms the guard and shutter electrodes. Four photodetectors with DTDCPB: $\text{C}_{70}$  HJ active regions are deposited on the anode, each connected to the nearest shift register electrode by a  $20\ \text{nm}$  thick  $\text{C}_{60}$  electron-transporting channel. Inside the shift register, the channel runs in a vertical stripe that extends past the guard electrode and terminates under the Ag cathode. The three shift register potential phases are denoted  $\Phi_1$ – $\Phi_3$ . The electrode nearest the guard electrode is  $\Phi_1$ , followed by  $\Phi_2$ ,  $\Phi_3$ ,  $\Phi_1$ , etc. A photograph of the device is shown in Fig. 7.64b.

Photocurrent is collected between the anode and cathode in response to illumination of the photodiodes. This current is cut off by applying  $< -8\ \text{V}$  at any one of the shutter, guard, or  $\Phi_1$  electrodes since they bisect the channels connecting the OPDs to the cathode. Charge transport is effected by first biasing

**Figure 7.64** (a) Top and cross-section schematic views of the OCCD, and the measurement circuit. The guard, shutter, and  $\Phi_3$  have a single contact pad each, while  $\Phi_1$  and  $\Phi_2$  electrodes have multiple pads that are connected externally. (b) Photograph of two,  $1.8\ \text{cm}$  long OCCDs located side by side. The contact pads and traces, alignment marks, and encapsulation cover slide attached to the substrate using UV cured epoxy are visible (Coburn et al., 2019).

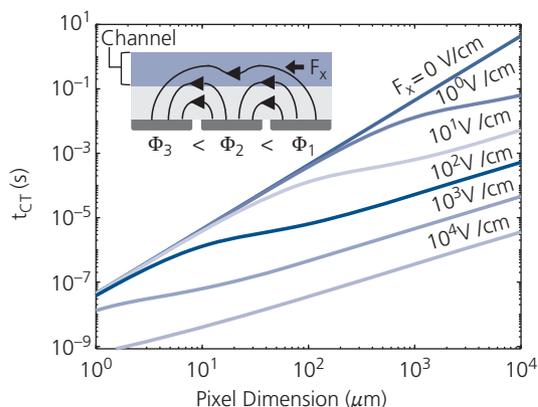

$\Phi_2$ ,  $\Phi_3$ , and shutter electrodes to  $-10\ \text{V}$ , and  $V_{\text{guard}} = -8.75\ \text{V}$ . This expels charge from the channel above the biased electrodes, leaving background charge packets confined above  $\Phi_1$ . The shift register is clocked using a phased sequence of three potentials, advancing the charge packets toward the cathode following the scheme in Fig. 7.65a. Because  $V_{\text{guard}} > -10\ \text{V}$ , electrons diffuse towards the cathode when expelled from above the adjacent  $\Phi_1$  electrode, preventing them from flowing back into the shift register. After expelling background charge,  $V_{\text{shutter}}$  swings to  $-9.6\ \text{V}$ , which blocks the background (dark) charge from leaking into the shift register. Then one HJ is illuminated, generating charges and raising the potential of electrons in the channel. This increases the rate of electrons leaking from the illuminated HJ over the shutter. Following exposure,  $V_{\text{shutter}}$  is switched back to  $-12\ \text{V}$  and the shift register is emptied by a

**Figure 7.65** (a) The potential sequence for electrodes at the end of the shift register. The electrode potentials are shown at times  $t_1$ – $t_3$ . High potentials repel the electron charge packets, indicated as shaded areas. (b) Measured signal for dark and single pixel illumination exposures. Here,  $t = 0$  corresponds to the first time  $\Phi_1$  swings negative following exposure.

series of eight clock cycles. Figure 7.65b shows the measured current in the dark and with illumination focused onto one pixel per measurement, resulting in a distinct current pulse observed at a time delay corresponding to the position of the illuminated pixel.

Using majority carrier electrons to store information contrasts with the operation of inorganic CCDs that transfer minority carriers. Using majority carriers precludes using attractive potentials (positive electrode bias, in the case of electrons) to confine charge packets because no depletion region would form. Also, the response of the OCCD is quite slow compared to inorganic CCDs, primarily due to its dependence on charge diffusion blocked by the shift register potentials. The speed of response can be significantly increased, however, by applying an electric field along the transport direction. This is shown via a calculation of the time required for 99.99% charge transfer between adjacent electrodes,  $t_{CT}$ , using the drift-diffusion equation as a function of electric field, with results in Fig. 7.66. The readout time for a  $N \times N$  matrix of pixels ( $N \gg 1$ ) is  $t_{RO} \approx t_{CT}(3 \times N)^2 / N_{amp}$ , where  $N_{amp}$  is the number of readout amplifiers. In the diffusion limit, a  $500 \times 500$  sensor with  $N_{amp} = 4$  requires 6–7  $\mu\text{m}$  diameter pixels to achieve  $t_{RO} < 1$  s, while 10  $\mu\text{m}$  pixels and  $N_{amp} = 500$  (1 per column) yields  $t_{RO} < 20$  ms. Introducing drift transport significantly decreases  $t_{RO}$ . Drift can be increased by fringing fields as shown in Fig. 7.66, inset.

**Figure 7.66** Simulated charge transfer time calculated from the solution to the drift-diffusion equation vs. electrode size and fringe field,  $F_x$ . The transfer time,  $t_{CT}$ , is the time at which 99.99% of the initial uniform charge distribution has transferred to the adjacent electrode. Inset: Illustration of the fringe fields for an electrode-channel spacing similar to the electrode width. The fields are established by applying voltages such that  $\Phi_1 > \Phi_2 > \Phi_3$ . Lines represent electric field lines in the direction of the arrows (Coburn et al., 2019).

Despite the inherently lower charge mobility in organic compared to inorganic semiconductors, OCCDs may find uses in space applications, where their light weight (Cardinaletti et al., 2018, Schreurs et al., 2018) and comparatively low sensitivity to cosmic radiation (Kumar et al., 2010, Paternò et al., 2017) can be beneficial. They can function as an element in ultralight optical imaging systems when used with thin film Fresnel lenses (O'Neill et al., 2003), or as lightweight memory devices. Additionally, stacked, semitransparent OCCDs with individual pixel triads absorbing in the red, green and blue spectral regions can produce color images.

### 7.3 Organic solar cells

Whenever there is significant opportunity to provide a social benefit that may also be financially rewarding, there are many contenders to capture the new market. The solar energy field is a singular example where benefits to the commercial sector as well as to the social welfare of humanity, abound. This has led to considerable competition attention and investment in next generation solar cells that deliver advantages beyond today's dominant source of solar power generation: crystalline and polycrystalline Si photovoltaics. It is important, therefore, to clearly establish the benefits afforded by new approaches such as OPVs for generating low cost and environmentally friendly electricity from solar energy. In the following, we attempt to lay out important considerations for new solar harvesting technologies that will clarify the

advantages, and potential application spaces that are available to OPV technology.

(i) *Cost*: The cost of the solar cell is wrapped up in all of its performance parameters, from efficiency to operational lifetime, to the bill of materials and manufacturing yield. Silicon solar provides a module cost of  $< \$0.50/W_p$ , (here  $W_p$  is the peak wattage output of the module). Added to this are *soft costs* (e.g. costs of financing, taxation, installation, etc.), inverters, support equipment, and so on. A disadvantage of Si, however, is in the transportation, installation, and support of heavy, fragile, glass-like panels. In contrast, OPVs can be fabricated on lightweight and flexible substrates that reduce the requirement for costly and heavy support structures. The cells can be applied to windows, rooftops, curved automobile surfaces, etc. in the form of tapes, panels, or adhesive appliques. Furthermore, roll-to-roll (R2R) fabrication of high efficiency single and multijunction cells on flexible substrates has a realistic opportunity to dramatically reduce cost, as OPVs are produced “by the kilometer” rather than traditional semiconductors fabricated in small batches of wafers.

(ii) *Efficiency*: Silicon module power conversion efficiencies (*PCE*) exceed 20%, with even higher efficiencies (nearly 29%) achieved for GaAs-based cells (Green et al., 2017). A sampling of efficiencies of several solar cell technologies is provided in Table 7.5. Among these examples, organic solar cells apparently have the lowest efficiencies. However, there are many other criteria beyond efficiency that must be met before a technology gains popular acceptance, including cost, reliability, environmental friendliness, and large-scale manufacturability. For example, comparison of

the costs of Si and GaAs technologies is an illustration of how efficiency is only one important parameter to consider. Multijunction, group III–V semiconductor cells have *PCE*  $\sim 46\%$  under intense solar concentration, but are prohibitively expensive for terrestrial commoditization. In many applications, efficiencies at or around 15% may be adequate, provided that other factors such as lower cost support equipment, longer lifetime, etc. compensate for the lower efficiency. OPV efficiencies are now poised to exceed 17% with the introduction of NFAs. Yet this is still significantly below the  $\sim 25\%$  thermodynamic efficiency limit for OPV single junction cells (Giebink et al., 2011), with even higher efficiencies projected for multijunction cells. Hence, it is reasonable to assume that with continued development of OPV materials and device architectures, efficiencies will eventually exceed 20%.

(iii) *Reliability*: Solar cell standards demand 20–25 year module lifetimes. Both Si and GaAs technologies meet this requirement. As noted above, reliability also ultimately factors into the total module cost of ownership, where a longer operational lifetime implies a longer period between panel disposal and replacement. Reduced manufacturing costs or higher efficiencies may reduce this requirement to some extent, but reliability must be high to achieve market acceptance. OPVs have been making substantial progress in this domain as well. Operational stability under accepted operating environmental conditions is still in its early stages, but lifetimes of some high efficiency cells are now well in excess of 20 years. Considerable strides are being made to understand

**Table 7.5** Example solar cell efficiencies

Cell type	Configuration	Max. PCE <sup>a</sup>	Ref. <sup>b</sup>
Inorganic, thermodynamic limit	Single junction	31%	(Shockley and Queisser, 1961)
OPV, thermodynamic limit	Single junction	22–27%	(Giebink et al., 2011)
Multijunction III–V cell	Concentrated	46%	(Green et al., 2017)
GaAs cell	Single junction	28.8%	(Green et al., 2017)
Crystalline Si cell	Si single junction	26.3%	(Green et al., 2017)
Crystalline Si cell	Module	24.0%	(Green et al., 2017)
CIGS	Thin film	24.4%	(Green et al., 2017)
Perovskite	Thin film	19.7%	(Green et al., 2017)
Organic cell	Single junction	15.7%	(Yuan et al., 2019)
Organic cell	Multijunction <sup>c</sup>	15.4%	(Li et al., 2018)

<sup>a</sup> Measured under AM1.5G spectrum at 1 kW/m<sup>2</sup>, except for the concentrated multijunction III–V cell measured at 508 suns intensity.

<sup>b</sup> Green et al. (2017) is a summary compilation of results. References to specific data quoted can be found in the compilation.

<sup>c</sup> Although higher efficiencies have been reported, multijunction cells are notoriously difficult to measure accurately. This is the highest known reliable value to date.

and reduce failure mechanisms. Based on experience in the now ubiquitous OLED display industry, the concerns for OPV lifetime are dissipating, yet considerable work remains for this technology to achieve widespread acceptance.

(iv) *Environmental friendliness*: The complete absence, or at least minimization of toxic materials used in both manufacturing and in the completed panels is essential. The ubiquitous deployment of solar panels magnifies even a small level of toxicity into a major environmental hazard. Here OPV excels beyond all other incumbents. The active materials are similar to dyes used in clothing, ink jet printers, displays (LCD and OLED), paints, and so on. In short, they are already widespread, and many materials are environmentally benign. The most problematic components are the inorganic materials used such as indium tin oxide. Heavy metals (e.g. Pb, Se, and Cd) and toxic and reactive chemicals (e.g. halide salts) are also largely absent in OPVs, and the synthetic processes are similar to those used in preparing dyes. Even less solvent-intensive methods are used in the production of fullerenes. These processes and their products tend to be low cost and importantly, a very low energy investment is required in the production of both the constituent materials as well as in the fabrication of the cells themselves. That is, the energy required for OPV production is rapidly returned early in their operational life.

(v) *New capabilities*. One factor in choosing a new technological paradigm is the features that it offers that cannot be easily replicated by existing solutions. In this regard, OPV technology has demonstrated its ability for efficient energy production even if the cells are transparent, or semitransparent in the visible. This is a result of the ability to tailor OPV materials sets that absorb primarily in the NIR between wavelengths of 650 nm to 1100 nm, thus capturing a significant amount of the solar power that is invisible to the human eye. This makes OPVs particularly attractive for coatings on windows or on building facades (so-called *building integrated photovoltaics* and *building applied photovoltaics*, or BIPV and BAPV, respectively). This feature distinguishes OPVs from conventional Si, GaAs, and other thin film inorganic technologies and provides unique opportunities for their early and rapid adoption by large, unserved markets when combined with other attributes of high efficiency and reliability, and low-cost manufacture.

(vi) *Leveraging existing industries and capabilities*: Starting up an entirely new manufacturing process with new materials where there is no significant existing technical base is prohibitively expensive. The

Si solar industry took advantage of, and leveraged the integrated circuit knowledge base and industrial capabilities for producing raw materials before it gained a sufficiently strong foothold to become self-supporting and sustainable on its own. Likewise, OPVs are building on the enormous economic base and manufacturing industry of OLED displays and lighting. The semiconductor equipment infrastructure industry for OLEDs alone is ~ \$US 20 bn/year. Much of this same equipment and expertise can be readily transferred to the OPV industry. Similarly, the OLED display panel industry represents a > \$US 20 bn market, with >2 bn OLED smartphone displays, more than a million TV sets, and a high number of electronic tablets that use large display panels in the hands of consumers today. Hence, the infrastructure and knowhow for manufacturing OPV panels is in place, and growing daily. Major OLED manufacturers are currently developing OPVs, recognizing the synergies that exist for rapid scaling into a major industry.

(vii) *Synergies with other industries, and workforce development*: The lessons learned in fabricating OPVs (e.g. by R2R production) can be rapidly translated into the R2R manufacture of low cost OLED lighting, and indeed can also be translated into the manufacture of inorganic semiconductor appliances. The workforce skill and expertise developed in exploring OPV technology has rapidly adapted to solve problems in these other industries. The intellectual curiosity and imaginative versatility one gains in studying organic electronics can lead to unanticipated advances in organic as well as inorganic semiconductor device research and technology.

In the remainder of this section, we explore many potential advantages of OPVs by describing their underlying physics and technology. Indeed, while OLEDs are the only clear example of an organic electronic technology making a large commercial impact, OPVs stand poised to be the second example owing to their inherent adaptability to large area, low cost, flexible devices that offer competitive performance.

### 7.3.1 Solar cell basics

A solar cell converts solar irradiance into electrical energy. In its simplest terms, a solar cell is a photodiode that is operated in the fourth quadrant of its  $j$ - $V$  characteristics, that is, it is operated in the photovoltaic mode. It is only in this quadrant that power can be produced. A solar cell must be optimized to capture the maximum solar irradiation with minimum loss, whereas a photodiode is tuned to have low noise and high sensitivity within a narrow spectral band. As such, the materials, the details of the active region,

the methods used for coupling broad solar radiation vs. a narrower wavelength band into the solar cell, and the contacts must be optimized for power rather than current generation.

Solar cell, or photovoltaic cell, operation can be understood from its  $j$ - $V$  characteristics in Fig. 7.67. The open circuit voltage ( $V_{OC}$ ) and short circuit current density ( $j_{SC}$ ) are defined by the intercepts of the  $j$ - $V$  characteristics with the  $V$  and  $j$  axes, respectively. Here,  $j_{SC} = j_T - j_D$ , where  $j_T$  is the total current and  $j_D$  is the dark current. Typically,  $j_{SC} \gg j_D$  such that it is simply equal to the photocurrent,  $j_{ph}$  at  $V = 0$ . In the fourth quadrant, the power density generated is  $P = -j_{ph}V < 0$ . In the first and third quadrants,  $P > 0$  and hence power is dissipated. By convention, in solar cells the power generated is taken as positive. The maximum power generated by the cell (called the *maximum power point*, or MPP) is defined by the largest area rectangle (shaded area) whose corner opposite the origin intersects with the  $j$ - $V$  curve. Using our sign convention, the maximum power density generated is given by

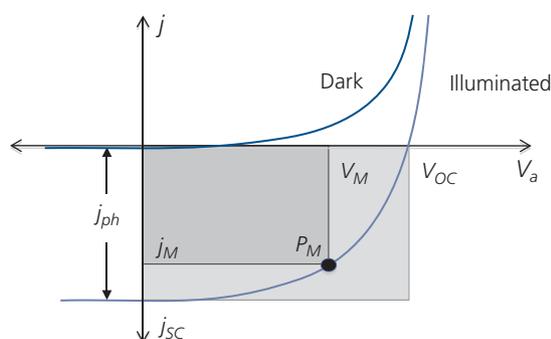

$$P_M = j_M V_M, \quad (7.117)$$

where  $j_M$  and  $V_M$  are the corresponding current and voltage at the MPP. It is convenient to define the cell figure of merit, the *fill factor*,  $FF$ , as the ratio of the areas of the rectangles defined by  $j_{SC}$  and  $V_{OC}$  to that at  $P_M$ , viz.

$$FF = \frac{j_M V_M}{j_{SC} V_{OC}}, \quad (7.118)$$

which, according to Eq. 7.55 for an organic HJ and the Shockley ideal diode equation (Eq. 4.282) for inorganic junctions, is always less than unity. Then the power conversion efficiency ( $PCE$  or  $\eta_P$ ) is the ratio of the electrical power generated by the cell to the optical power density incident from the sun,  $P_{opt}$ . Thus,

$$\eta_P = \frac{j_M V_M}{P_{opt}} = \frac{FF(j_{SC} V_{OC})}{P_{opt}}. \quad (7.119)$$

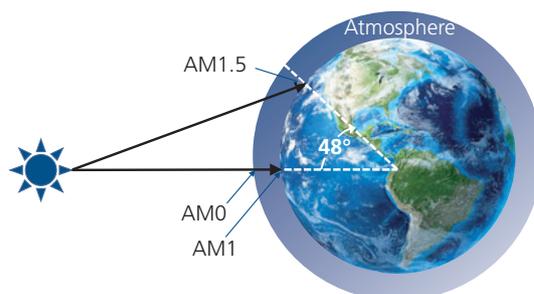

**Figure 7.67** Current-voltage characteristics of a solar cell in the fourth quadrant. Variables are defined in text.

Clearly, we seek designs that have the highest fill factor, that is, that conform most closely to a diode whose ideality factor,  $n \approx 1$ . This requires a minimum series resistance and a maximum shunt resistance that approaches the thermal resistance of the junction (see Section 7.1.2).

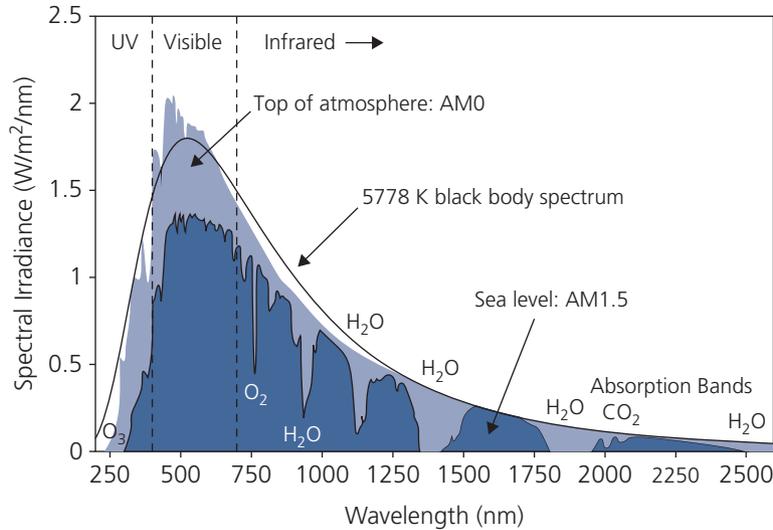

The short circuit current density depends on the efficiency of the solar cell and its overlap with the solar spectrum:

$$j_{SC} = q \int \eta_{ext}(\lambda) \phi_{sun}(\lambda) d\lambda, \quad (7.120)$$

where  $\phi_{sun}(\lambda)$  is the solar spectral flux density. The reference solar spectrum standards are set by the American Section of the International Association of Testing Materials (ASTM). The flux at the Earth's surface is a function of the spectral properties of the intervening atmosphere, or the *air mass* (AM) that acts as a filter to solar radiation. Referring to Fig. 7.68, the irradiance arriving at the top of the atmosphere from a solar black body source with a temperature of approximately 5800 K is known as the AM0 reference spectrum, ASTM-490-00, with an intensity of  $1.353 \text{ kW/m}^2$ . This spectrum is primarily used by the aerospace community for determining satellite solar panel efficiencies. The AM1 spectrum corresponds to light impinging normal to the surface at the zenith ( $z = 0^\circ$ , i.e. at normal incidence). This spectrum is observed within the Earth's equatorial regions and has an intensity of  $1 \text{ kW/m}^2$ . The most commonly used spectral standard is that found in the temperate regions, where the intensity is  $9638 \text{ W/m}^2$ , but for convenience is often simply taken as  $1 \text{ kW/m}^2$ . The spectrum is different from that at the equator, since light travels through a deeper blanket of atmosphere. The reference spectrum (ASTM G-173-03) is known as the *global* AM1.5, or AM1.5G spectrum. This reference is an average of collection of the solar irradiance from a network of observation points across the United States. It assumes incidence

**Figure 7.68** Solar irradiance on the Earth and the corresponding air mass designations.

**Figure 7.69** Spectra for several different illumination conditions.

on a tilted surface at  $37^\circ$ , and a zenith at  $z = 48^\circ$  facing due south.

Different illumination conditions, along with the corresponding spectral irradiance intensities are shown in Fig. 7.69. The AM1.5G spectrum shows the strong effects of atmospheric absorption, particularly by  $\text{H}_2\text{O}$  across the IR. The measurement of solar cell efficiency begins with this understanding of reference spectra. However, the process of standardized quantification of cell efficiency is made more complicated due to the absence of such spectra in the laboratory where the solar cell is evaluated; a topic that is covered in Section 7.3.3.

An approximate relation between solar intensity and the air mass at sea level with the sun at the zenith is given by

$$I = 1.1 \cdot I_0 [0.7]^{AM^{0.678}}. \quad (7.121)$$

Here,  $I_0 = 1.353 \text{ kW/m}^2$  corresponds to the AM0 intensity at the top of the Earth's atmosphere, and 1.1 assumes that there is an additional 10% power due to diffuse scattering.

Another quantity in Eq. 7.119 that determines the power conversion efficiency is  $V_{OC}$ . From Eq. 7.55, setting  $j = 0$ , we obtain

$$V_{OC} = \frac{nsk_B T}{q} \log \left( \frac{j_{ph}}{j_0} + \frac{k_{PPd}}{k_{PPd,eq}} \right) \approx \frac{nsk_B T}{q} \log \left( \frac{j_{SC}}{j_0} + 1 \right). \quad (7.122)$$

In the expression to the right, we take  $j_{ph} = j_{SC}$  at  $V_a = 0$  for convenience, and that ionization of PPs is small, such that  $k_{PPd} = k_{PPd,eq}$ . This is rarely, if ever the

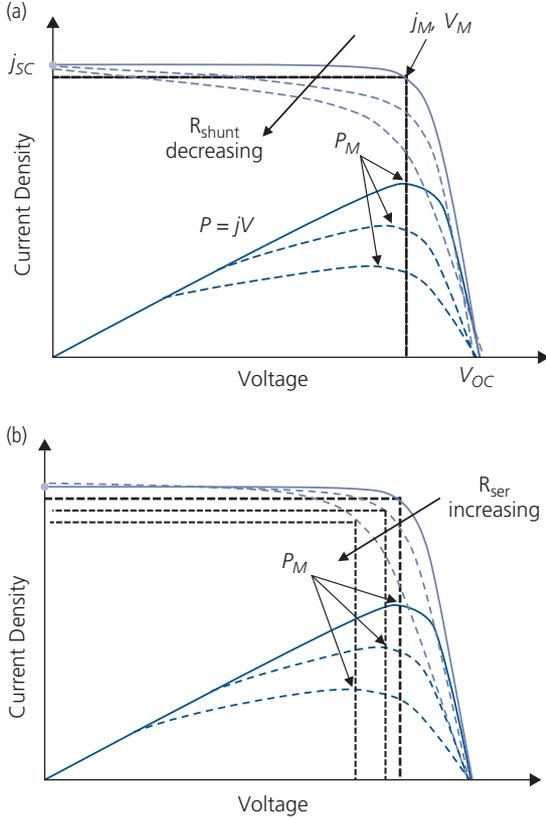

case for OPVs, and hence this latter expression can lead to errors. In any case,  $V_{OC}$  increases logarithmically with the photocurrent, and with decreasing dark saturation current.

Plots of the fourth quadrant  $j$ - $V$  characteristics for several different shunt and series resistances and their implication on the maximum power generated by a solar cell ( $P_M$ ) are shown in Fig. 7.70a and b. In describing solar cell characteristics, the fourth quadrant is often "flipped" into the first quadrant, plotting both  $j_{ph}$  and  $V$  as positive quantities. The generated power has a maximum at  $P_M$ , falling off as  $V_a$  deviates from this point. The power curves, therefore, are the locus of areas of the rectangles within each point of the  $j$ - $V$  characteristic. A decreasing  $R_{shunt}$  decreases the curvature at the MPP, which depresses both  $j_M$  and  $V_M$ . Similarly, an increasing series resistance decreases the forward-biased slope, which results in a decreased  $V_M$ . The fill factor is strongly influenced by both the series and shunt resistances.

Now, from Chapter 4, and using Eq. 7.56 for  $j_0$ ,  $V_{OC}$  for a symmetric junction is

$$qV_{OC} = \Delta E_{HL} - ns k_B T \ln \left[ \left( \frac{k_{rec} k_{PPr}}{k_{PPd} + k_{PPr}} \right) \frac{qa_0 N_S^2}{j_{ph}} \right]. \quad (7.123)$$

In Section 4.7.2, we showed that the PP dissociation rate is determined by Onsager–Braun ionization at small electric fields (Braun, 1984). Then,  $k_{PPd} \rightarrow \frac{3}{4\pi a_0^3} k_{rec} \exp(-E_B/k_B T)$ , where  $E_B$  is the PP binding energy and  $a_0$  is its radius (approximately equal to

**Figure 7.70** Power-generating quadrant of a solar cell. The ideal  $j$ - $V$  characteristics (grey solid lines) and with (a) decreasing shunt and (b) increasing series resistances (grey dashed lines) are shown. The blue lines (solid and dashed) are the corresponding power output curves equal to  $jV$ . The maximum power outputs,  $P_M$ , at the MPPs are indicated.

the molecular separation distance at the HJ). In the limit of very high illumination intensity or low temperature, this expression leads to a maximum open circuit voltage of

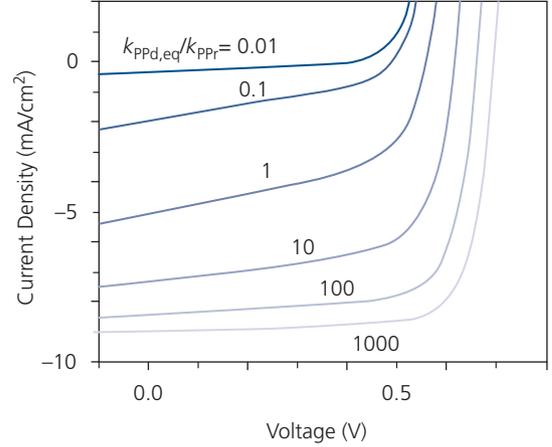

$$qV_{OC}^{max} \rightarrow \Delta E_{HL} - E_B \quad (7.124)$$

(cf. Eq. 4.308). Hence, an essential challenge for optimizing OPV efficiency is to reduce  $E_B$ . We will show that NFAs are effective in reducing this loss channel compared with conventional fullerene-based OPVs.

Equation 7.123 shows that  $V_{OC}$  is dependent on several factors. Notably, there is a competition between PP recombination vs. dissociation, expressed by the recombination efficiency of

$$\eta_{PPr} = \frac{k_{PPd}}{k_{PPr} + k_{PPd}}. \quad (7.125)$$

When the dissociation rate is increased relative to recombination (i.e.  $k_{PPd} > k_{PPr}$ ), the losses are decreased, leading to an increase in  $V_{OC}$ . The

**Figure 7.71** Calculated  $j$ - $V$  characteristics in the fourth quadrant for an archetype planar HJ photodiode in reverse bias ( $V_a < 0$ ) under AM1.5G solar illumination at an intensity of  $100 \text{ mW/cm}^2$ . The curves correspond to different ratios of the PP dissociation and recombination rates,  $k_{PPd}$  and  $k_{PPr}$ , respectively (Renshaw et al., 2012).

trade-off is illustrated in Fig. 7.71 where the  $j$ - $V$  characteristics are plotted for an ideal HJ diode for varying ratios of  $k_{PPd}$  to  $k_{PPr}$  (Renshaw et al., 2012). Interestingly, the decrease in  $FF$  and  $j_{SC}$  with decreasing  $k_{PPd}/k_{PPr}$  is even larger than the decrease in  $V_{OC}$ . This is due to curvature in the  $j$ - $V$  characteristics as a result of field-induced PP ionization and current losses from recombination. Hence, not only is it essential to reduce  $k_{PPr}$ , but also to increase  $a_0$  to achieve high efficiency. We will show in the following sections that these factors are controlled by molecular design as well as the morphologies of the donor and acceptor phases within mixed and BHJ active regions.

The maximum power is found by multiplying the current in Eq. 7.55 by  $V_a$  and then setting the first derivative to zero. Once  $P_M$  is found, then from Eq. 7.117, it can be shown that

$$V_M = V_{OC} - \frac{n_s k_B T}{q} \log \left( \frac{q V_M}{n_s k_B T} - \chi(V_M) \right), \quad (7.126)$$

where  $\chi(V_M) = \frac{k_{PPd}(V_M)}{k_{PPd,eq}}$  and we assume for convenience that the change in  $\chi$  is small and nearly constant with  $V_a$ . Now, setting  $\beta = (j_{SC} + j_M)/j_{SC}$ , then at the maximum power

$$\beta_M = \left[ \chi(V_M) + \log \left( \beta_M \frac{j_{SC} + j_D}{j_D} \right) \right]^{-1}. \quad (7.127)$$

Here, we have replaced the saturation current,  $j_0$ , with  $j_D$ , which includes all parasitic sources that contribute to the dark current. The  $FF$  in the absence of series

resistance, and for  $R_{shunt} \rightarrow \infty$ , can now be expressed in terms of  $\beta_M$  as

$$\begin{aligned} FF(R_{shunt}, R_{ser}) &= FF(\infty, 0) \\ &= \frac{(\chi(V_M) - \beta_M) \log[\beta_M(j_{SC} + j_D)/j_D]}{\log[(j_{SC} + j_D)/j_D]}. \end{aligned} \quad (7.128)$$

Hence, the fill factor depends on both the dark and the short circuit currents (and hence the incident power). An increase in power results in an increase in  $j_{SC}$ , which in turn decreases  $\beta_M$ . Ultimately, this increases  $FF$ . An increasing dark current,  $j_D$ , has the opposite effect; its presence results in a decrease in  $FF$ , as implied by the results in Fig. 7.71 where  $j_0 \propto (1 - k_{ppd,eq}/k_{ppr})$  for a large PP recombination rate.

A realistic model of cell performance must include the dependence of  $FF$  on the parasitic cell resistances. For this, we define the *power loss penalty* ( $f_{PLP}$ ), which is the fractional decrease in power from its value in the absence of series resistance, and an infinite shunt resistance. For a finite shunt resistance  $R_{shunt}$ , and  $R_{ser} \rightarrow 0$ , then,

$$f_{PLP} = \frac{V_M^2}{R_{shunt}} / j_M V_M = \frac{V_M}{j_M R_{shunt}} \approx \frac{V_{OC}}{j_{SC} R_{shunt}}. \quad (7.129)$$

Similarly, for a nonzero  $R_{ser}$  and  $R_{shunt} \rightarrow \infty$ ,

$$f_{PLP} = \frac{j_M^2 R_{ser}}{j_M V_M} = \frac{j_M R_{ser}}{V_M} \approx \frac{j_{SC} R_{ser}}{V_{OC}}. \quad (7.130)$$

Combining the results of Eqs. 7.129 and 7.130 we have

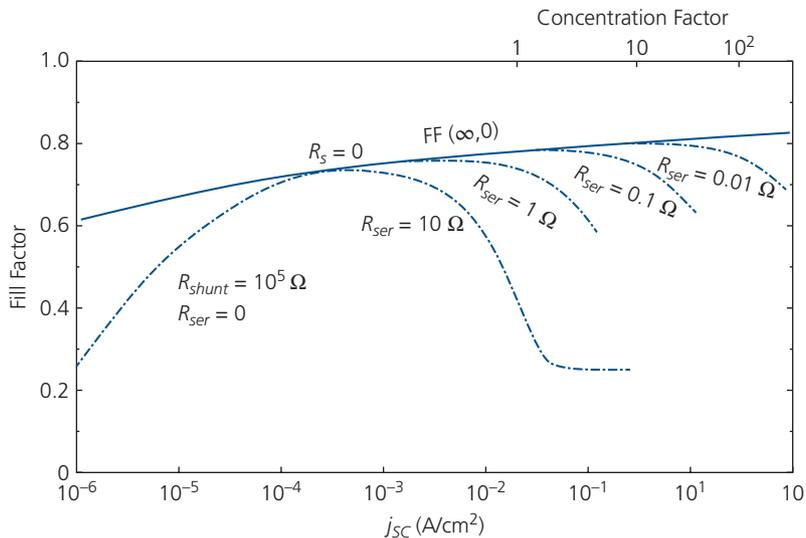

$$\begin{aligned} FF(R_{shunt}, R_{ser}) &= FF(\infty, 0)(1 - f_{PLP}) \\ &= FF(\infty, 0) \left( 1 - \frac{V_{OC}}{j_{SC} R_{shunt}} - \frac{j_{SC} R_{ser}}{V_{OC}} \right). \end{aligned} \quad (7.131)$$

Figure 7.72 shows a plot of  $FF$  as a function of  $j_{SC}$  for a solar cell with several values of  $R_{ser}$  and  $R_{shunt}$ . The increase of  $FF$  with increasing current, and its decrease in the presence of parasitic resistances is apparent. Note that this plot extends beyond one sun intensity, showing the  $FF$  for concentrated illumination. The concentration factor of a solar cell is equal to

$$CF = \frac{P_{inc}}{1 \text{ kW-m}^{-2}}. \quad (7.132)$$

### 7.3.2 Thermodynamic limits to OPV efficiency

Before embarking on an exploration of means for achieving high performance OPVs, we first calculate the fundamental limits to their efficiency. The *Shockley-Queisser (SQ) thermodynamic efficiency limit* (Shockley and Queisser, 1961) was derived for inorganic solar cells using the principle of detailed balance (Shockley and van Roosbroeck, 1954), which requires that the absorbed and emitted radiation fluxes be equal for a cell in thermal equilibrium. The SQ treatment is based on the premise that photon interactions with the cell occur via the generation

**Figure 7.72** Fill factor vs. short circuit current density for several values of series and shunt resistances,  $R_{ser}$  and  $R_{shunt}$ . The cell has the following properties:  $j_{SC} = 1 \text{ nA/cm}^2$ ,  $n_s = 1$ , active area =  $1 \text{ cm}^2$ .  $R_{shunt} = \infty$  except for the dashed curve. The concentration ratio is defined as the intensity of the light relative to 1 sun ( $1 \text{ kW/m}^2$ ). After Bube and Fahrenbruch (1981).

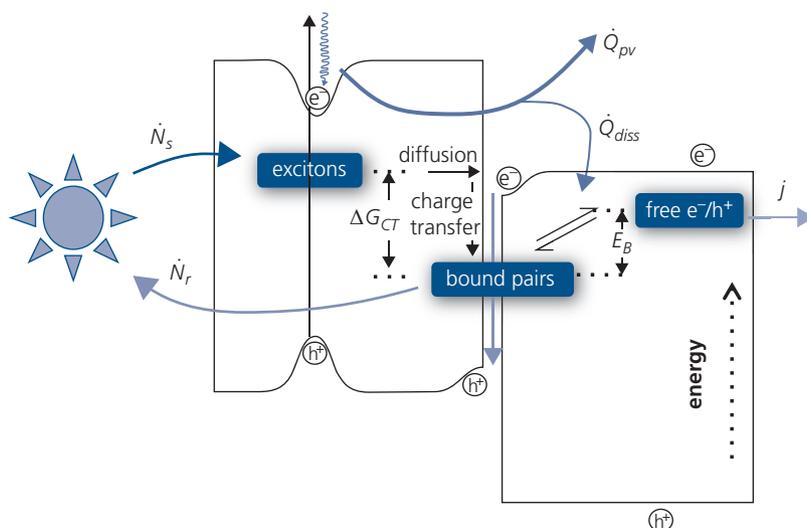

and recombination of free electron–hole pairs. This is a good assumption for inorganic semiconductor solar cells because photon absorption leads to the direct generation of free carriers. As a result, the chemical potential,  $\mu_{ph}$ , of emitted photons is the same as that of the electron and hole quasi-Fermi level splitting, which for an ideal cell is equal to the voltage difference between its contacts. That is,  $\mu_{ph} = V_{ar}$ , and the emitted light intensity is increased by  $\exp(q\mu_{ph}/k_B T)$  relative to equilibrium (Luque et al., 2002, Luque and Marti, 2003, Würfel and Würfel, 2009).

The situation is fundamentally different in organic semiconductors, where the primary excitations are tightly bound Frenkel and charge transfer excitons with binding energies ranging from 0.3 to 1.2 eV. Thus, photons interact only with the bound exciton population, and hence the photon chemical potential is that of the exciton population, not that of the free electrons and holes. The efficiency limit of an excitonic solar cell consequently depends on both the optical energy gap and the exciton and PP (or CT) binding energies, which is in stark contrast to the SQ limit for inorganic cells, which applies to the special case where these binding energies can be neglected.

Charge generation in organic semiconductors via exciton and PP dissociation leads to the diode equations in materials containing, or are free of traps in Sections 4.7.2 and 7.2. It is a multistep process that

begins by photon absorption that generates Frenkel excitons within either the donor or acceptor layer. On reaching the D-A HJ, the exciton dissociates into a charge transfer state whose Gibbs's free energy is less than that of the excitonic precursor by  $\Delta G_{CT}$  (see Fig. 7.73). This state also leads to increased radiative and/or non-radiative recombination. The last step in the charge generation process is the liberation of the CT state binding energy,  $E_B$ , to generate free charges.

The thermodynamically limited efficiency can be obtained using the detailed balanced approach of Shockley and Queisser, although this generally requires the implicit and artificial inclusion of losses arising from formation of, and radiation by the intermediate CT state (Kirchartz et al., 2009). Here, we present a treatment by Giebink et al. (2011) based on the Second Law of Thermodynamics where the inclusion of the free energy loss,  $\Delta G_{CT}$ , is an explicit element of the model. We make the following assumptions. (i) The cell consists of only a single junction. Stacked, multijunction cells can exceed the limits calculated here, as we will show in subsequent sections. Nevertheless, single elements within such stacked structures are still limited by these results. (ii) Each photon can only generate a single exciton. Multiexciton generation processes such as singlet fission are not included. (iii) Every incident photon with energy greater than the optical energy gap,  $E_{opt}$ , of

**Figure 7.73** The photogeneration of free charge in an excitonic solar cell in the radiative limit. The incident solar photon flux ( $\dot{N}_s$ ) is fully absorbed by the cell, forming bound excitons. Radiative exciton recombination produces the luminescent photon flux ( $\dot{N}_r$ ) emitted from the cell. Alternatively, excitons dissociate at the D-A heterointerface with a loss in free energy of  $\Delta G_{CT}$ , to form polaron pairs with binding energy,  $E_B$ . Subsequent formation of free carriers requires heat input ( $\dot{Q}_{diss}$ ) to overcome  $E_B$ , subtracting from the heat produced in the photovoltaic process,  $\dot{Q}_{pv}$ . The current from the free electrons ( $e^-$ ) and holes ( $h^+$ ) is given by  $j$ . In an ideal OPV, recombination only occurs from PP states since all excitons reach the HJ (Giebink et al., 2011).

Reprinted figure with permission from Giebink, N. C., Wiederrecht, G. P., Wasielewski, M. R. & Forrest, S. R., Phys. Rev. B, 83, 195326, 2011. Copyright 2011 by the American Physical Society.

either the donor or acceptor is absorbed ( $\eta_A = 1$ ). (iv) A photogenerated exciton ultimately arrives at the HJ with unity efficiency, that is,  $\eta_{ED} = 1$ . (v) All photo-generated free charges,  $n$ ,  $p$ , are collected at their corresponding contacts ( $\eta_{CC} = 1$ ). Finally, (vi) the solar radiation at the Earth's surface is that of a perfect black body with a surface temperature of  $T_s = 5778$  K. Thus, effects due to atmospheric absorption that define the AM1.5G spectrum in Fig. 7.69 are ignored.

The exciton dissociation process must be accompanied by a net decrease in Gibb's free energy, whose change is given by (Lewis and Randall, 1961, Zemansky and Dittman, 1981, Giebink et al., 2011)

$$dG = \mu dN = dE - TdS + PdV < 0. \quad (7.133)$$

Here,  $N$  is the particle number,  $E$  is the internal energy,  $S$  is the entropy,  $P$  is the pressure, and  $V$  is the volume. Since the particle flux is equal to the cell current,  $I = jA$ , and for a constant volume, the Gibb's free energy flux is (Luque and Marti, 2003)

$$\Delta\dot{G}_{diss} = (\mu_{eh} - \mu_{pp})I = (E_{eh} - E_{pp})I/q - T_a\Delta\dot{S}_{diss}, \quad (7.134)$$

where  $T_a$  is the cell temperature, and the subscripts  $PP$  and  $eh$  refer to the bound polaron pair and free electron/hole pairs, respectively. Since the entropy change is equal to the heat supplied to the reaction,  $T_a\Delta\dot{S}_{diss} = \dot{Q}_{diss}$ , and since  $E_B = E_{eh} - E_{pp}$ , we have

$$q(\mu_{pp} - \mu_{eh}) = -E_B + q\dot{Q}_{diss}/I > 0. \quad (7.135)$$

Note that the difference between the exciton binding energy,  $E_X$ , and that of the PP is the free energy decrease,  $\Delta G_{CT}$ . That is,

$$E_{pp} = E_X + \Delta G_{CT}, \quad (7.136)$$

where  $\Delta G_{CT} < 0$ .

According to Eq. 7.135, photocurrent is generated if the entropy increase upon dissociation (i.e. heat input,  $\dot{Q}_{diss}$  in Fig. 7.73) fully compensates for  $E_{pp}$ . This process, therefore, results in cooling of the OPV. Hence, when  $\dot{Q}_{diss} > (I/q)E_B$ , the heat flux is sufficient to drive exciton dissociation, and the exciton chemical potential can, in principle, equal the cell voltage which simply recovers the SQ result (Shockley and Queisser, 1961, Luque and Marti, 2003). However, when  $\dot{Q}_{diss} < (I/q)E_B$ , the heat input is insufficient and  $\mu_{pp}$  must exceed  $V_a$  by the amount required to compensate for this deficiency.

The total luminescent photon flux radiated from the cell, assuming that it is a black body, is determined by integrating the flux at each energy:

$$\begin{aligned} \Phi(\mu, E_{opt}, T, f_\omega) &= \frac{2f_\omega}{h^3c^2} \int_{E_{opt}}^{\infty} \frac{E^2}{\exp[(E - q\mu)/k_B T_a] - 1} dE \\ &= \frac{2f_\omega}{h^3c^2} \int_{E_{opt}}^{\infty} \phi(E, T_a) dE, \end{aligned} \quad (7.137)$$

where  $E = hc/\lambda$  is the photon energy and  $f_\omega$  is the étendue of the source. The lower integration limit,  $E_{opt}$ , is the minimum exciton absorption energy of the cell (i.e. its optical energy gap, see below), and  $\phi(E)$  is the photon flux between  $E$  and  $E + dE$ . The possible increase of  $\mu$  relative to  $V_a$  as discussed above increases the radiative recombination rate compared to an inorganic solar cell, and leads to a maximum efficiency that is lower than that given by the SQ limit. Physically, the increase in exciton chemical potential indicates that the exciton density must increase relative to that of free electrons and holes to compensate for the large exciton binding energy and small internal electric field, and thereby maintain a total dissociation flux that is capable of supplying the cell photocurrent.

The étendue is the geometrical extent of the source (sun) as seen from the system (i.e. the solar cell). That is,  $f_\omega$  is the product of the area of the solar cell and the solid angle subtended by the source at the solar cell at the Earth's surface. The angular acceptance of the cell is  $\pi$ . If the half angle subtended by the sun is  $\theta_{sun}$ , then,

$$f_\omega = \pi \sin^2 \theta_{sun} = \pi \sin^2(0.267^\circ) = 5.52 \times 10^{-5}. \quad (7.138)$$

The entropy generated by charge generation is given by (Luque and Marti, 1997, 2003, Luque et al., 2002)

$$\begin{aligned} T_a \dot{S}_{PV} = \dot{Q}_{PV} &= -IV_a + (\dot{E}_s - T_a \dot{S}_s) - (\dot{E}_r - T_a \dot{S}_r) \\ &= \int_{E_{opt}}^{\infty} [q(\mu_s - V_a)\phi_s(E) \\ &\quad - q(\mu_{pp} - V_a)\phi_r(E) + (\dot{\omega}_s - \dot{\omega}_r)] dE, \end{aligned} \quad (7.139)$$

where the subscripts  $s$  and  $r$  correspond to thermodynamic fluxes of radiation from the sun and cell, respectively, and  $\dot{Q}_{PV}$  is the heat from the excess energy used to generate an exciton with energy,  $E_{opt}$  (see Fig. 7.73). In Eq. 7.139,  $\dot{\omega}$  is the spectral energy flux. Also, we take  $\mu_s = E(1 - T_a/T_s)$  as the chemical potential equivalent of the sun at  $T_s$  (Luque and Marti, 2003).

The first line of Eq. 7.139 shows that the entropy generation is equal to the difference between the

Helmholtz free energy flux of incoming solar radiation and that of the outgoing luminescent radiation, less the work done by the cell (Luque and Marti, 1997). Since only radiative recombination occurs in an ideal cell, that is,  $I = q(\dot{N}_s - \dot{N}_r)$ , then from Eqs. 7.135, 7.137, and 7.139 we obtain

$$E_B \int_{E_{opt}}^{\infty} (\phi_s - \phi_r) dE = \int_{E_{opt}}^{\infty} q(\mu_s - V_a) \phi_s dE - \int_{E_{opt}}^{\infty} q(\mu_{PP} - V_a) \phi_r dE + \int_{E_{opt}}^{\infty} (\dot{\omega}_s - \dot{\omega}_r) dE, \quad (7.140)$$

where  $\phi_s(E)$ ,  $\phi_r(E)$ ,  $\dot{\omega}_r$ , and  $\dot{\omega}_s$  are evaluated by assuming that the only radiative species is the PP state, since all excitons reach the HJ where these states are formed. Equation 7.140 allows for an implicit solution of  $\mu_{PP} = V_a$  (Giebink et al., 2011).

The PP or CT state can also absorb photons, as required by detailed balance, and as observed experimentally (see Section 4.7.2) (Vandewal et al., 2009, 2010). Since the PP is an extended interface state, both its oscillator strength and density are considerably smaller than that of the bulk exciton. Ideally, the bulk absorbance of the cell,  $\alpha(E)$ , is unity above the exciton energy gap. However, in OPVs,  $\alpha(E)$  is significantly lower in the region between  $E_{PP}$  and the exciton binding energy,  $E_X$ . From these assumptions, the current for the HJ cell is

$$j_{SC} = q \int_{E_{PP}}^{\infty} \alpha(E) (\phi_s(E) - \phi_r(E)) dE, \quad (7.141)$$

where

$$\alpha(E) = \begin{cases} 0 & \text{for } E < E_{PP} \\ a_{PP} & \text{for } E_{PP} < E < E_X, \\ 1 & \text{for } E > E_X \end{cases}, \quad (7.142)$$

and the domain of the CT absorption and emission region is  $E_{PP} - E_X = \Delta G_{CT}$  (cf. Eq. 7.136). The ratio between absorption by the exciton and the PP state is typically  $a_{PP} = 10^{-3}$  (Vandewal et al., 2009, 2010). Equations 7.141 and 7.142 imply that the larger energy gap of bulk materials dominates in absorption (at  $E > E_X$ ), whereas the smaller binding energy of the pairs dominates the emission (at  $E_X > E > E_{PP}$ ). Consequently, the radiative recombination rate is

increased, since it occurs via low energy bound pair states. This formulation of the absorption coefficient has also been approximated by a Gaussian distribution for  $\alpha(E)$ , which follows the approximately Gaussian tail of CT emission in polymer solar cells (Kirchartz et al., 2009).

Once a solution for  $\mu_{PP} = V_a$  is found from Eqs. 7.140–7.142, then using the  $j$ - $V$  characteristics for an ideal excitonic HJ (e.g. Eq. 7.57 with  $n_S = 1$ ,  $R_{ser} = 0$ ) and  $T_s = 5778$  K, the extracted power density is

$$P_{pv} = V_a j(V_a). \quad (7.143)$$

Now the solar power density, or solar irradiance, is given by Planck's black body law:

$$P_{sun} = \frac{2f_{\omega}}{h^3 c^2} \int_0^{\infty} \phi(E, T_s) E dE = \frac{2f_{\omega}}{h^3 c^2} \int_0^{\infty} \frac{E^2}{\exp(E/k_B T_s) - 1} E dE. \quad (7.144)$$

Then it follows that

$$\eta_p(V_a) = \frac{V_a j(V_a)}{P_{sun}}, \quad (7.145)$$

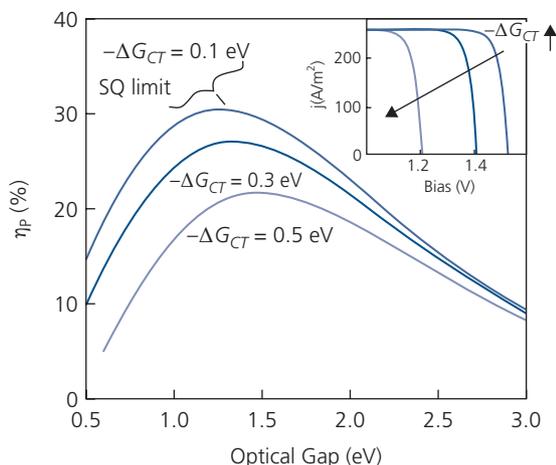

which has a maximum at

$$\frac{d}{dV_a} (V_a j(V_a)) = 0. \quad (7.146)$$

The energy loss that ultimately determines the cell efficiency limit is a function of the saturation current ( $j_0$  in Eq. 7.56), which is an exponential function of the energy level offset at the D-A HJ, and the PP dissociation and recombination rates (found in  $\eta_{PPd}$ ) that are implicit in the foregoing analysis.

Figure 7.74 shows the cell efficiency vs. the organic absorber optical energy gap for several values of the free energy loss for charge transfer,  $-\Delta G_{CT}$ , calculated using Eqs. 7.141 and 7.142 assuming  $T_s = 5778$  K and  $T_a = 300$  K. The calculations assume that the integrated solar intensity at the Earth's surface is equal to 1 kW/cm<sup>2</sup>. The SQ limit is shown for  $-\Delta G_{CT} \rightarrow 0$ , although such a minimal free energy difference, in practice, produces negligible power since there is no driving force for excitons to form bound PPs. As  $-\Delta G_{CT}$  increases, the theoretical efficiency peak monotonically decreases and shifts toward higher optical gap energies.

The peak efficiency depends on the CT state absorbance,  $a_{PP}$ . Equation 7.141 shows that the SQ limit of  $\eta_p = 31\%$  is recovered when either  $a_{PP} \rightarrow 0$  or  $a_{PP} \rightarrow 1$ . However,  $a_{PP} > 0$  with its maximum value limited by the low oscillator strength of the PP state. In the physically relevant range of  $10^{-4} < a_{PP} < 10^{-2}$ , the

**Figure 7.74** Maximum efficiency for an ideal single junction OPV cell as a function of exciton optical energy gap and several values of the free energy for charge transfer at the HJ,  $-\Delta G_{CT}$ . Increased recombination from the lower energy bound pair states leads to reduced efficiency due to the decrease in  $V_{OC}$ , as shown in the inset for a cell with  $E_X = 1.8$  eV (Giebink et al., 2011).

efficiency decreases for increasing  $\alpha_{pp}$ . Although the efficiency limits are based on values chosen for  $\alpha_{pp}$  as obtained from experiment, the conclusion is general: *any heterojunction OPV cell where exciton dissociation results in a lower energy state with incomplete coupling to the radiation field, necessarily operates with an efficiency below the SQ limit* (Street, 2008).

A practical lower limit of  $-\Delta G_{CT} \sim 0.2$  eV is required for efficient charge transfer, leading to photocurrent generation (Rand et al., 2007). However, we will find in the following sections that  $-\Delta G_{CT}$  between 0.4 eV and 0.8 eV are common. Taking  $-\Delta G_{CT} = 0.3$  to 0.5 eV, as typical of high efficiency OPVs (Rand et al., 2007, Veldman et al., 2009), a maximum single junction solar cell efficiency of  $\eta_p = 27\text{--}22\%$  at energy gaps of 1.35 eV and 1.5 eV, respectively, is obtained from Fig. 7.71.

The inset of Fig. 7.71 shows that the decrease in efficiency is entirely due to a decrease in  $V_{OC}$ , and is not affected by  $j_{SC}$  due to our assumptions that all photons absorbed ultimately result in PP formation. Since the small PP binding energy does not limit dissociation, then  $V_a = \mu_{pp}$ . In this case, the maximum open circuit voltage is  $qV_{OC}^{max} = \Delta E_{HL} - E_B = E_{pp}$  which, as we have shown in our derivation of the excitonic HJ diode equations, occurs in the high intensity limit (e.g. under optical concentration), or as  $T_a \rightarrow 0$  (Rand et al., 2007, Giebink et al., 2010b, Vandewal et al., 2010).

It should now be apparent that PP absorption and radiative emission introduce fundamental limitations to the efficiency of OPVs. Materials with a high external radiative quantum efficiency

(and hence a low recombination efficiency) will produce a higher efficiency solar cell, independent of whether that cell is based on organic semiconductors where charge generation is mediated by an intermediate PP state, or in inorganic semiconductors that generate charge directly from band-to-band transitions (Miller et al., 2012).

Including the effects of non-radiative processes that often dominate recombination in practical organic solar cells suppresses  $V_{OC}$  from the limiting case treated above. Decreasing the electronic interaction between the D and A molecules across the HJ reduces both the oscillator strength of the bound pair (i.e. its coupling to the radiation field via  $\alpha_{pp}$ ) and the orbital overlap that facilitates non-radiative decay, thus increasing  $V_{OC}$ . This has been observed in experiments where the degree of  $\pi$ - $\pi$  intermolecular orbital overlap between donor and acceptor molecules is varied (Perez et al., 2009, Zimmerman et al., 2012), suggesting this is a useful design strategy for increasing cell efficiency.

From the foregoing discussion and that of Miller et al. (2012), the dependence of  $\eta_{ext}$  on the observed (vs. the theoretical maximum) open circuit voltage can be analytically determined. Equation 7.122 shows that the open circuit voltage is dependent on the logarithm of the ratio of  $j_{SC}$  to  $j_0$  (or  $j_D$ ). For a cell with external quantum efficiency  $\eta_{ext}$ , a CT state electroluminescence quantum efficiency of  $\eta_{CT}$  due to electrical injection of charges (which is proportional to the number of radiative CT states), and an ambient (at  $T_a$ ) black body flux of  $\phi_{BB}$ , we can write (Rau, 2007)

$$j_{SC} = q \int_0^{\infty} \eta_{ext}(E) \phi_s(E, T_s) dE \quad (7.147)$$

and the dark current is

$$j_0 = \frac{q}{\eta_{CT}} \int_0^{\infty} \eta_{CT}(E) \phi_{BB}(E, T_a) dE. \quad (7.148)$$

When  $\eta_{CT} = 1$ , all the recombination is radiative (the *radiative limit*), and  $j_0 = j_0^{rad}$ . This results in a minimum  $j_0$  at a maximum voltage (sometimes referred to as the SQ voltage)  $V_{OC}^{max} = V_{OC}^{rad}$ , where

$$\begin{aligned} V_{OC}^{rad} &= \frac{k_B T}{q} \ln \left( \frac{j_{SC}}{j_0^{rad}} + \frac{k_{ppd}}{k_{ppd,eq}} \right) \\ &= \frac{k_B T}{q} \ln \left( \frac{\int_0^{\infty} \eta_{ext}(E) \phi_s(E, T_s) dE}{\int_0^{\infty} \eta_{ext}(E) \phi_{BB}(E, T_a) dE} + \frac{k_{ppd}}{k_{ppd,eq}} \right). \end{aligned} \quad (7.149)$$

Now, in the absence of a PP state,  $\alpha_{PP} = 1$  at  $E > E_G$ , and is zero elsewhere. This condition yields the dark current in the SQ limit from Eq. 7.148 by setting  $\eta_{EL} = 1$ :

$$j_0^{SQ} = q \int_{E_{opt}}^{\infty} \eta_{ext}(E) \phi_{BB}(E, T_a) dE, \quad (7.150)$$

where  $\eta_{ext} = 1$  for  $E > E_X$ , and  $\eta_{ext} = 0$  otherwise. The maximum or SQ-limited voltage is, therefore,

$$V_{OC}^{max} = \frac{k_B T}{q} \ln \left( \frac{j_{SC}}{j_0^{SQ}} + \frac{k_{PPd}}{k_{PPd,eq}} \right) \\ = \frac{k_B T}{q} \ln \left( \frac{\int_0^{\infty} \eta_{ext}(E) \phi_s(E, T_s) dE}{\int_{E_G}^{\infty} \eta_{ext}(E) \phi_{BB}(E, T_a) dE} + \frac{k_{PPd}}{k_{PPd,eq}} \right). \quad (7.151)$$

To account for the formation of the PP at the organic HJ, we must include the effects of PP absorption using the expression for  $\alpha(E)$  in Eq. 7.142. This absorption incurs a loss compared to the S-Q voltage of

$$\Delta V_{OC}^{PP} = V_{OC}^{max} - V_{OC}^{rad}. \quad (7.152)$$

Finally, in a practical diode, we must consider that CT state radiation is not 100% efficient, that is, where  $\eta_{CT} < 1$ . Then, there is an additional voltage loss of

$$\Delta V_{OC}^{nr} = V_{OC}^{rad} - V_{OC} = -m \left( \frac{k_B T}{q} \right) \log(\eta_{CT}) \quad (7.153a)$$

or

$$\Delta V_{OC}^{nr} = -m \left( \frac{k_B T}{q} \right) \log \left( \frac{\eta_{EL}}{\gamma \chi_{em}} \right) \quad (7.153b)$$

where  $m$  is a parameter that accounts for non-idealities such as charge that recombines in regions remote from the HJ including interfaces and contacts,  $\eta_{EL}$  is the measured external radiative quantum efficiency,  $\gamma$  is the charge balance factor and  $\chi_{em}$  is the ratio of emissive CT states to the number of injected electron-hole pairs (e.g. in a conventional OLED where there is significant exchange energy splitting between  $^3CT$  and  $^1CT$ ,  $\chi_{em} = 1/4$ , see Chapter 6.2.1). In Eq. 7.153b, we write the internal CT electroluminescence efficiency,  $\eta_{CT}$ , in terms of the measurable quantity,  $\eta_{EL}$ , taking into account effects of charge balance (which can be strongly dependent on voltage and current) and emissive CT exciton fraction following Eq. 6.1.

Combining the above results, the open circuit voltage is

$$qV_{OC} = E_X^{min} - E_{loss}, \quad (7.154)$$

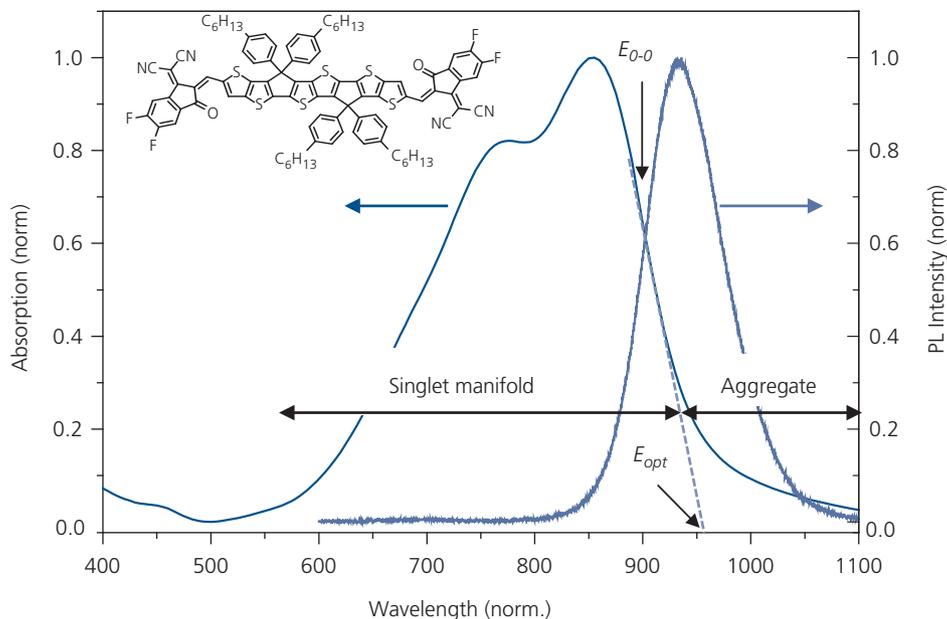

where the minimum exciton energy is  $E_X^{min}$  and (Liu et al., 2016a)

$$E_{loss} = (E_X^{min} - qV_{OC}^{max}) + (qV_{OC}^{max} - qV_{OC}^{rad}) \\ + (qV_{OC}^{rad} - qV_{OC}) \\ = (E_X^{min} - qV_{OC}^{max}) + q\Delta V_{OC}^{PP} + q\Delta V_{OC}^{nr}. \quad (7.155)$$

In an ideal diode,  $E_{loss}$  is the sum of the free energy losses for both the D and A materials,  $\Delta G_{CT}$ , which is the second term in the expression on the right hand side of Eq. 7.155 (cf. Eq. 7.136). Including the effects of non-radiative recombination and other non-idealities gives the third term. Then, the efficiency limit in Fig. 7.74 is found by replacing  $\Delta G_{CT}$  with  $E_{loss}$ .

The fundamental differences and similarities between inorganic and organic semiconductor junctions are accounted for by all three terms on the right in Eq. 7.155. (i) In the first term, the band gap energy of an inorganic is replaced by the excitonic absorption in organics. (ii) Although below band gap absorption in inorganics must be considered in calculating its thermodynamic limit, the spread in energies of PP states can be very large, making the second term more significant in organic compared with inorganic HJs. (iii) For both systems, a high external radiative quantum efficiency results in a reduced energy loss. Unfortunately, the radiative efficiency tends to be very low ( $< 10^{-3}$ ) for materials used in OPVs. This introduces losses in the third term that are considerably greater than in inorganics. However, this constraint provides guidance in the design of molecules with much higher  $\eta_{EL}$  for use in high efficiency OPV active regions.

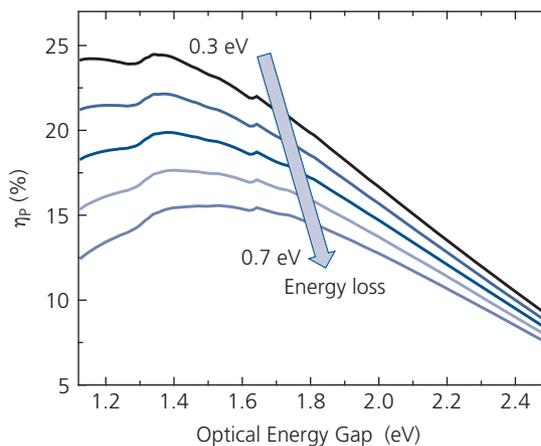

Accurate determination of  $E_X^{min}$ , which is equivalent to  $E_{opt}$ , can be complicated by the existence of strong aggregate or CT absorption below the exciton energy. We showed in Section 3.5.3 that the energy gap can be assigned to the energy at the crossing point between the zero phonon energies of the absorption and emission spectra (the so-called 0-0 crossing point energy,  $E_{00}$ ). An method often used to determine  $E_{opt}$  particularly in cases where the emission spectrum is unavailable or weak, is to linearly extrapolate along the low energy tail of the exciton absorption from its peak to its intercept with the energy axis, as shown in Fig. 7.75 for the NFA molecule, TT-FIC. The molecule features a rigid conjugated backbone that promotes  $\pi$ -stacking, which gives rise to intense aggregate absorption at wavelengths  $> 950$  nm. Obtaining  $E_{opt}$  from the intercept of the tail with the abscissa can underestimate its value. In contrast, extrapolating from the exciton peak as shown in Fig. 7.75 (dashed line)

**Figure 7.75** Absorption and exciton emission spectra of TT-FIC, whose molecular formula is shown in the inset. The 0–0 crossing,  $E_{0-0}$ , and optical energy gap found from extrapolation of the exciton peak,  $E_{opt}$ , are indicated. The long absorption tail starting at  $\sim 925$  nm is due to aggregates. The lowest singlet state absorption range is also indicated.

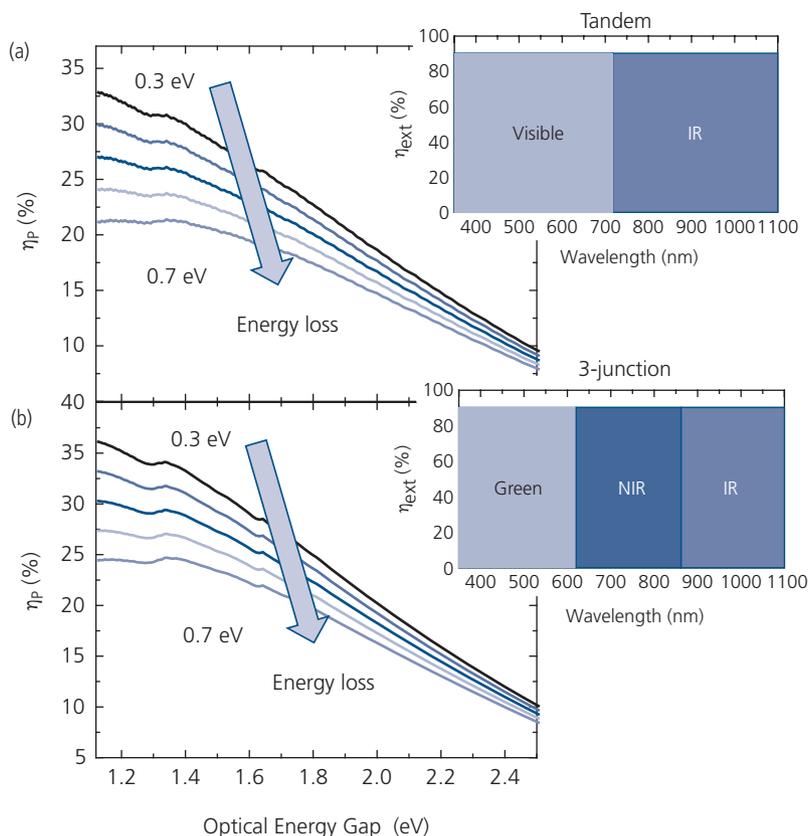

gives a value closer to  $E_G$ , but at smaller energies than the 0–0 crossing. The difference between  $E_{0-0}$  and  $E_{opt}$  estimated by extrapolation is  $\sim 70$  meV. In spite of possible inaccuracies, the extrapolation method is straightforward and has the advantage of avoiding errors incurred by using the weak, but extended aggregate tail.

We now calculate the short circuit current using the AM1.5G reference spectrum,  $E_{REF}(\lambda)$  in Fig. 7.69 to find  $\eta_P$  for a more realistic (i.e. non-ideal) OPV. The  $j_{SC}$  is obtained by integrating the OPV responsivity given by  $R(\lambda) = q\eta_{ext}(\lambda)[\lambda/hc]$ , and  $E_{REF}(\lambda)$ . As in the calculations above, we assume that  $\eta_{ext}$  is constant across the visible spectrum up to  $E_X$ , the low energy onset of the absorbing material. It is likely that in a high performance bulk or mixed HJ cell, that  $\eta_{ED}, \eta_{CC} \approx 1$ . With these assumptions along with Eq. 7.154, we can estimate the power conversion efficiency using several device characteristics that are within reasonable reach using current technology. An example efficiency calculation shown in Fig. 7.76, assuming benchmark values of  $\eta_{ext} = 90\%$  (vs.  $\eta_{ext} = 100\%$  in Fig. 7.74) and  $FF = 0.75$ . For fullerene-based OPVs,  $E_{loss}$  is between 0.5–0.7 eV, whereas for NFAs (see Section 7.4.3),  $E_{loss}$  typically lies between 0.4–0.6 eV. The ripples in the curves in Fig. 7.76 arise from using a reference AM1.5G spectrum in contrast to the

**Figure 7.76** Approximate power conversion efficiency vs. long wavelength absorption onset for an OPV with  $\eta_{ext} = 90\%$  and  $FF = 0.75$  for several values of  $E_{loss}$ . The reference spectrum is AM1.5G (Che, 2018).

smooth black body radiation function employed for Fig. 7.74. As an example, we assume that  $E_X^{min} = 1.4$  eV (corresponding to  $\lambda \approx 900$  nm) and  $E_{loss} = 0.5$  eV. Then we obtain a power conversion efficiency of 19.9% for a single junction cell, which falls somewhat short of 22% for  $\Delta G_{CT} = E_{loss} = 0.5$  eV in Fig. 7.74. In both cases, however, the peak efficiency is achieved for an optical gap of approximately 1.4 eV, revealing a practical guideline in the design of light absorbing materials for use in OPVs.

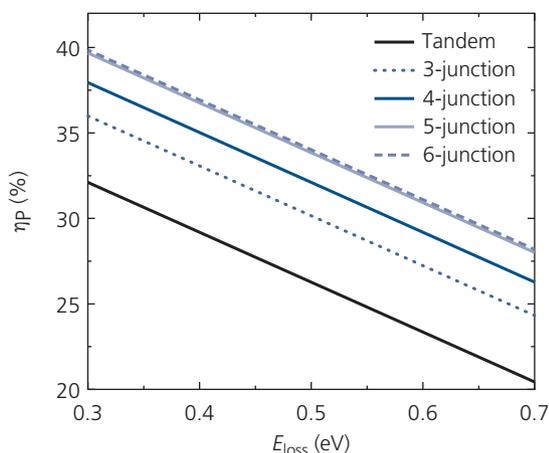

**Figure 7.77** Power conversion efficiency vs. long wavelength absorption onset for the reddest absorbing subcell in (a) tandem and (b) triple junction, series-connected OPVs with  $\eta_{ext} = 90\%$  and  $FF = 0.75$ . The energy loss,  $E_{loss}$ , of each subcell is assumed to be equal. The insets show the external quantum efficiencies assumed for each subcell, for an OPV whose reddest subcell has  $E_G = 1.1$  eV. The reference spectrum is AM1.5G (Che, 2018).

Using this same approach, we can calculate the realistically achievable efficiencies of series-connected multijunction cells, assuming that the cell comprises materials with completely non-overlapping absorption spectra. Current continuity requires that each subcell generate the same photocurrent, which determines the absorption band that can be occupied by each subcell, from 350 nm up to the optical gap of the lowest energy-absorbing subcell. For simplicity, we assume that the individual subcells equally divide the absorption spectrum. Results of these calculations are shown in Fig. 7.77, where once again we use  $\eta_{ext} = 90\%$ ,  $FF = 0.75$  and  $E_{loss}$  is the same for each cell in the stack. We also assume that there are no optical or electrical losses introduced by the CRZs. That is, the total cell  $V_{OC}$  is the sum of  $V_{OC}$  of the individual subcells, see Eq. 7.49. The efficiencies in the stacked cells are considerably higher than for the single junction cells, even when single junction cells operate at the thermodynamic limit. The tandem cell (again taking  $E_{loss} = 0.5$  eV) gives  $\eta_P = 27\%$  and the triple junction

device yields  $\eta_P = 29\%$ . While the efficiency increases slowly from  $E_G = E_X^{min} < 1.4$  eV to  $E_X^{min} = 1.1$  eV, there is little advantage gained by including materials with longer wavelengths in the reddest absorbing subcell.

The improvement between one, two, and three subcells suggests that the efficiency can be further increased by simply increasing the depth of the stack. Figure 7.78 shows a plot of  $\eta_P$  vs.  $E_{loss}$  for cells comprising as many as six series-stacked subcells. While there is a monotonic increase in efficiency with the number of cells, the increase becomes negligible for greater than five subcells. The reduced benefit of adding more cells arises from the diminished current contributed by each successive cell that absorbs an ever-smaller slice of the solar spectrum.

Note that these calculations only provide guidance to expectations for multijunction cell efficiencies. In fact, the actual efficiencies will be even lower than shown in Figs. 7.76–7.78 since  $\eta_{ext}$  is not expected to be a step function with abrupt cutoffs at high and low energies, and each subcell will undoubtedly have

**Figure 7.78** Power conversion efficiency vs. energy loss for series-connected multijunction cells with a long wavelength cutoff energy of  $E_G = 1.1$  eV (Che, 2018).

Reprinted with permission.

different  $E_{loss}$ ,  $FF$ , and maximum  $\eta_{ext}$ . Also, no assumptions have been made about the match of the optical field with the absorption spectrum of a particular subcell; it is only assumed that these factors combine to result in  $\eta_{ext} = 90\%$  across each absorption band. Nevertheless, these calculations provide insights into the factors that govern, and ultimately limit practical OPV efficiencies.

### 7.3.3 Measuring solar cell efficiency

Accurate quantification of solar cell performance is essential for making valid comparisons of results from different laboratories, and for qualification of devices for commercial production and use. The fundamental challenge of measuring efficiencies of cells based on technologies that employ new, unproven materials sets and device architectures is that the laboratory devices are often small (1–10 mm<sup>2</sup> is typical) and unstable. Complicating matters further is that the measurement of solar cell power conversion efficiency is considerably more involved than simply measuring the external quantum efficiency of a photodetector. The elements required for measuring  $\eta_P$  are as follows:

- (i) *Calibrated reference detector.* The reference should cover at least the same spectral range as the test device. Reference detector calibrations should be traceable to a qualified standards laboratory such as the US National Institute of Standards and Technology (NIST).
- (ii) *Solar reference spectrum.* The standard for AM1.5G illumination is currently ASTM G-173-03.

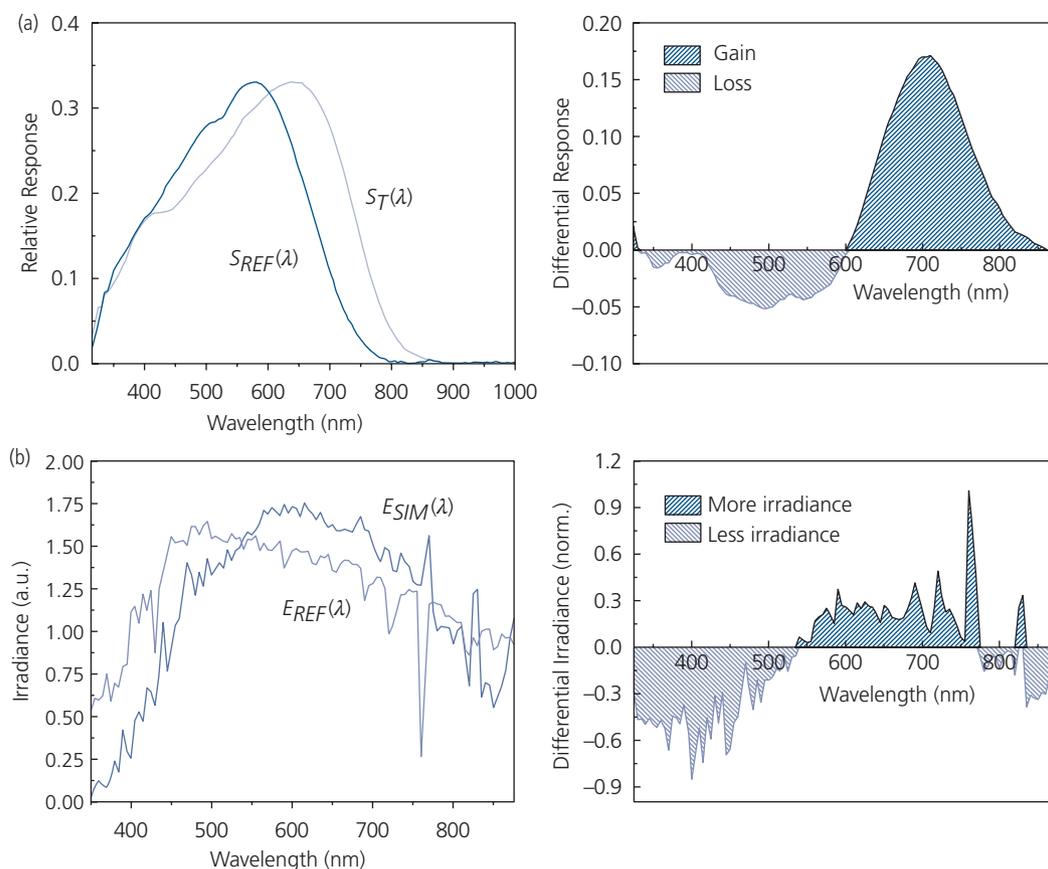

- (iii) *Solar simulator lamp with an appropriate optical filter.* Xenon lamps are most frequently employed due to their long operational lifetime, and coverage of the visible and NIR spectra that approximately corresponds to the solar spectrum. The output of the simulator should be adjusted using the appropriate optical filter (e.g. AM1.5G) to match the reference spectrum as closely as possible. The output illumination should be uniform across the entire test and reference cell areas, and its intensity should reach, at a minimum, 1 sun (1 kW/m<sup>2</sup>). Higher power is desirable for full characterization of the cell performance.
- (iv) *Test cell.* This is the device to be characterized. Its area should be as large as possible. However, the highest efficiency laboratory “hero” results typically use small cells to avoid loss due to parasitic resistances. Such small cells can lead to inaccuracies in determining the device active area, whose uncertainty is a function of the square of the cell linear dimensions.
- (v) *Optical mask.* This is used to shade the cell periphery from the incident light to avoid collection of charge beyond the presumed active area, as defined by the region of overlap between anode and cathode contacts (Kim et al., 2008, Burlingame et al., 2018).
- (vi) *Monochromator.* To assure accuracy, the cell efficiency should be measured by two different methods: (1) using a solar simulator to measure  $j_{SC}$ ,  $FF$ , and  $V_{OC}$  under prescribed measurement conditions, and (2) by measuring  $\eta_{ext}$  vs.  $\lambda$ . The integral of the quantum efficiency spectrum convolved with the reference spectrum is then used to calculate  $j_{SC}$ . The integral method is generally more accurate than that obtained with a solar simulator, and hence should always be employed as a check of the other measurement. For this purpose, and for quantifying the simulated spectra and the response of the reference detector, a monochromator is required.

Ultimately the complexity of measuring  $\eta_P$  arises from inaccuracies in determining the differences between the lamp (i.e. solar simulator) and the solar spectra, and the effects that those differences have on determining  $j_{SC}$ . The  $FF$  and  $V_{OC}$  are easily and accurately extracted from the  $j$ - $V$  characteristics in the 4th quadrant. Since  $V_{OC}$  is only logarithmically dependent on  $j_{SC}$  (Eq. 7.122), and since it is straightforward to set the incident power accurately with a calibrated detector, the open circuit voltage can be obtained to within 1%.

Methods for accurately measuring the spectrally dependent photocurrent have been described previously (Seaman, 1982, Emery and Osterwald, 1986, Osterwald, 1986, Shrotriya et al., 2006). Here we outline the measurement process, particularly with reference to difficulties encountered with small diameter OPVs. If followed carefully, this procedure should yield the power conversion efficiency to within a few percent (relative). To assure the highest confidence in the outcome, an independent laboratory should also duplicate the measurements. Several precision measurement laboratories such as the National Renewable Energy Laboratory in (Golden, CO, USA), Fraunhofer Institute for Solar Energy Systems (Fraunhofer ISE, Freiburg, Germany), and the Tokyo Laboratory Japan Electrical Safety & Environment Technology Laboratories (JET) are three such examples.

The devices should be measured under *standard reporting conditions* (SRC) which are  $P_{inc} = 1 \text{ kW/m}^2$ , AM1.5G reference spectrum, and a cell temperature of 25°C. The importance of calibrating the detector

and source lamp spectral responses can be understood from the sample data in Fig. 7.79 for the test and reference cells, the Xe source lamp with an AM1.5G filter, and the reference spectrum. The test cell comprises the structure: glass/ITO/MoO<sub>3</sub> (10 nm)/DTDCPB:C<sub>70</sub> (1:1, 80 nm) HJ/BPhen:C<sub>60</sub> (8 nm)/BPhen (5 nm)/Ag (100 nm) (Griffith et al., 2015). The reference is a KG5-filtered Si photodiode whose calibration is traceable to a NIST standard. The *relative*, or *normalized*, spectral responsivities of the OPV and the Si reference detector are  $S_T(\lambda)$  and  $S_{REF}(\lambda)$ , respectively in Fig. 7.79a. This is not an optimal situation since  $S_{REF}(\lambda)$  does not fully overlap  $S_T(\lambda)$  at long wavelengths, leading to a significant difference in photocurrent generated by the two diodes at  $800 \text{ nm} > \lambda > 600 \text{ nm}$ , shown on the right in Fig. 7.79a. Nevertheless, the responses are sufficiently similar to compensate for their mismatch, as shown below. Similarly, the normalized irradiance spectra of the solar simulator source ( $E_{SIM}(\lambda)$ ) and the reference ( $E_{REF}(\lambda)$ ) are shown in Fig. 7.79b. Again, there are areas of the spectra where the overlap is poor, particularly at

**Figure 7.79** (a) Relative detector responses ( $S$ ) and (b) irradiance ( $E$ ) of the AM1.5G filtered Xe source, and reference AM1.5G spectra. The subscript *REF* is the reference Si detector and reference solar spectrum, *T* is the detector under test, and *SIM* is the lamp spectrum. The differential detector response and spectral irradiance are shown to the right of the corresponding data.

$\lambda < 450$  nm. The fractional error in the measured photocurrent using these two spectra is

$$f_{error} = \frac{j_{SIM}^T}{j_{REF}^T}, \quad (7.156)$$

where  $j_{SIM}^T$  and  $j_{REF}^T$  are the short circuit currents for the test device illuminated by the simulated and reference spectra, respectively. The currents are expressed by integrals over the two spectra:

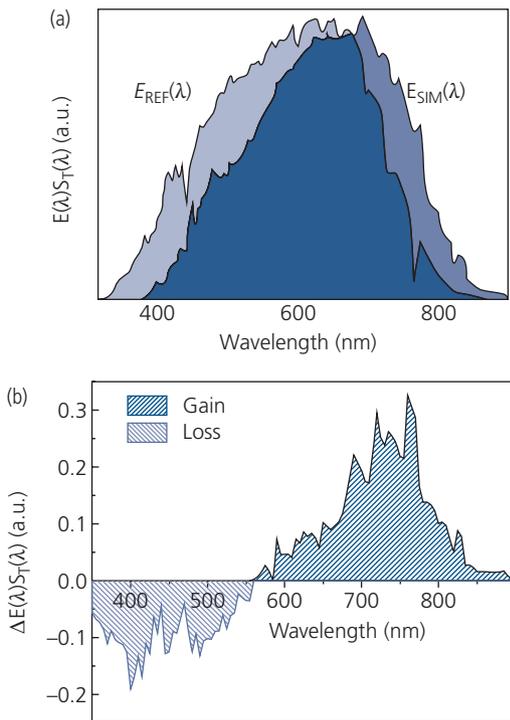

$$j_{SIM}^T = \int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_T(\lambda) d\lambda \quad (7.157a)$$

and

$$j_{REF}^T = \int_{\lambda_1}^{\lambda_2} E_{REF}(\lambda) S_T(\lambda) d\lambda, \quad (7.157b)$$

where the limits of integration,  $\lambda_1$  and  $\lambda_2$ , should extend across the entire range of response of the detector under test.

The products  $E_{REF,SIM}(\lambda)S_T(\lambda)$  of the spectra in Fig. 7.79 are presented in Fig. 7.80a, along with the difference in the two spectra in Fig. 7.80b. The differences are indeed quite large, even though the reference

**Figure 7.80** (a) The irradiance–OPV responsivity product obtained using a reference ( $E_{REF}$ ) and a simulated ( $E_{SIM}$ ) AM1.5G spectra with the device data in Fig. 7.79. These products are the integrands in Eq. 7.158. (b) Differential values of the integrands for the two measurements in (a).

and simulated spectra in Fig. 7.80 overlap reasonably well. The currents obtained using Eq. 7.157 are  $j_{SIM}^T = 16.3$  mA/cm<sup>2</sup>, whereas  $j_{REF}^T = 14.6$  mA/cm<sup>2</sup>. This is nearly a 12% overestimation of the short circuit current using the simulated spectrum, which would lead to a similar overestimation of  $\eta_p$ . The discrepancy arises primarily from the differences between the OPV response and that of the Si detector with a filter that cuts off at a shorter wavelength. However, there are many detectors to choose from.

Sample spectra for Si detectors with different filter types are provided in Fig. 7.81. The most complete overlap with the OPV spectrum in Fig. 7.79 is achieved with a KG3 or perhaps KG2 filtered Si detector.

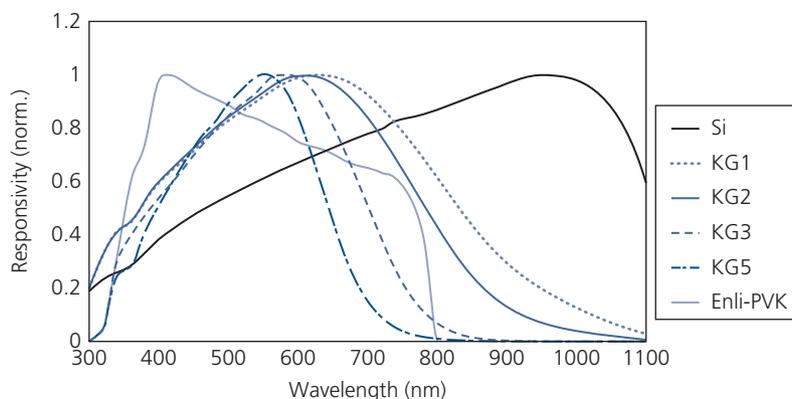

By replacing  $S_T(\lambda)$  with  $S_{REF}(\lambda)$  in Eq. 7.157, analogous expressions exist for the reference cell current under simulated and reference illumination ( $j_{SIM}^{REF}$  and  $j_{REF}^{REF}$ , respectively). Substituting these expressions into Eq. 7.156, we obtain a measurement error of

$$f_{error} = \frac{\int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_T(\lambda) d\lambda}{\int_{\lambda_1}^{\lambda_2} E_{REF}(\lambda) S_T(\lambda) d\lambda} \frac{\int_{\lambda_1}^{\lambda_2} E_{REF}(\lambda) S_{REF}(\lambda) d\lambda}{\int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_{REF}(\lambda) d\lambda} \left( \frac{j_{SIM}^{REF}}{j_{REF}^{REF}} \right). \quad (7.158)$$

The differential responses and spectra can be compensated to obtain an accurate match of the reference and source spectra by calculating the *spectral mismatch correction factor*,  $M$ , given by

$$M = \frac{j_{SIM}^T j_{REF}^{REF}}{j_{REF}^T j_{SIM}^{REF}} = \frac{\int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_T(\lambda) d\lambda \int_{\lambda_1}^{\lambda_2} E_{REF}(\lambda) S_{REF}(\lambda) d\lambda}{\int_{\lambda_1}^{\lambda_2} E_{REF}(\lambda) S_T(\lambda) d\lambda \int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_{REF}(\lambda) d\lambda}, \quad (7.159)$$

such that  $f_{error} = M(j_{SIM}^{REF}/j_{REF}^{REF})$ . Note that this correction factor has several interesting properties. For example, if the simulated and reference spectra are identical,  $M = 1$  and no correction is required. Similarly, if the responsivities of the test and reference detectors are equal,  $M = 1$  and once again, no correction is required. Thus, for accurate measurements,  $M$  should be as close to unity as possible, and preferably the difference should be  $< 10\%$ . This is achieved by making the simulator and solar reference spectra, or the reference and test detector responsivity spectra as similar as possible.

**Figure 7.81** Relative Si detector responsivities using several different front-surface filters.

Using Eqs. 7.157–7.159 in Eq. 7.156, we obtain the calibrated short circuit current of the test cell for the reference spectrum:

$$j_{REF}^T = \frac{j_{REF}^{REF} \cdot j_{SIM}^T}{M \cdot j_{SIM}^{REF}} \quad (7.160)$$

Measurement of  $j_{REF}^T$  begins by calibrating the integrated power of the simulator to the total solar irradiance,  $E_{REF}$ , under SRC. This is done by setting  $j_{SIM}^{REF} = j_{REF}^{REF}$ . Furthermore, the simulator spectrum,  $E_{SIM}(\lambda)$ , must be obtained using the monochromator system. Now, the *effective irradiance* of the solar simulator is only that fraction of total power that overlaps the response of the reference detector, and is given by

$$E_{SIM}^{eff} = M \cdot j_{SIM}^{REF} / CN, \quad (7.161)$$

where  $CN$  is the calibration number, which is the ratio of the short circuit current of the reference to the total irradiance,  $E_{TOT}$ . By setting the simulator intensity to  $E_{SIM}^{eff} = E_{REF}$ , then  $j_{REF}^{REF} = CN \cdot E_{REF}$  and

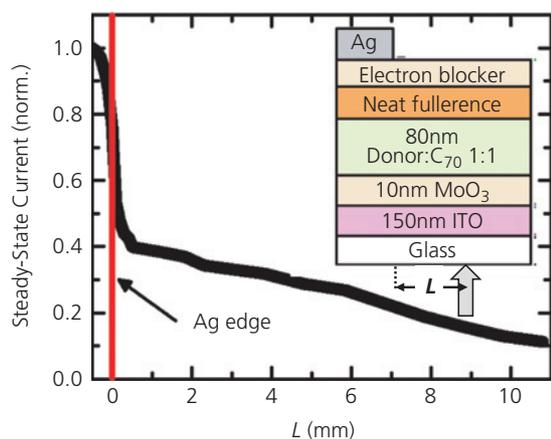

$$\frac{j_{SIM}^{REF}}{j_{REF}^{REF}} = \frac{E_{SIM}^{eff}}{M \cdot E_{REF}} \quad (7.162)$$

Returning to our device in Fig. 7.78, the first ratio on the right in Eq. 7.159 taken from data in Fig. 7.79 is  $16.3/14.6 = 1.116$ . Balancing the power such that  $E_{SIM}^{eff} = E_{REF}$  yields an adjustment of  $12.2 \text{ mA/cm}^2$  for the reference current using the simulated spectrum, and  $11.4 \text{ mA/cm}^2$  for the reference spectrum. By making the lamp intensity the same as  $E_{REF}$ , however, the second ratio on the right hand side of Eq. 7.159 is equal to unity and is ignored. In this example, therefore, we have  $M = 1.116$ , which is larger than desired for an accurate measurement.

The test device is mounted directly beneath a mask of known area that is smaller than that of the solar cell to underfill the device area. Then under short circuit conditions, we obtain  $j_{SIM}^T$ . The mask should then be removed. The fourth quadrant  $j$ - $V$  characteristics measured at  $E_{REF}$  then yield  $V_{OC}$  and  $FF$ . Using these measured values and Eq. 7.160, we obtain the calibrated test cell response.

A cross-check of the efficiency can be obtained by measuring the absolute detector responsivity,  $S_T(\lambda)$ , using illumination from a monochromator that is varied from  $\lambda_1$  to  $\lambda_2$ , and calculating  $j_{REF}^T$  from Eq. 7.157b. This measurement should be done while the device is flooded by simulator illumination of  $\sim 1$  sun intensity to avoid errors due to recombination at low light levels, or resistive losses at higher intensities. Also, the monochromator output intensity should be calibrated at each wavelength using the reference detector. Finally, as in the case of the  $j$ - $V$  measurement, the monochromatic optical beam should underfill the device area to ensure that all incident photons are detected. If the measurements are accurate, the short circuit current calculated from Eq. 7.157b should agree with that of Eq. 7.160 to within 5%.

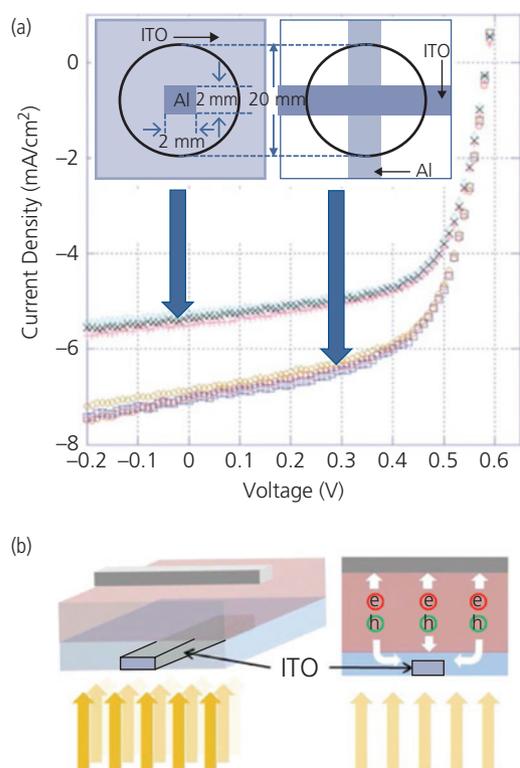

Underfilling the device active area by using a mask or a focused light source is crucial for obtaining accurate results, especially with small diameter OPVs whose peripheral area is a substantial fraction of the total device area. In some OPV structures, light sensitivity extends beyond the area defined by the contacts, which leads to errors in precisely determining device active area when calculating  $j_{SC}$ . A striking example of peripheral charge generation is shown in Fig. 7.82 for a planar-mixed small molecule OPV whose structure is shown schematically in the inset. The donor for this experiment is DTDCBP that was used in the devices in Figs. 7.78 and 7.79. Illumination

**Figure 7.82** Normalized steady state current vs. distance from the cathode,  $L$ , of a  $< 40 \mu\text{m}$  diameter focused beam at a wavelength of 633 nm. The red vertical line shows the edge of the cathode contact. Inset: OPV structure used in the measurement (Burlingame et al., 2018). Burlingame, Q., Coburn, C., Che, X., Panda, A., Qu, Y. & Forrest, S. R. 2018. Centimetre-scale electron diffusion in photoactive organic heterostructures. *Nature*, 10.1038/nature25148

from an optical fiber placed in close proximity to the glass substrate is projected into the active region of the OPV. The current is measured as the fiber is slowly scanned across the diode diameter defined by the Ag cathode, and well beyond its periphery to a distance,  $L$ . Excitons generated in the mixed layer dissociate into holes that are immediately collected in the underlying ITO anode, but electrons must enter the 10 nm thick neat fullerene (C<sub>60</sub>) layer where they are trapped between the BCP electron blocking layer and the donor. The photocurrent collection is efficient, even when the optical beam is located 1 cm from the Ag cathode (Burlingame et al., 2018). This is an extreme case of edge current collection that depends on the unconventional choice of donors and details of the architecture employed. If one attempted to measure the efficiency of the device with overfilled illumination that extended well beyond the Ag cathode, the current would be far greater than anticipated. This would lead to a substantial overestimation of efficiency, since practical solar cells are large area devices where peripheral currents, even as large as in this example, do not significantly contribute to the total cell current.

The cell layout (i.e. the contact arrangement) also can affect the magnitude of the peripheral currents in small area devices. For example, the  $j$ - $V$  characteristics from ITO/PEDOT:PSS (65 nm)/P3HT:PC<sub>61</sub>BM (1:1, 150 nm)/LiF (1 nm)/Al (100 nm) BHJ OPVs with two different electrode arrangements are illustrated in Fig. 7.83 (Kim et al., 2008). Both devices have

**Figure 7.83** (a) Current–voltage characteristics of two (2 mm)<sup>2</sup> P3HT:PC<sub>61</sub>BM OPVs using different contact arrangements. The region of the 20  $\mu\text{m}$  diameter light spot illuminating the device is outlined by the black circle. Inset: The contact arrangements are the island (left) and crossbar geometry (right). (b) Model for explaining the large current observed for the crossbar geometry, where the PEDOT:PSS layer (blue) overcoats the ITO contact, providing a larger effective anode for charge collection along the length of the perpendicular Al cathode (gray). The device active region is shown in red (Kim et al., 2008).

overlapping cathode/anode contact areas of (2 mm)<sup>2</sup>, but in one device the Al cathode is an isolated island on the large area active layer and ITO anode, whereas in the second OPV the cathode and anode form an overlapping crossbar pattern. A large optical beam overfills the contacted areas with AM1.5G, 1 sun illumination. The short circuit currents obtained from these otherwise identical devices are significantly different; the island layout gives  $j_{\text{SC}} = 5.5 \text{ mA/cm}^2$ , whereas the crossbar gives  $7 \text{ mA/cm}^2$  (Fig. 7.83a). The difference is attributed to excess edge currents in the latter device, illustrated in Fig. 7.83b. The conducting PEDOT:PSS layer overlaps the ITO stripe, providing a route for the collection of photogenerated holes along the orthogonal Al stripe, thus providing a larger effective area than the overlap of the two stripes. Edge collection is considerably reduced when the cathode is only an island, and can be further reduced or even eliminated if the PEDOT:PSS layer is

omitted. In either case, this points to the large errors that can be incurred when the illumination overfills the contact area of an OPV.

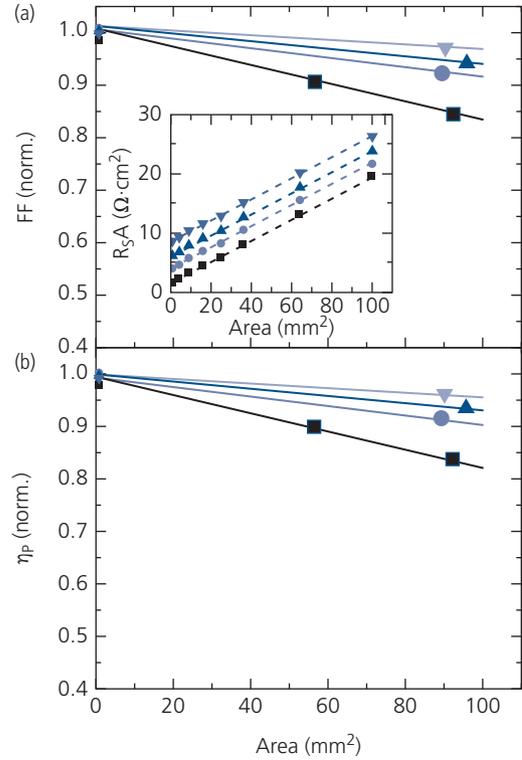

The most effective means to reduce edge effects is to increase the device area. However, this comes at the price of reduced efficiency due to increased series resistance of the ITO anode. Hence, the areas of cells developed to demonstrate the highest efficiencies are typically minimized to eliminate extrinsic resistances that decrease the  $FF$ , and hence both  $V_M$  and  $I_M$  (Green, 2017). The effect of contact size for single and multijunction cells was systematically compared using devices with generic structures shown schematically in Fig. 7.9. Specifically, single, tandem, triple and four junction OPV cells based on the donors, DTDCTB and DBP, were combined with  $C_{60}$  and  $C_{70}$  acceptors. A DBP: $C_{70}$  planar-mixed HJ was employed as a blue-green absorbing subcell (SC-1 in Fig. 7.9) while DTDCTB: $C_{60}$  PM-HJ primarily absorbs in the NIR (SC-2). The stacked subcells are interconnected with a CRZ comprising a BPhen: $C_{60}$  mixed layer (1:1, 5 nm)/Ag (0.1 nm)/ $MoO_3$  (5 nm) (see Section 7.5.2). Four-junction cells comprised (from the cathode): Ag (100 nm)/BPhen (7 nm)/SC-1/CRZ/SC-2/CRZ/SC-1/CRZ/SC-2/ $MoO_3$  (10 nm)/ITO. For triple, tandem and single junction cells, the subcells and CRZs closest to the anode were eliminated according to the number of stages (e.g. a tandem had active regions of SC-1/CRZ/SC-2) (Xiao et al., 2015).

The  $FF$  and  $\eta_P$  vs. cell area are shown in Fig. 7.84a and b, respectively, for single, double, triple, and quadruple junction cells. The  $j_{SC}$  and  $V_{OC}$  are unaffected by device area over the limited range explored, consistent with the effects of increased series resistance inferred from Fig. 7.70. The performance characteristics of each cell type as area,  $A \rightarrow 0$  are provided in Table 7.6. Among various devices, single junction cells exhibit the largest drop in  $\eta_P$  of 17% as area increases from  $1 \text{ mm}^2$  to  $1 \text{ cm}^2$ , whereas tandem, triple and four junction cells suffer reductions of 8.5%, 6%, and 4%, respectively. The reduced loss in efficiency for multijunction cells is primarily due to their increased  $V_{OC}$  and reduced  $j_{SC}$  with each additional sub-element. That is, the incremental power loss due to series resistance,  $\Delta P_{loss} = I^2 R_{ser}$ , decreases with the square of the cell current.

The specific series resistance ( $R_{ser}A$ ) of the OPV is given by

$$R_{ser}A = \frac{R_{\square}LA}{W} + \sum_N (\rho_O t_O + r_{int}), \quad (7.163)$$

where the sum is over each element in the stacked device consisting of  $N = 1, 2, 3,$  or  $4$  sub-elements,  $R_{\square}$

**Figure 7.84** (a) Normalized fill factor and (b) power conversion efficiency vs. area of single (squares), tandem (circles), triple (up triangles), and quadruple junction (down triangles) OPVs whose structures are described in text. Inset: Series resistance vs. area. Adapted from Xiao et al. (2015).

**Table 7.6** Performance of  $1 \text{ mm}^2$  single, tandem, triple, and quadruple junction OPV cells (Xiao et al., 2015)

No. junctions	$j_{SC}$ (mA/cm <sup>2</sup> )	$V_{OC}$ (V)	$FF$	$\eta_P$ (%)
Single	11.3	0.92	0.59	6.1
Tandem	7.5	1.70	0.58	7.4
Triple	5.3	2.59	0.58	8.0
Quadruple	4.7	3.34	0.57	8.9

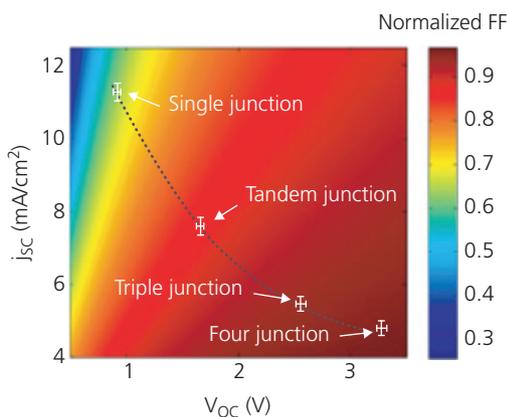

is the sheet resistance of the ITO anode,  $L$  and  $W$  are the length and width of the ITO contact,  $\rho_O$  is the resistivity of the organic layer,  $t_O$  is its thickness, and  $r_{int}$  is the specific interface resistance within the cell stack. The first term on the right is due to the ITO anode resistance, while the terms in the summation are due to the organic layer and interface resistances. This expression is simplified by assuming that the total internal junction resistance,  $r_{jn}$ , of each subcell is the same. Then,

$$R_{ser}A = \frac{R_{\square}LA}{W} + Nr_{jn}. \quad (7.164)$$

As shown in the inset of Fig. 7.84a,  $R_{ser}A$  increases linearly with device area, as expected. The slopes of the lines give an average junction resistance  $\bar{r}_{jn} = 2.1 \Omega \text{ cm}^2$ . For the  $1 \text{ mm}^2$  single junction cell,  $R_{\square}A = 0.015 \Omega \text{ cm}^2$ , which is small compared with  $r_{jn}$ . However, for the  $1 \text{ cm}^2$  single junction cell,  $R_{\square}A$  increases to  $18 \Omega \text{ cm}^2$ , which now dominates. Multijunction cells show similar trends. However, since the total resistance of the organic layers is higher for multijunction than for single junction OPVs due to the increased number of layers and interfaces, scaling of resistance with area is not as pronounced as for single junction OPVs, and hence the ITO sheet resistance plays a relatively small role in the latter cells compared to contributions from  $r_{jn}$ . For large area cells, the sheet resistance dominates, leading to a significant drop in  $\eta_P$ .

The results of this analysis for the normalized fill factor of  $FF(\infty, R_{ser}A)/FF(\infty, 0)$  vs.  $j_{SC}$  and  $V_{OC}$  for  $1 \text{ cm}^2$  cells are shown in Fig. 7.85. Consistent with our previous discussion,  $FF$  is maximized as  $j_{SC}$  is reduced and  $V_{OC}$  is increased in multijunction cells.

Measurement of  $\eta_P$  for multijunction cells is considerably more challenging than for single junction cells since the subcells cannot be independently contacted, and therefore Eq. 7.159 can no longer be used to calculate the spectral mismatch factor. The total current in a series-connected cell is limited by the subcell that passes the lowest current. Therefore, the current at a given wavelength generated by measuring the quantum efficiency of one subcell is inherently ambiguous due to current simultaneously generated by the other subcells in the stack. To reduce the error in  $j_{REF}^T$ , therefore, a reference detector whose efficiency spectrum most closely matches

**Figure 7.85** Calculated normalized  $FF = FF(\infty, R_{ser})$  as a function of  $j_{SC}$  and  $V_{OC}$ . The stars represent the measured coordinates of OPV cells whose properties are listed in Table 7.6. The dashed line is a guide to the eye (Xiao et al., 2015).

that of the test device, that is,  $j_{SIM}^{REF} \approx j_{SIM}^T$ , can be employed along with a simulator whose spectrum approximates that of the reference AM1.5G spectrum. This, however, provides no more than a loose approximation of efficiency that does not substitute for a precise measurement.

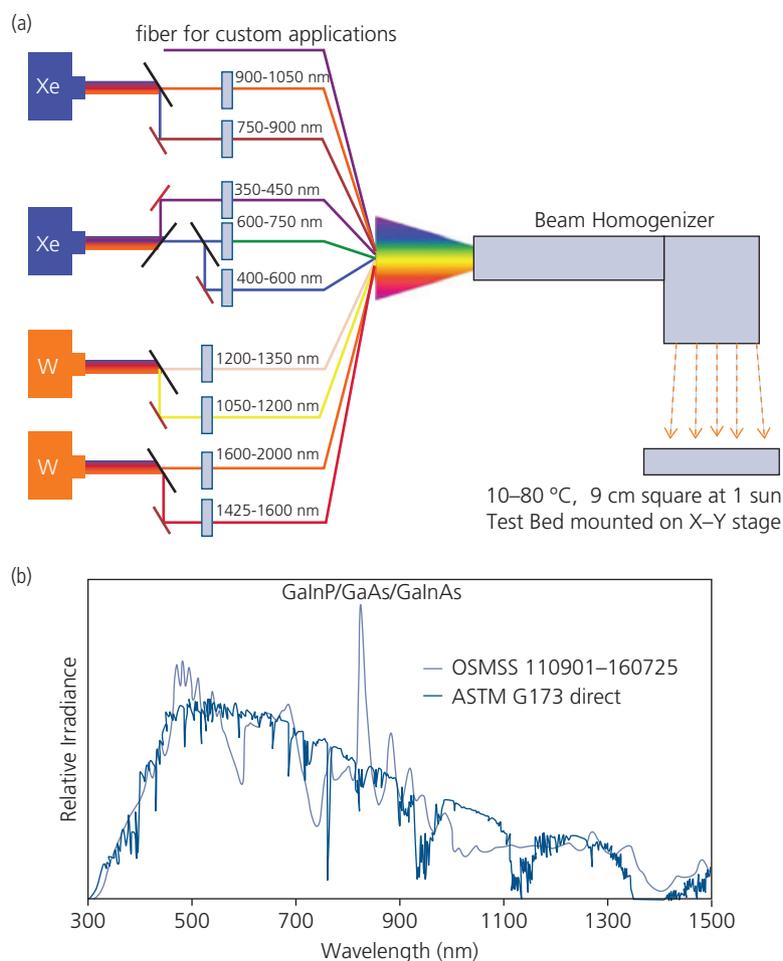

Inaccuracies can be reduced by measuring the cell efficiency out-of-doors on a clear day, making sure to measure the solar spectrum and intensity under which the cell is being tested. However accurate this test may be, it is not a practical solution since the solar irradiance depends on many factors including latitude, atmospheric conditions, time of day, etc. Hence, such a measurement does not conform to a standard by which other cells, measured elsewhere and at different times can be compared. A standardized laboratory method for multijunction cell efficiency measurements has been implemented at NREL using the so-called one sun multisource solar simulator (OSMSS) shown in Fig. 7.86a (Moriarty et al., 2012). This apparatus consists of nine spectral channels whose intensities can be independently varied to create a 1 sun intensity spectrum that reasonably approximates that of the reference spectrum. The procedure for finding this spectrum for a particular test subcell is accomplished by independently exciting each subcell via optical biasing. This requires the illumination of subcells not being tested by wavelengths not absorbed by the subject subcells. Optical biasing thus avoids the other devices in the stack from limiting the total current. Then, as before, the current of the  $i$ th cell in the stack is

$$j_{SIM,i}^T = \int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_T^i(\lambda) d\lambda. \quad (7.165)$$

The ratio,  $R_{ij}$ , of currents between any combination of two subcells  $i, j$ , is then adjusted to

$$R_{ij} = \frac{\int_{\lambda_1}^{\lambda_2} E_{REF}(\lambda) S_T^i(\lambda) d\lambda}{\int_{\lambda_1}^{\lambda_2} E_{REF}(\lambda) S_T^j(\lambda) d\lambda} \frac{\int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_T^j(\lambda) d\lambda}{\int_{\lambda_1}^{\lambda_2} E_{SIM}(\lambda) S_T^i(\lambda) d\lambda} = 1. \quad (7.166)$$

Once the spectrum is constructed by iteratively setting  $R_{ij} = 1$  for all  $i, j$  (usually at an intensity within each band of  $\sim 0.5$  sun for that band), the full intensity is set to 1 sun using a reference detector. The power conversion efficiency is then obtained by dividing  $j_{SIM}^T$  by the mismatch factor which is the same for the  $N$  subcells by following the procedure that sets all

**Figure 7.86** (a) Schematic of the one sun multisource solar simulator (OSMSS). (b) The spectrum constructed for a GaInP/GaAs/GaInAs triple junction cell using the OSMSS vs. the reference AM1.5G ASTM G173 direct spectrum (Moriarty et al., 2012).

$R_{ij} = 1$ . The complex OSMSS system can be replaced by a single, intense light source with a series of filters that are switched in and out to measure the currents of the individual subcell pairs.

An example spectrum constructed in this manner for a triple junction GaInP/GaAs/GaInAs cell is shown in comparison to an AM1.5G reference spectrum in Fig. 7.86b. The spectral agreement is sufficient that the photocurrents generated in each subcell were within 1% of their value under the reference.

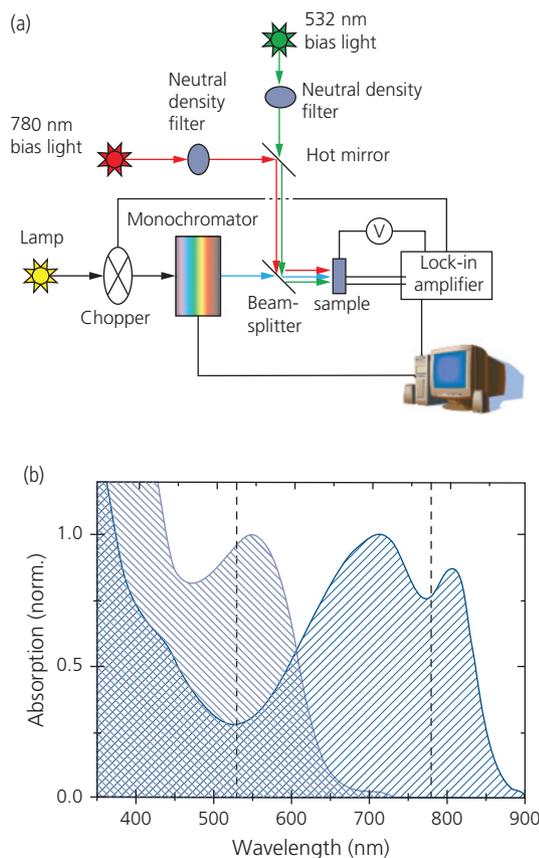

As we will find in subsequent sections, multijunction OPVs can deliver superior performance to single junction cells. As such, it is not practical to send all experimental cells to standards laboratories whose measurements are more suitable for qualifying solar cells for commercial use. Indeed, sending model cells to such laboratories is both time consuming and often unnecessary. Nor can every laboratory afford a complex system such as the

OSMSS, nor have the expertise to operate it properly. For these reasons, one requires a method that provides a reliable efficiency measurement that is simple, inexpensive and accurate. The light biasing setup illustrated in Fig. 7.87a provides a means for such an efficiency measurement.

The measurement procedure is as follows for the example tandem cell whose individual subcell spectra are shown in Fig. 7.87b. The device should comprise subcells whose individual spectra have at least one region that does not overlap the spectra of other subcells in the stack. Then, a high intensity monochromatic light source operating in the transmission window of the subcell under test is used to selectively “turn on” the other cells such they deliver a current close to  $j_{SC}$  under 1 sun illumination. Then a weak, chopped light source is passed through a monochromator to excite the subcell under test to obtain its current at each wavelength, and hence its

efficiency spectrum,  $\eta_{ext}(\lambda)$ . To avoid current generated from the bias light source due to residual absorption by the subcell under test, the monochromatic light must be synchronously detected at the frequency of the chopper. This procedure is reproduced to capture  $\eta_{ext}(\lambda)$  for each cell in the stack. The placement of a red and blue bias light for the example tandem spectrum is shown in Fig. 7.87b.

The overlap of the spectra of the long and short wavelength cells allows the short wavelength bias illumination at 530 nm to effectively “turn on” both cells, while also enabling a measurement of  $\eta_{ext}(\lambda)$  of the long wavelength cell. In contrast, the short wavelength subcell does not absorb the long wavelength bias beam at 780 nm. Thus, the efficiency measured for the short wavelength cell must be corrected for very low intensity excitation, since in some OPVs the subcell efficiency varies with intensity, decreasing as

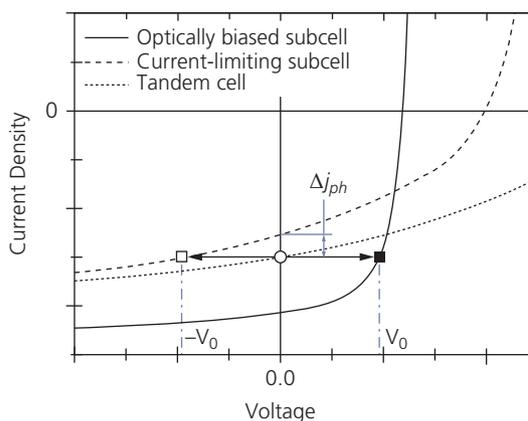

**Figure 7.87** (a) Experimental setup for measuring the efficiency of subcells in a tandem OPV using the light biasing method. Example spectra of the subcells in a tandem OPV. The dashed lines are the wavelengths of the bias illumination sources. Bias illumination at 530 nm is used during measurement of the red absorbing subcell, and bias at 780 nm is used during measurement of the blue-green cell (Gilot et al., 2010b).

Copyright © 2010 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

$P_{inc} \rightarrow 1$  sun. This correction is easily obtained by fabricating single junction subcells that are similar to those used in the stacked OPV and measuring  $\eta_{ext}(-P_{inc})$  for each at 1 sun, AM1.5G simulated illumination.

A further complication common to OPVs is that the charge extraction efficiency increases with reverse bias. The  $j$ - $V$  characteristics for a strongly optically biased and a current-limiting subcell in a tandem are illustrated in Fig. 7.88 (dotted line). These conditions show that the current-limiting subcell is reverse biased at  $-V_0$  (dashed line), yielding a higher  $j_{ph}$  than its own  $j_{SC}$ . Hence, the measured  $\eta_{ext}(\lambda)$  must be corrected to account for the overestimation by  $\Delta j_{ph}$ . This is accomplished by forward biasing the tandem by  $+V_0$  during the efficiency measurement. The amount of forward bias to apply to arrive at  $\Delta j_{ph} = 0$  is once again obtained from the response of discrete cells engineered to closely resemble the subcells in the multijunction device (Gilot et al., 2010a, 2010b).

Once the light bias measurements are obtained, and suitable corrections for voltage and intensity-dependent efficiency have been applied, the total quantum efficiency of the tandem is obtained from the sum of the external efficiencies of the constituent subcells. Then, integrating over the reference spectrum,  $J_{REF}^T$  is obtained without requiring a measurement of the spectral mismatch factor. Consequently, this provides  $\eta_P$  once  $V_{OC}$  and  $FF$  are measured under SRC. While it is increasingly complicated to obtain accurate efficiencies of devices with more than two subcells, the approach is general and can in principle be extended to

**Figure 7.88** Current-voltage characteristics of a tandem OPV, and the current-limiting, and the optically biased subcells. Under short circuit conditions,  $V_0 = -V_0$  such that the total tandem cell bias is  $V = 0$  V. Adapted from Gilot et al. (2010b).

multijunction cells with any number of stacked elements (Di Carlo Rasi et al., 2017).

## 7.4 Architectures, morphologies, and materials for OPVs

Three critical factors that determine the efficiency of an organic solar cell are the device layering scheme, or architecture, the morphologies of the layers with particular focus on the optically active and exciton blocking regions, and the materials used in all of the layers. Having laid the general groundwork for understanding the operation, quantification of performance, and limits to the efficiency of OPVs, we are prepared to look at specific methods to attain high efficiency and long lifetime by optimizing the several cell attributes.

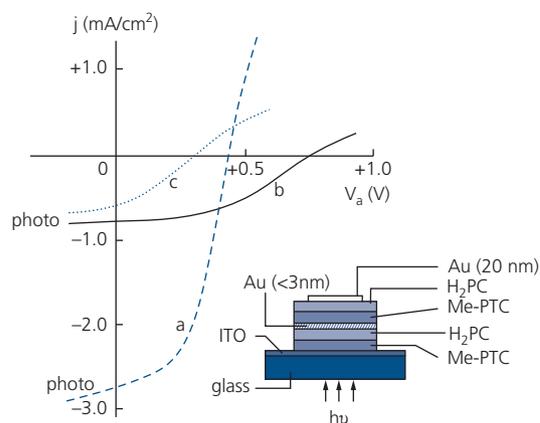

We begin this section with a brief history of OPVs that have led to current devices with operational lifetimes >20 years and efficiencies >16%. The advances in OPVs can be divided into six periods, each marked by discoveries in architecture, layer morphology, and materials. These innovations, or stepping stones in OPV development, are the demonstration of (i) Schottky barrier solar cells (Chamberlain, 1983), (ii) bilayer junction solar cells (Tang, 1986), (iii) multijunction cells (Hiramoto et al., 1990) with subcells separated by optically lossless CRZs (Yakimov and Forrest, 2002), (iv) the BHJ OPV by both solution (Halls et al., 1995, Yu et al., 1995) and vacuum processing (Xue et al., 2005), (v) fullerene acceptors in both solution (Yu et al., 1995) and vacuum deposited (Peumans and Forrest, 2001) OPVs, and (vi) high efficiency, non-fullerene-based OPVs (Cnops et al., 2014). While these are largely technological advances, OPVs are second only to OLEDs in igniting the revolution in our understanding of the physics and chemistry of organic electronic materials.

The earliest OPVs comprised only a single organic semiconductor sandwiched between two metal electrodes with different work functions that create an internal field. One of the contacts is non-Ohmic, thereby creating a rectifying Schottky barrier diode. Excitons that drift to the blocking electrode undergo dissociation, and the generated free charges are collected (Chamberlain, 1983). The highest efficiencies were achieved using the metal-free phthalocyanine, H<sub>2</sub>Pc, or merocyanine dyes as the active layer due to their stability and relatively broad spectral coverage (Morel et al., 1978, Chamberlain and Clooney, 1979). The disadvantage of this architecture is the thin photoactive region that is confined near to the

dissociating electrode, the lack of a large Schottky energy barrier limiting the open circuit voltage while introducing large background currents, and the narrow spectral range spanned by only a single chromophore. Hence, these devices exhibited power conversion efficiencies <0.1% and fill factors of ~0.25 were not uncommon ( $FF = 0.25$  corresponds to a linear dependence of  $j$  vs.  $V$  in the fourth quadrant, where  $j_M V_M = [\frac{1}{2} j_{SC}] [\frac{1}{2} V_{OC}]$ ).

Most, if not all of the deficiencies of the metal-organic OPV were eliminated by the introduction of the bilayer OPV comprising a PTCBI acceptor and CuPc donor layers (Tang, 1986). The device shown in Fig. 7.36 employs a type II HJ to efficiently dissociate excitons. This device represents a transformative advance in organic solar harvesting devices. The OPV showed a  $V_{OC} = 0.45$  V,  $j_{SC} = 2.3$  mA/cm<sup>2</sup>, and  $FF = 0.65$  under AM2 (75 mW/cm<sup>2</sup>) illumination, producing  $\eta_P = 0.95\%$ . Even more remarkable than the relatively high efficiency was the close to ideal diode rectifying characteristic of the diode with very low leakage current; characteristics that are essential to reaching high performance. Lastly, the materials employed are stable if kept in an oxygen- and moisture-free environment.

The next significant advance was the demonstration of a multijunction cell that delivers increased power at low current and high voltage, in contrast to a single junction cell that sources low voltage at high current. The challenge to successful multijunction cell operation is to create a zone for efficient charge recombination between the front and back cells (see Section 7.1.2). The first attempt used a thin

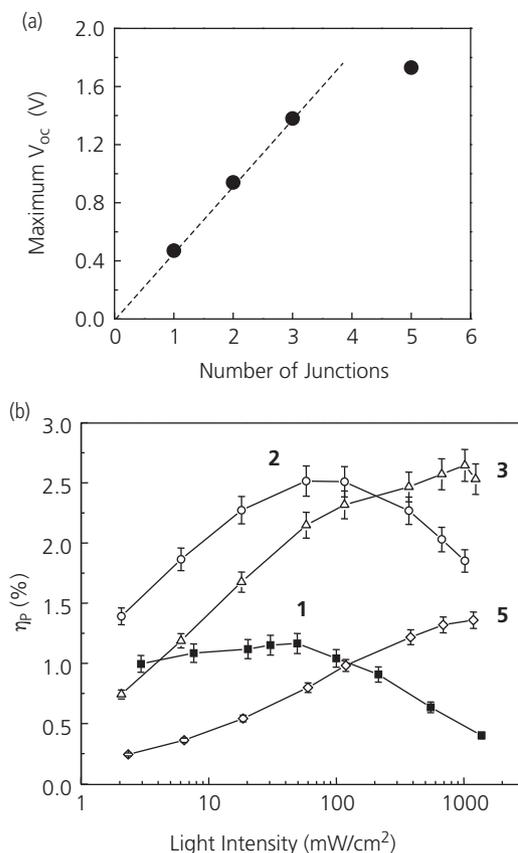

**Figure 7.89** Measured  $j$ - $V$  characteristics under 78 mW/cm<sup>2</sup> illumination for (a) single junction, (b) tandem OPVs with a 2 nm thick Au charge recombination layer, and (c) a tandem cell without the Au layer. Inset: Cell structure. Adapted from Hiramoto et al. (1990).

( $\sim 2$  nm) Au sheet between the subcells, as shown in Fig. 7.89 (Hiramoto et al., 1990). Both the front and back cells used Me-PTC as the acceptor, and the donor in both cells was  $H_2Pc$ . While the Au recombination layer increased the cell voltage, it unfortunately formed a rectifying contact with the  $H_2Pc$  layer in the front cell. Furthermore, the Au layer was sufficiently thick to be optically absorbing. For these reasons, the voltage was increased by approximately 80% from the single junction cell, but the current was reduced by nearly a factor of three. Hence,  $\eta_p$  was lower than for the single junction cell.

Problems with the device in Fig. 7.89 were resolved by depositing an ultrathin layer (0.5 nm) of Ag in place of the thicker Au. The thin Ag is discontinuous, only forming sub-nanometer clusters while still being completely transparent (Yakimov and Forrest, 2002). The nanoclusters provided efficient charge recombination sites with no barrier formation with the organic films. The introduction of the electrically lossless Ag nanoparticle CRZ led to the stacking of up to five identical PTCBI/CuPc planar subcells whose  $V_{OC}$  increased linearly up to three subcells (Fig. 7.90a). Furthermore,  $\eta_p$  of the stacked cells increased superlinearly between a single junction and tandem cell, and the devices remained efficient even under intense illumination of 10 suns ( $1 \text{ W/cm}^2$ ). This indicated that the CRZs are also optically lossless. Figure 7.90b shows that increasing the number of cells beyond two leads to a decrease in efficiency since the front-most cells absorb much of the light required in the back cells, thus limiting the maximum attainable  $j_{SC}$ . While the fabrication of multijunction cells is more challenging than for single junction OPVs, the introduction of loss-free CRZs provided motivation to combine multiple subcells, each absorbing in different spectral region to reduce thermalization losses, increase voltage, and ultimately increase power conversion efficiency.

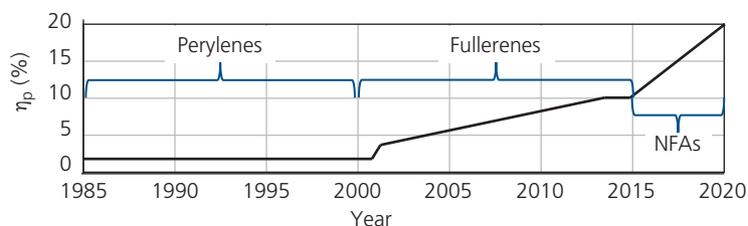

The devices described thus far comprise a planar HJ structure. However, as already shown, the exciton diffusion length is typically considerably smaller than the optical absorption length, leading to a low  $\eta_{ED}$  in Eq. 7.48. This efficiency bottleneck was eliminated by the introduction of the BHJ and mixed HJ architectures, where excitons dissociate throughout the active region volume (Halls et al., 1995, Yu et al., 1995, Xue et al., 2005). This eliminates exciton diffusion, resulting in  $\eta_{ED} = 1$ , although optimization of layer morphology is essential in preventing a reduction in the charge collection efficiency due to disorder within the absorbing region. A discussion of these morphologies is found in Section 7.4.2.

**Figure 7.90** (a) Maximum  $V_{OC}$  vs. number of PTCBI/CuPc junctions in multilayer OPVs. Each subcell is separated by a  $5 \text{ \AA}$  thick Ag charge recombination layer. (b) Power conversion efficiency of the cells vs. light intensity from 0.01 to 10 sun, AM1.5 solar spectrum. The number of subcells in the stacked OPV are indicated (Yakimov and Forrest, 2002).

The introduction of the BHJ was contemporaneous with a second important advance: the use of fullerenes (specifically  $PC_{61}BM$ ) as an acceptor molecule in a photodiode operating in the photovoltaic mode (Yu et al., 1995). Rapid donor–acceptor charge transfer, along with the high spatial symmetry of the spherical or nearly spherical fullerenes led to a remarkable improvement in the charge transfer efficiency and electron conductivity (and thus an increase in  $\eta_{CC}$ ) compared to previously employed perylene-based acceptors. Following the introduction of solution processable  $PC_{61}BM$ , the first solar cells based on vapor-deposited  $C_{60}$  were employed in a so-called *double heterostructure* OPV with an efficiency of 3.6% (Peumans and Forrest, 2001). Using planar-mixed active regions, fullerene-based OPV efficiencies increased to 5% (Xue et al., 2005).

Significant improvements in device performance have been accompanied by innovations in materials and device architectures (i.e. the planar HJ, BHJ, and

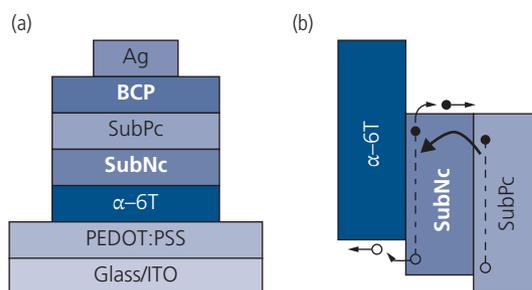

**Figure 7.91** Rapid increases in cell efficiency have been paced by the introduction of new acceptor molecules grouped into three major categories: perylenes, fullerenes, and NFAs.

the double HJ that included an exciton blocking layer; Xue et al., 2005). In this context, introducing new acceptors, starting with the perylenes, then the fullerenes, and most recently the NFAs have led to concomitant increases in OPV efficiencies. In fact, any material can be used as an acceptor provided that it forms a type II HJ with the selected donor with sufficiently large energy offsets ( $\sim 0.5$  eV) to drive exciton dissociation. A suitable acceptor must also have high electron mobility and a LUMO energy that approximately matches the cathode metal work function. We have seen in Chapter 4 that materials with high electron mobilities are uncommon, which is one reason that the fullerenes dominated OPV designs for over a decade.

The importance of the development of new acceptors is illustrated in the OPV efficiency timeline in Fig. 7.91. We have seen in foregoing sections that the diode efficiency depends on the product of the absorption, electron diffusion, charge transfer, and charge collection efficiencies. All of these factors depend on a combination of materials properties (i.e. absorption coefficient and HOMO–LUMO energy offsets at the D–A interface), as well as layer morphology. Indeed, exciton diffusion and charge mobility intimately depend on the film structure at the nanometer scale. The fullerenes improved the coverage of the solar spectrum due to their broad absorption compared to the perylenes, and their spherical or near-spherical symmetries allow close packing, which in turn increases the exciton diffusion length and mobility.

Because of these attributes, the fullerenes supported an extended run of efficiency increases, although the rate of improvement slowed in the late 2010s, primarily due to the large energy loss from the large fullerene exciton binding energy. Also, while spectrally broad, fullerene absorption does not extend into the NIR. The acceptor palette expanded when a high efficiency non-fullerene cell based on halogenated subphthalocyanines was demonstrated. Recent innovations in NFAs

**Figure 7.92** (a) Structure of the NFA-based OPV cell. (b) Proposed energy level diagram showing an exciton cascade that transports excitons within the acceptor to the dissociating HJ between  $\alpha$ -6T and SubNc (Cnops et al., 2014).

have resulted in single junction cell efficiencies exceeding 16% (Yuan et al., 2019).

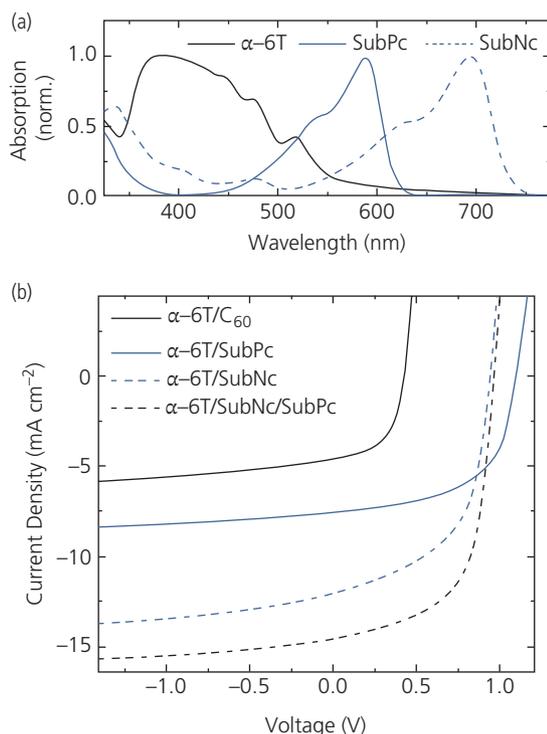

An early high efficiency cell containing only non-fullerene-based materials is shown in Fig. 7.92. This device employed the low ionization energy  $\alpha$ -6T donor forming a planar HJ with a bilayer of the NFAs, SubNc, and SubPc. The trilayer cell provides a site for the absorption of high energy photons in the 18 nm thick SubPc, and lower energy photons in the 12 nm thick SubNc layer. Exciton transport from SubNc to SubPc is via Förster resonant energy transfer, and subsequently drift to the dissociating interface with the  $\alpha$ -6T.

The use of these three materials provides broad spectral coverage shown in Fig. 7.93a, extending from  $<400$  nm due to the  $\alpha$ -6T, to 750 nm, which is the long-wavelength cutoff of SubNc. The  $j$ - $V$  characteristics of several different combinations of acceptors, including  $C_{60}$ , SubPc, SubNc, and SubPc/SubNc are shown in Fig. 7.93b. The larger spectral coverage of the NFAs results in a substantial increase in  $j_{SC}$ . Importantly, the  $V_{OC}$  increases from 0.42 V for  $C_{60}$  to 1.09 V for SubPc. The voltage increase is due to the larger HOMO–LUMO offset energies between the subphthalocyanines and  $\alpha$ -6T, and to the lower exciton binding energies of the NFAs. The highest

efficiency achieved is with the SubPc/SubNc device, with  $V_{OC} = 0.96$  V,  $j_{SC} = 14.55$  mA/cm<sup>2</sup>,  $FF = 0.61$ , resulting in  $\eta_P = 8.4\%$  (Cnops et al., 2014). Since this demonstration, advancements in developing NFAs with absorption deeper into the NIR and with smaller binding energies have continued apace. A more thorough discussion of NFAs and solar cell architectures developed to exploit their properties is found in Section 7.4.4.

### 7.4.1 Architectural elements of high performance OPVs

The basic architectural elements of conventional single junction cells include, starting from the substrate, a transparent anode contact, anode buffer, optically absorbing region, an exciton blocking/electron transporting cathode buffer, and the cathode contact. Multijunction cells also include a CRZ between subcells. Inverted and transparent cells contain similar elements but sometimes stacked in reverse order. In this section we discuss each of the elements in the order in which they are stacked in a conventional OPV structure, starting from the substrate.

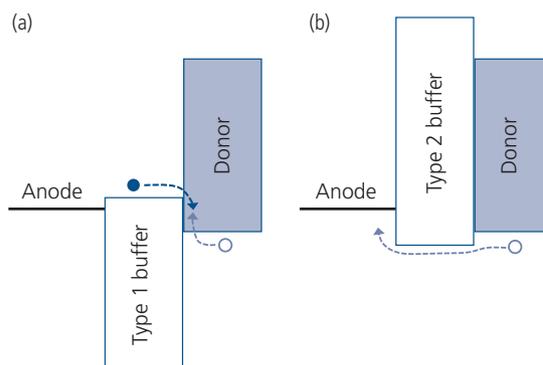

**Figure 7.93** (a) Normalized absorption spectra of the materials employed in the device in Fig. 7.92. (b) Measured  $j$ - $V$  characteristics of several devices using fullerene and non-fullerene acceptors under simulated, 1 sun intensity solar illumination (Cnops et al., 2014).

#### 7.4.1.1 Anode buffers

The anode buffer reduces injection barriers to holes exiting the donor, allowing for low resistance transport to the high work function anode (typically ITO) contact. There are two principal architectures that accomplish this purpose: the high LUMO energy, or large work function electron injecting buffer in Fig. 7.94a, or the low HOMO energy, large energy gap (and hence transparent) hole transporting buffer in Fig. 7.94b. These are Type 1 and Type 2 buffers, respectively. Note that interface dipoles can exist between the donor, anode, and the anode buffer. These substantially alter the simple pictures in Fig. 7.94, and indeed their presence can ultimately determine the efficiency of charge injection altogether (Kanai et al., 2010). The origins and effects of interface dipoles have been discussed in Section 4.6.

Type 1 buffers inject electrons that recombine with photogenerated holes in the donor. Commonly, the anode is the p-type ITO. The energy level alignments with the buffer depend on processing conditions that can change the stoichiometry, and hence the work function and ionization potential of the anode. ITO typically has a valence band maximum energy of  $-4.7$  eV and an energy gap of 3.75 eV (Méndez-Pinzón et al., 2010). A wide energy gap organic material that satisfies the Type 1 criterion is HAT-CN with an ionization energy of  $-9.44$  eV, energy gap of 4.24 eV, and a Fermi energy located only 0.26 eV below the LUMO (Oh et al., 2017). The LUMO energy, therefore, is positioned  $\sim 0.5$  eV below that of ITO, allowing for barrier-free injection of electrons from the buffer LUMO into ITO.

In contrast, Type 2 buffers have an ionization energy comparable to that of the donor and the anode contact, allowing for efficient hole conduction.

**Figure 7.94** (a) Type 1 electron injecting and (b) Type 2 hole conducting anode buffers that connects the anode contact with the donor in the active region. Interface dipoles that may exist depending on materials combinations used, are omitted.

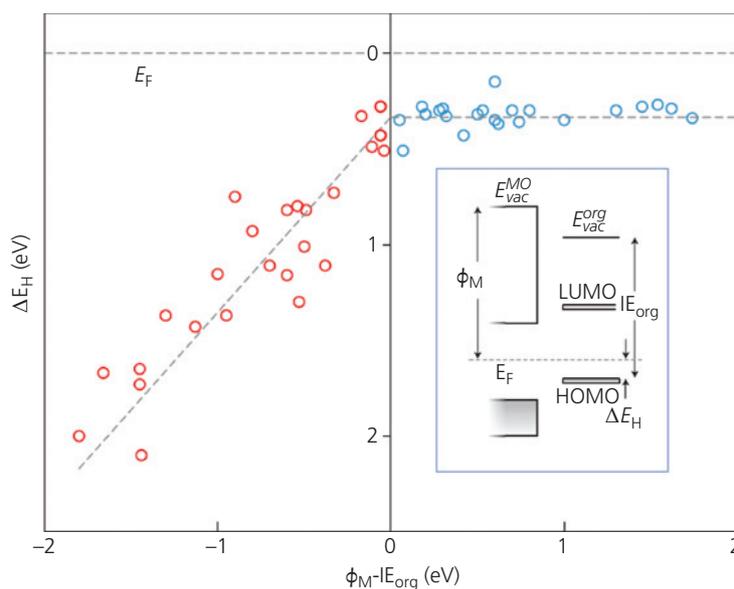

An example of a Type 2 buffer is PEDOT:PSS (Zhang et al., 2007). Like ITO, the energy levels and their alignments are dependent on the precise mixtures, and preparation of this material. Using photoelectron spectroscopic probes, the ionization energy of p-type PEDOT:PSS is 4.9 eV, and the energy gap is  $\sim 1.6$  eV which places its HOMO level at only  $\sim 0.2$  eV below that of the valence band maximum of ITO (Ratcliff et al., 2012). Its narrow energy gap makes this material weakly absorbing in the visible. Thus only very thin layers can be employed in efficient OPVs.

*Transparent metal oxides* (TCOs, or  $\text{MO}_x$ ) have been extensively exploited as anode buffers (Han et al., 2009, Kanai et al., 2010, Dasgupta et al., 2013, White et al., 2016, Guo et al., 2017). This class of materials has a broad range of energy gaps and Fermi energies, yet they generally serve as reasonably efficient hole buffers. The most often used oxide is  $\text{MoO}_3$ , which has a deep conduction band minimum of close to 7 eV, thus forming a Type 1 buffer. Numerous models have been advanced to explain its apparent ability to transport holes, which is opposite to the electron conducting mechanism in Fig. 7.94a. The models impute the presence of very large interface dipoles, or transport through mid-energy gap states due to oxygen vacancies that give rise to a defect-induced hole transport band (Kanai et al., 2010, Dasgupta et al., 2013). However, these scenarios are unlikely since the hole conductivity within an impurity band with a limited

density of states would presumably be far less than the electron conductivity in the conduction band, as both would serve the same purpose of transporting charge from the donor to the anode.

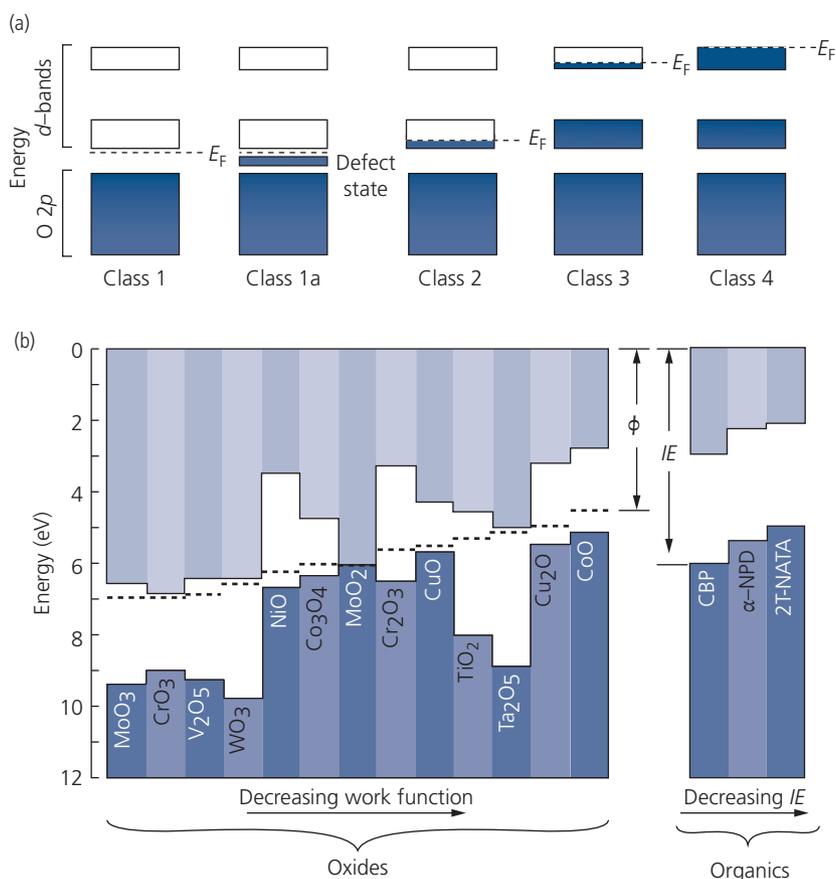

The ability of TCOs to conduct holes to the anode is explained by the differences in HOMO energies between several molecular solids such as  $\alpha$ -NPD, 2T-NATA, and CBP and the work function,  $\phi_M$ , of a range of TCOs. As shown in Fig. 7.95, the energy difference fits on a universal curve when plotted against  $\phi_M - IE_{org}$ . Here,  $IE_{org}$  is the ionization energy of the organic overlayer measured by ultraviolet photoelectron spectroscopy (see Appendix C). The offset energy between the Fermi energy of the metal oxide and the donor HOMO,  $\Delta E_H$ , increases linearly for  $\phi_M - IE_{org} < 0$ , until  $\phi_M - IE_{org} = 0$ , at which point the HOMO energy is pinned at  $\Delta E_H \approx 0.3$  eV. Increasing  $\phi_M$  further does not result in a change in the HOMO energy relative to the metal oxide. This trend indicates that details of the organic, and the electronic structure or the reconstruction of the  $\text{MO}_x$  surface, has little if anything to do with the energy level alignments.

The apparently universal relationship results from filling of oxygen vacancies in the transition metal oxide via charge exchange with the organic layer on its surface. The electronic structure of transition metal oxides is primarily determined by filling their *d*-band orbitals, as illustrated in Fig. 7.96a. The metal oxides can be broadly separated into four classes. Class 1 oxides

**Figure 7.95** HOMO offset energy,  $\Delta E_H$ , vs. the difference in metal oxide work function,  $\phi_M$ , and organic ionization energy,  $IE_{org}$ , for a variety of metal oxides and organic semiconductors. The Fermi energy,  $E_F$ , is shown at  $\Delta E_H = 0$ . Inset: Definition of the variables used in the plot (Greiner et al., 2012).

**Figure 7.96** (a) Schematic illustration of the energy band structure of transition metal oxides with different  $d$ -band occupancies. Also shown are the O  $2p$  orbitals. (b) Energy gaps and Fermi energies of metal oxides whose energies are plotted in Fig. 7.95, along with the organics used to form the heterojunctions (Greiner et al., 2012).

(e.g. V<sub>2</sub>O<sub>5</sub>, MoO<sub>3</sub>, WO<sub>3</sub>, TiO<sub>2</sub>, Ta<sub>2</sub>O<sub>5</sub>) are  $d^0$  insulators in their native state since they have empty conduction levels. Since these materials generally are non-stoichiometric compounds due to a high density of oxygen vacancies, the  $d$ -bands are only partially occupied. The vacancies form defect states below the Fermi energy, giving them n-type character (Class 1a). Class 2 metal oxides have partially filled  $d$ -bands with a low density of electrons at energies higher than  $d^0$ , giving them metallic character. Examples of Class 2 materials are WO<sub>2</sub>, TiO, MoO<sub>2</sub>, and Cr<sub>2</sub>O<sub>3</sub>. Class 3 oxides have a large number of electrons in these energy bands, filling them to even higher energies (examples include Co<sub>3</sub>O<sub>4</sub>, CoO, NiO, CuO). Finally, oxides whose bands are completely filled (known as the  $d^{10}$  oxides) form Class 4 semiconductors (Ag<sub>2</sub>O, Cu<sub>2</sub>O).

The relative positions of the MO<sub>x</sub> Fermi energies to those of the organics are illustrated in Fig. 7.96b. In spite of the variety of electronic structures, energy gaps and compositions of the oxides, the Fermi energies all lie within a narrow range from approximately

4.5 eV for CoO to 7 eV for MoO<sub>3</sub>. Many of the oxides are suitable as Type 1 (e.g. MoO<sub>3</sub>, WO<sub>3</sub>, etc.) or Type 2 (Cu<sub>2</sub>O, NiO, etc.) buffers, depending on the organic used as the donor.

The dependence of  $\Delta E_H$  on  $\phi_M - IE_{org}$  and the source of the Fermi level pinning in Fig. 7.95 are explained as follows: As the HOMO energy of the organic moves closer to the vacuum level,  $E_{vac}^{org}$ , than  $E_F$  of the MO<sub>x</sub>, there is electron transfer from the molecular layer to the oxide. The number of cation molecules,  $M^+$ , formed is given by Fermi statistics, viz. (Greiner et al., 2012)

$$[M^+] = \frac{[M^0]}{1 + g \exp(E_{form}/k_B T)}, \quad (7.167)$$

where  $[M^+]$  is the concentration of ionized molecules,  $[M^0]$  is the total concentration of molecules,  $g$  is the degeneracy factor which is equal to the total number of equivalent charge states of the molecule, and  $E_{form}$  is the formation energy of the charged molecular state. Once the Fermi energy equals, or exceeds the HOMO energy, charge transfer no longer occurs, and

the number of ionized molecules becomes saturated. Increasing the Fermi energy further, therefore, does not lead to a concomitant increase in  $[M^+]$ .

From this analysis, the HOMO energy relative to  $E_F$  is given by

$$\Delta E_H = IE_{org} - a\phi + \Delta + \frac{q^2 \rho d}{2\epsilon_0} \sum_{i=0}^{\infty} \frac{1}{1 + g \exp(E_{form}^i/k_B T)}, \quad (7.168)$$

where  $a$  is a constant dependent on the degree of screening of the surface potential by the molecular layer,  $\Delta$  is the interface dipole energy,  $\rho$  is the area density of molecules in each layer, and  $d$  is the distance between the molecular plane and the substrate. The sum is over the layers from the  $MO_x$  surface into the bulk, each with different formation energies,  $E_{form}^i$ , due to the decreasing relaxation energy of the molecules located at increasing distances from the interface. That is, the formation energy for a molecular ion,  $M^+$ , in layer  $i$  is  $E_{form}^i = IE_{org} - \phi_M - iE_{relax}$ , where  $E_{relax}$  is the energy relaxation between each layer.

The fit to the data by Eq. 7.168 gives evidence for charge transfer. This universal dependence also rules out the possibility that the energy level offsets for  $MO_x$ -based anode buffers depends on details of surface chemistry, conduction via defect states, etc. Indeed, the phenomenon is neither process nor surface-chemistry dependent, making the metal oxides ideal candidates for anode buffers.

#### 7.4.1.2 Active regions: cascade and ternary blend OPVs

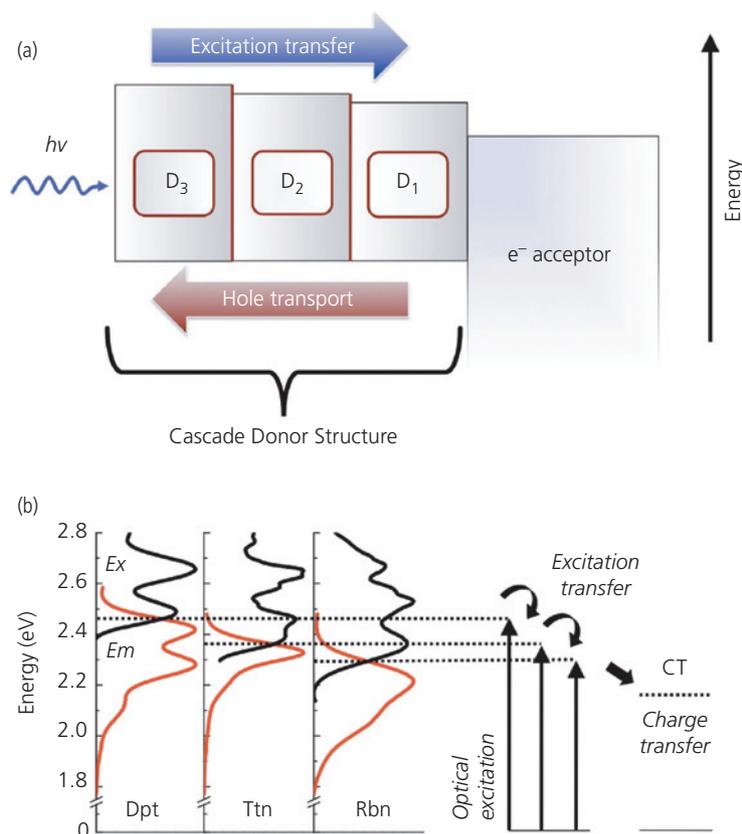

In Section 7.1.2 we introduced the generic structures of the planar HJ, the BHJ, the planar-mixed device, and the so-called “controlled” HJ comprising a nearly ideal morphology comprising finger-like protrusions of the donor into the acceptor region with diameters on the scale of the exciton diffusion length, and finger lengths comparable to the optical absorption length. Beyond these basic structures, many alternatives have been demonstrated that are designed to increase  $\eta_{ext}$ ,  $V_{OC}$ , and  $FF$  to overcome the characteristically low mobility and exciton diffusion lengths of organic thin films.

There are two variants of these structures known as *cascade* and *ternary blend* OPVs. We have already introduced an acceptor cascade OPV in Fig. 7.92, utilizing a three layer, planar, thin film active region comprising a donor layer along with two acceptor layers whose energy gaps increase with distance from the D-A HJ (Cnops et al., 2014). The second variation of the cascade is one that blends either two donors and one acceptor molecule, or vice versa, into a

single bulk or mixed HJ structure. These architectures will be separately discussed, since their operating principles differ in a few important respects, although in both cases their purpose is to extend the coverage of the solar spectrum by increasing the number of absorbing molecular species within the active region.

Often, properties of a specific donor material that favorably impact one performance metric, negatively impact another. For example, molecular geometries that frustrate intermolecular electronic interactions at the D-A junction can result in an increased open circuit voltage (cf. Section 4.7.2). In contrast, exciton diffusion and charge transport are generally enhanced by strong interactions within the layers (Servet et al., 1994, Coropceanu et al., 2007). The competition between conflicting requirements can be resolved by combining several donor or acceptor materials, each optimized for a different function, within the active region. The cascade structure in Fig. 7.97a offers this multifunctional design strategy by partitioning the donor region into a multilayer stack of complementary materials,  $D_1$ ,  $D_2$ , and  $D_3$ , with successively larger energy gaps according to their distance to the D-A HJ. The progression in energy gaps allows for directed transfer of excitons generated in large energy gap layers to the lower energy gap layers, until the excited state ultimately arrives in  $D_1$  where it can diffuse to the HJ. Here,  $D_3$  is designed to prevent exciton diffusion to the anode while suppressing dark current and absorbing the highest energy photons.  $D_1$  absorbs the longest wavelength light while also facilitating exciton transfer to the D-A interface. Also,  $D_1$  should maximize  $V_{OC}$  by choosing a material with the largest possible HOMO–LUMO offset energy that permits efficient exciton dissociation. The intermediate donor,  $D_2$  is used to complete the coverage of the solar spectrum. In the design in Fig. 7.97a, the HOMO energies of all donors are aligned such that holes generated at the HJ are transported to the anode without encountering a significant energy barrier that would decrease  $\eta_{CC}$ .

The energy gap ordering of  $D_3 > D_2 > D_1$  for the series Dpt, tetracene (Ttn), and rubrene (Rbn) is shown in Fig. 7.97b. Due to the spectral overlap between the emission and absorption spectra of molecules in adjacent layers, excitations in Dpt Förster transfer to Ttn, and likewise, Ttn excitations transfer to Rbn. A summary of the device performances for several devices employing these donors contacting a 40 nm thick  $C_{60}$  acceptor in a planar junction OPV are provided in Table 7.7. The  $V_{OC}$  of the cascade device is 0.74 V, which is noticeably lower than that of the single donor Rbn OPV. This is attributed to singlet fission

**Figure 7.97** (a) Multi-donor ( $D_1$ ,  $D_2$ ,  $D_3$ ) energy cascade OPV. (b) Excitation (Ex) and emission (Em) spectra of the three donors, Dpt, Ttn, and Rbn, along with transitions obtained from optical absorption and charge transfer at the HJ. The excited state energy cascade progression is shown by the successively lower energies from Dpt to Rbn (Schlenker et al., 2011).

**Table 7.7** Comparison of performance of cascades and single donor devices using materials in Fig. 7.94 (Schlenker et al., 2011)

Donor <sup>a</sup>	$j_{sc}^b$ (mA/cm <sup>2</sup> )	$V_{oc}$ (V)	$FF$	$\eta_p$ (%)
Dpt (10 nm)	1.1	0.65	0.41	0.30
Ttn (45 nm)	2.9	0.54	0.54	0.83
Rbn (20 nm) <sup>c</sup>	2.4	0.92	0.43	0.92
Dpt (10 nm)/Ttn (35 nm)	1.4	0.79	0.37	0.41
Dpt (5 nm)/Ttn (20 nm)/Rbn (20 nm)	2.6	0.74	0.50	0.95

<sup>a</sup> All devices employed a 40 nm  $C_{60}$  acceptor, 10 nm BCP blocking layer, and an Al cathode.

<sup>b</sup> Measurements made under 1 sun intensity, AM1.5G simulated illumination.

<sup>c</sup> Data from Perez et al. (2009).

that lowers the photovoltage, and perhaps leads to inefficient energy transfer between the various layers in the cascade (Schlenker et al., 2011). Nonetheless, the cascade device performance (including  $FF$  and  $j_{sc}$ ,

and consequently,  $\eta_p$ ) is improved compared to any of the single donor combinations studied.

A marked improvement in donor cascade devices was achieved using the triple donor stack comprising Dpt (10 nm)/Rbn (10 nm)/DBP (10 nm) along with a  $C_{60}$  (35 nm) acceptor followed by a  $C_{60}$ :Bphen (1:1, 8nm)/Bphen (5 nm) exciton blocking and electron filtering buffer layer (see Section 7.4.1). The optical gaps of Dpt ( $D_1$ ), Rbn ( $D_2$ ), and DBP ( $D_3$ ) are 2.5eV, 2.2 eV, and 2.0 eV, respectively, whereas the HOMO energy of each donor is at 5.4 eV referenced to vacuum. Hence, this triad of materials satisfies the architectural requirements of a cascade in that the energy gaps allow for transfer from  $D_1 \rightarrow D_2 \rightarrow D_3$ , whereas the HOMO energy alignment creates a path for efficient hole extraction to the anode (Griffith and Forrest, 2014).

The absorption and emission spectra of the various donor constituents used in conjunction with their exciton diffusion lengths of  $L_D = 30$  nm, 35 nm, 20 nm, and 28 nm for Dpt, Rbn, DBP, and  $C_{60}$ , respectively, provide a quantitative determination of the contribution to the total short circuit current of the cascade

**Table 7.8** Short-circuit current density contributions to the total cascade OPV current calculated for each organic active layer (Griffith and Forrest, 2014)

Donor	$j_{SC}$ (Dpt) <sup>a</sup>	$j_{SC}$ (Rbn)	$j_{SC}$ (DBP)	$j_{SC}$ (C <sub>60</sub> )	Total $j_{SC}$
Dpt/Rbn/DBP	0.13 (1.8%)	0.11 (1.5%)	3.88 (51.0%)	3.48 (45.7%)	7.61
Rbn/DBP	—	0.12 (1.7%)	3.63 (50.7%)	3.41 (47.6%)	7.16
Dpt/Rbn	0.15 (3.8%)	0.20 (5.0%)	—	3.57 (91.2%)	3.92
DBP	—	—	2.01 (33.9%)	3.92 (66.1%)	5.93
Rbn	—	0.20 (6.1%)	—	3.14 (93.9%)	3.34
Dpt	0.21 (8.4%)	—	—	2.28 (91.6%)	2.49

<sup>a</sup> Relative percentage contributions of a given material to  $j_{SC}$  are in parentheses. All values in mA/cm<sup>2</sup>.

device from each layer. This analysis assumes that absorption in each layer is followed by diffusion to the interface with the next layer. The exciton is then transferred via FRET to the following layer, and the process continues until exciton dissociation occurs at the DBP/C<sub>60</sub> HJ. Calculated estimates of the  $j_{SC}$  contributions from each layer are summarized in Table 7.8. In single donor devices, the preponderance of the short circuit current is generated in the C<sub>60</sub> layer due to its long diffusion length and its broad spectral absorption. However, in the cascades (with the exception of the Dpt/Rbn double cascade), photocurrent generation is more balanced. Indeed, the triple cascade device shows that the current is primarily generated in the donors, although only a small fraction is due to transfer from Dpt to Rbn, and Rbn to DBP, which is attributed to the low absorption coefficients of Dpt and Rbn.

Although the currents contributed by D<sub>1</sub> and D<sub>2</sub> are not substantial, the power conversion efficiency of the triple cascade (7.1%) is markedly higher than any of the single donor devices, where the largest efficiency of 4.3% is obtained for the DBP/C<sub>60</sub> bilayer OPV (see Table 7.9). Exciton blocking by large energy gap Dpt and Rbn layers is likely responsible for this significant improvement in  $\eta_P$ , which from Table 7.9 appears to arise primarily from an increase in  $j_{SC}$ . That is, excitons generated in DBP are prevented from diffusing to the anode where they are quenched.

These early demonstrations indicate that cascades can significantly improve OPV efficiency if the various layers are selected for high absorption coefficients, with limited overlap of absorption between layers. Several materials with approximately equal HOMO energies that might prove useful in donor cascades are provided in Fig. 7.98. Using these and many other materials available, there appears to be no limit to the number of donors or acceptors that can be employed in an efficient cascade as long as the design criteria of descending energy gaps and nearly equal transport level energies are met.

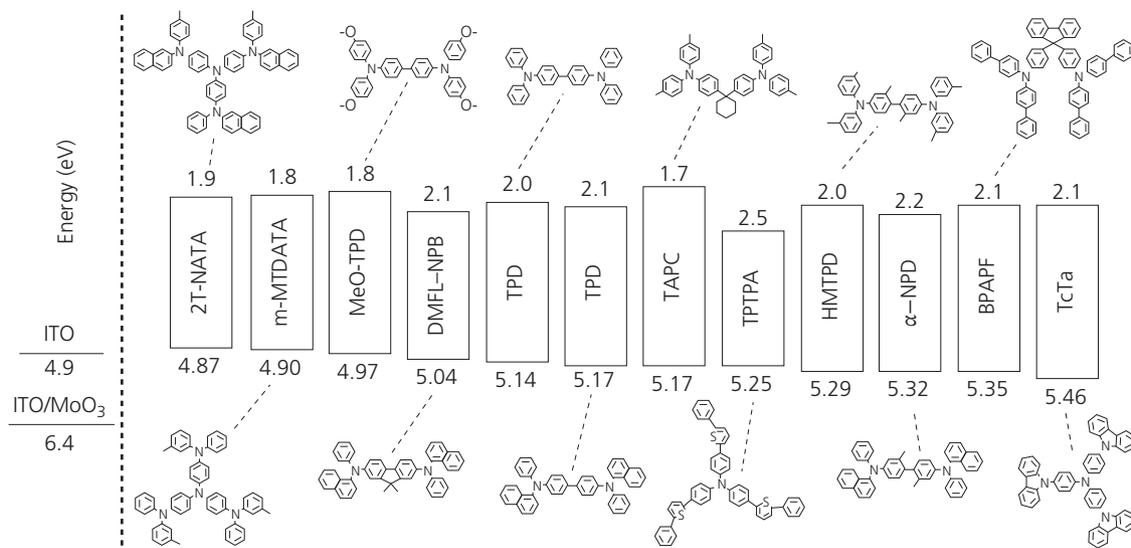

**Table 7.9** Performance of 3, 2, and 1 donor cascade OPVs (Griffith and Forrest, 2014)

Donor	$V_{OC}$ (V)	$j_{SC}$ <sup>a</sup> (mA/cm <sup>2</sup> )	FF	$\eta_P$ (%)
Dpt/Rbn/DBP	0.94	10.6	0.71	7.1
Rbn/DBP	0.94	9.3	0.68	6.0
Dpt/Rbn	0.90	3.9	0.52	1.9

Rbn	0.89	3.8	0.47	1.6
Dpt	0.80	2.7	0.39	0.8

<sup>a</sup> Values measured 1 sun AM 1.5G simulated illumination.

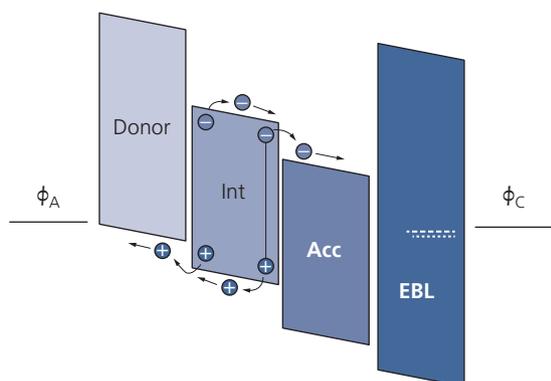

The NFA cascade in Fig. 7.92 provides an example of how to balance contributions from each of the layers. In Fig. 7.93, the absorption from the donor ( $\alpha$ -6T) and the two acceptors (SubNc, acceptor A<sub>1</sub>, and SubPc, acceptor A<sub>2</sub>) have only a limited spectral overlap. Contrary to the donor cascades, the acceptor LUMO energies must be approximately matched. There is a LUMO barrier of 0.23 eV between SubPc and SubNc, which may result in a small loss in electron collection efficiency at the cathode (Endres et al., 2016). Nevertheless, this materials combination results in a broad spectral response, extending from 350 nm to nearly 750 nm with an average of  $\eta_{ext} \sim 60\%$ . As a result, the efficiency of the double acceptor cascade is  $\eta_P = 8.4\%$ , whereas the D/A<sub>1</sub> device has  $\eta_P = 6.0\%$ , and D/A<sub>2</sub> gives 4.7% (Cnops et al., 2014).

Thus far we have considered cascades where excitons are funneled to a single, dissociating D-A HJ. The lack of differences in HOMO energies in the donor cascades prevents dissociation within the donor region itself. Intermediate charge generation is possible using an energy staircase at both the HOMO and LUMO energies, as shown in Fig. 7.99. This results in multiple exciton dissociation sites within the active region that eliminate the need for energy

**Figure 7.98** Molecules and their HOMO and LUMO energies useful in donor cascades (Barito et al., 2014).

© 2014 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

**Figure 7.99** Proposed equilibrium energy level diagram of a multijunction cascade OPV consisting of a donor layer, an intermediate layer (Int), an acceptor (Acc), and an exciton blocking layer (EBL).

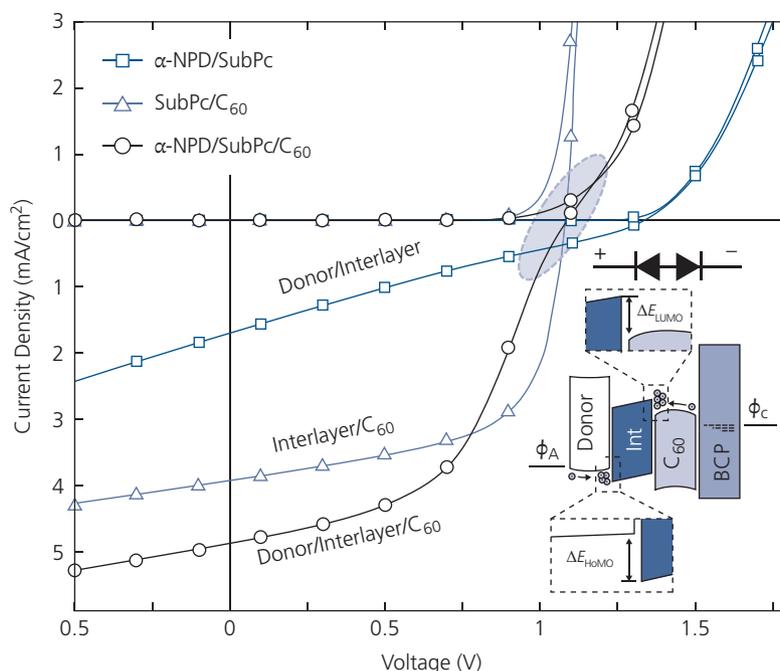

transfer along the entire cascade to the HJ (Hong et al., 2009, Heidel et al., 2011, Barito et al., 2014). The use of multiple HJs eliminates the trade-off between a short diffusion length and the longer optical absorption length, that often limits the efficiency in bilayer planar HJ cells.

The photodetection process in the multijunction cascade is shown in Fig. 7.99. There are two sites for exciton dissociation, one at the donor/intermediate layer (Int), and one at the Int/acceptor (Acc) HJ. Both HJs must have sufficiently large HOMO–LUMO energy offsets to induce charge transfer in the forward direction. In fact, the two junctions serve as two photocurrent generators in series. The interlayer serves as both the acceptor for the left-most junction as well as

the donor to the right-most junction. This shared purpose also affects the total device voltage.

The benefit of this design is that the multiple layers provide charge generation sites within a diffusion length of the photon absorption site. Also, the layer compositions can be chosen to give broad spectral coverage. Beyond having complementary absorption spectra, efficient multistep devices must satisfy two further design criteria that are not easily met. As noted, the HOMO–LUMO offsets at each HJ must be sufficiently large to promote efficient exciton dissociation. Also, current continuity requires that the electron and hole mobilities of Int be approximately equal to avoid electron or hole pile-up at the junction. Charge pile-up creates an internal voltage that bends the energy levels opposite to that in Fig. 7.99, which eventually stops the current flow, to significantly reduce efficiency.

The  $j$ - $V$  characteristics of a multistep  $\alpha$ -NPD/SubPc/ $C_{60}$  cascade device shown in Fig. 7.100 exhibit the benefits and challenges of the architecture. The open circuit voltage is approximately equal to that of a SubPc/ $C_{60}$  OPV, but considerably lower than the  $\alpha$ -NPD/SubPc device. The multistep cascade features an inflection in the characteristics near  $V_{OC}$  that substantially decreases  $FF$  from 0.62 for the bilayer lacking the donor, to 0.49 for the multistep OPV (Barito et al., 2013). The inflection is characteristic of two energy barriers that can be modeled by the back-to-back diode circuit shown in the inset. The intermediate SubPc layer has a significantly higher hole than electron mobility. This leads to pile-up of

**Figure 7.100** Current density–voltage characteristics of a multistep cascade device at 1 sun, AM1.5 simulated solar illumination, and in the dark. Individual bilayer devices comprised of the same materials are also shown. The layer thicknesses and compositions are  $\alpha$ -NPD (donor, 5 nm), SubPc (Int, 13 nm),  $C_{60}$  (Acc, 36 nm). The active layers are sandwiched between an ITO/MoO<sub>3</sub> anode and a 10 nm thick BCP EBL and an Al cathode. The oval highlights the inflection in the cascade device characteristics. After Barito et al. (2013). Inset: Proposed energy level diagram at open circuit (bottom) along with an equivalent circuit (top). After Barito et al. (2014).

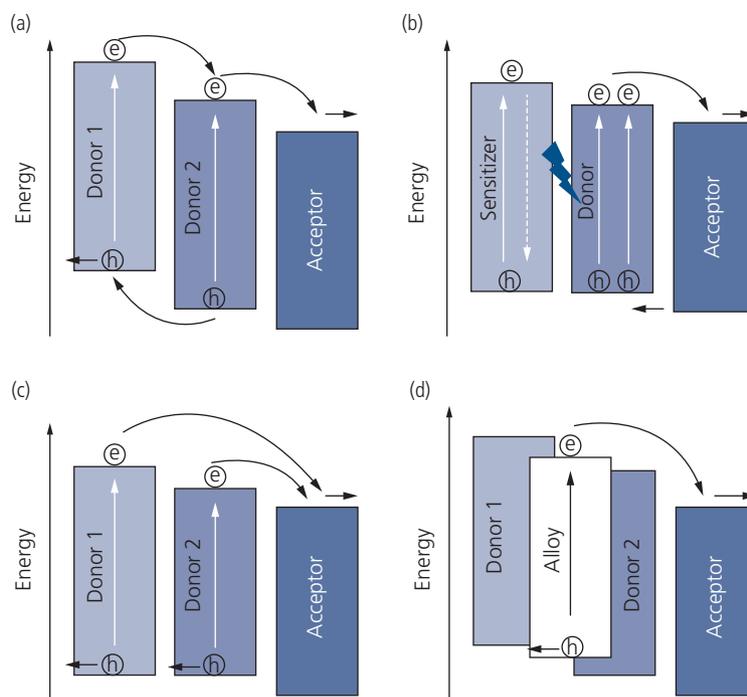

electrons at the  $C_{60}$ /Int interface, and holes at the donor/Int interface that, in turn, reduces the junction potential, thereby reversing the internal electric field. The reduction in current produces the inflection. This problem has been observed to a greater or lesser extent in other such cascade devices (Heidel et al., 2011, Barito et al., 2014). The inflection is expected to be more pronounced with increasing light intensity, and hence increased charge accumulation at the junctions. Thus, the OPV can switch from a conventional single diode-like characteristic at low light intensity with the two junctions serving as current generators, to a device at high intensity with two opposing junctions that effectively shut off the current flow.

The characteristics in Fig. 7.100 reflect the existence of internal energy barriers within the cascade that can only be reduced by a careful choice of materials. This choice, however, may ultimately result in compromises in other materials properties that are required to achieve high performance. Consequently, multistep cascade devices have not offered improved performance over BHJ, mixed HJ or exciton cascade devices.

Planar junction architectures of three or more components can be replaced by ternary *blend* BHJs of those same components to simplify the active region

structure. The blended cells can consist of two donors and an acceptor (i.e.  $D_1D_2A$ ), or two acceptors with a single donor ( $DA_1A_2$ ) (Ameri et al., 2013, Fu et al., 2018). The blends are generally cast from solution, although they can also be realized by co-deposition by VTE (Rand et al., 2005b, Yang et al., 2008). The exciton generation and charge transport processes are analogous to those found for exciton and multi-junction cascades, although the complete intermixing of three components can lead to parallel processes in contrast to serial transport experienced using cascades of individual layers to a single dissociating junction. Unlike cascades, the blended ternary BHJ performance critically depends on morphology. The ability to extract charge through complex networks comprising three or more constituents amplifies morphological challenges already confronted in binary BHJs, and in small molecule mixed regions.

The possible routes to photogeneration in  $D_1D_2A$  ternary cells are illustrated in Fig. 7.101. The three constituents are represented by their individual frontier energy diagrams, although they are homogeneously intermixed in the actual structures. Figure 7.101a shows parallel charge transfer, where excitons are generated in both  $D_1$  and  $D_2$  (as well as

**Figure 7.101** Possible photocurrent generation routes of  $D_1D_2A$  ternary blend BHJs. (a) Parallel charge generation, (b) FRET transfer from a sensitizer ( $D_1$ ) to a donor ( $D_2$ ), (c) parallel exciton dissociation, and (d) dissociation at A in a “molecular alloy” formed by mixing  $D_1$  and  $D_2$  with A.

in A, but not shown). Electrons generated by dissociation at the  $D_1/D_2$  HJ diffuse through  $D_2$  and onward to the acceptor. Similarly, holes generated between  $D_1$  and  $D_2$  transfer to  $D_1$  for conduction to the anode, and electrons diffuse through A to the cathode. Of course, dissociation also occurs at the  $D_2/A$  interface, given that these are homogeneous blends of all three constituents. Direct charge transfer occurs when there is weak or no overlap between the emission spectrum of  $D_1$  and the absorption of  $D_2$ , thus reducing the probability for FRET. The blend operates on the same principle as the multi-junction cascade in Fig. 7.99.

Energy transfer (Fig. 7.101b) is another potential route to charge generation that is active when there is significant overlap between the emission spectrum of  $D_1$  (the “sensitizer”) and the absorption spectrum of  $D_2$  (Honda et al., 2011, Huang et al., 2013). This mechanism is identical to that for the energy cascade in Fig. 7.97, except that the active region morphology is a blend as opposed to discrete layers. The wide energy gap material transfers photogenerated excitons to the lower energy gap donor, where they subsequently dissociate at the HJ between  $D_2$  and A. Also, direct exciton generation is possible in  $D_2$  itself.

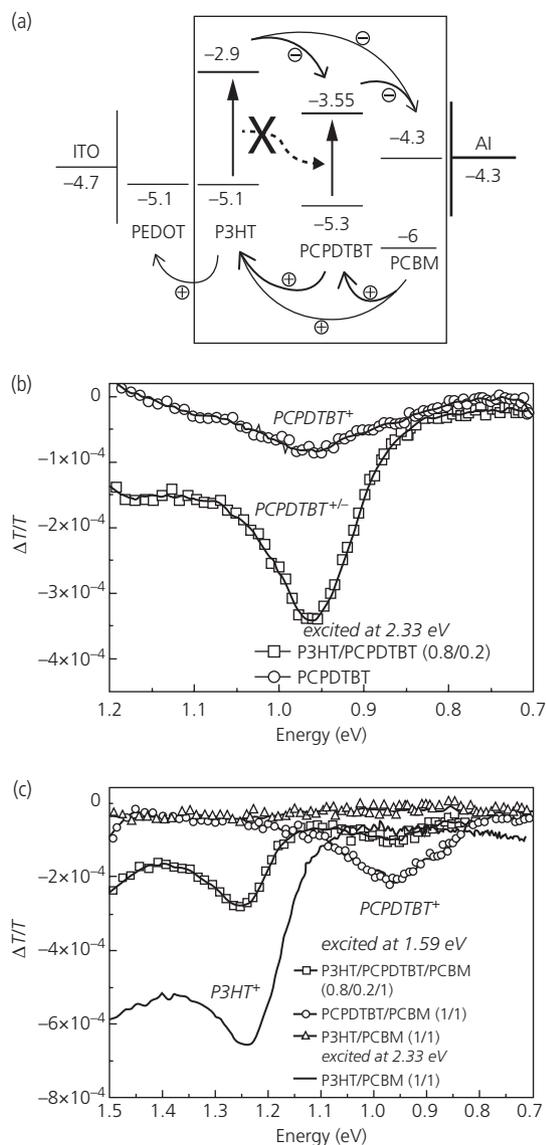

The mechanism in Fig. 7.101c models the ternary blend cell as two parallel, rectifying junctions

comprising  $D_1A$  and  $D_2A$ . Both junctions independently generate excitons by absorption of light. The excitons transport through the donors where they dissociate into free charges at both D-A junctions. Subsequently, the holes are transported to the anode within the donors in which they originated. This system does not undergo significant energy transfer between donors as in Fig. 7.101b, nor do the donors share conductive pathways for charges generated on the other components in the blend.

The so-called “alloy” model in Fig. 7.101d is qualitatively different than the other three mechanisms. In this picture, a new material, or *molecular alloy* is formed by mixing of several materials in a common active region. The alloy thus formed has emergent properties that are not characteristic of the original materials of which it is comprised.

Parallel charge generation has been proposed for the  $D_1D_2A$  ternary mixture of P3HT, PCPDTBT and PC<sub>61</sub>BM, whose energy levels are shown in Fig. 7.102a (Koppe et al., 2010). Since in the blend, all materials contact each other, several transfer paths ( $D_1 \rightarrow D_2 \rightarrow A$ ,  $D_1 \rightarrow A$ , and  $D_2 \rightarrow A$ ) are possible. Also, the diagram suggests that FRET from  $D_1$  to  $D_2$  is not active in this materials combination due to their poor spectral overlap.

*Photoinduced absorption* (PA) was used to study parallel charge transport in the device. The method uses a

**Figure 7.102** (a) Proposed energy level diagram and the various charge transfer processes in a P3HT:PCPDCTBT:PC<sub>61</sub>BM D<sub>1</sub>D<sub>2</sub>A OPV. “X” indicates the absence of FRET from D<sub>1</sub> to D<sub>2</sub>. Photoinduced absorption spectrum of (b) annealed PCPDCTBT and PCPDCTBT radicals in a P3HT/PCPDCTBT (0.8/0.2) blend, and (c) for various blends and pumping conditions shown in the legend (Koppe et al., 2010).

pump to excite the film at one wavelength, and a probe to measure the resulting change in transmission ( $\Delta T/T$ ). The PA spectra are shown in Fig. 7.102b and c for two different excitation energies. The PCPDCTBT film absorbs at 1.59 eV, where P3HT is transparent. Exciting the films at 2.33 eV where both films absorb (Fig. 7.102b) generates a radical cation, PCPDCTBT<sup>+</sup>, leading to an absorption peak at 0.96 eV. The larger peak for the P3HT:PCPDCTBT (1:1) indicates that photogenerated electrons efficiently transport from

P3HT to PCPDCTBT, as noted by the bold line between their LUMOs in Fig. 7.102a. In Fig. 7.102c, excitation at 2.33 eV of the P3HT:PC<sub>61</sub>BM (1:1) junction results in hole polaron absorption in P3HT at 1.25 eV. This signal disappears when pumped at 1.59 eV where P3HT is nearly transparent. In contrast, pumping the PCPDCTBT:PC<sub>61</sub>BM (1:1) film at 1.59 eV gives rise to a secondary hole polaron peak in P3HT at  $\sim 0.95$  eV, suggesting that holes are transported directly from PC<sub>61</sub>BM to PCPDCTBT. The strong P3HT polaron absorption band found in the double donor structure of P3HT:PCPDCTBT:PC<sub>61</sub>BM is due to efficient hole transport from the low to the high energy gap donors. These data provide evidence that the primary routes for charge generation are due to exciton dissociation at both the D<sub>1</sub>A and D<sub>2</sub>A interfaces, and then conduction of both electrons and holes through the entire D-A network to the electrodes. Lack of evidence for energy transfer strengthens these conclusions (Koppe et al., 2010).

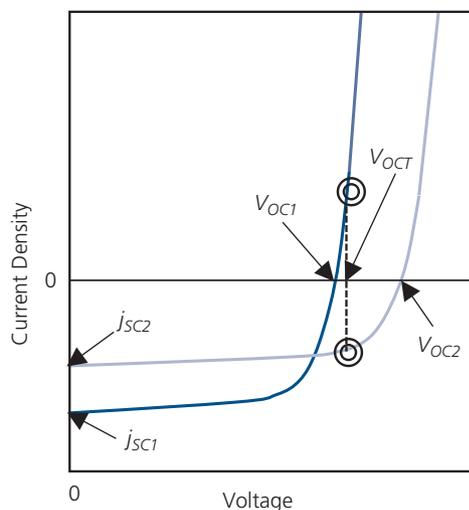

The photoluminescence lifetime of D<sub>1</sub>D<sub>2</sub>A blends was analyzed to confirm that FRET leads to the energy transfer from D<sub>1</sub> to D<sub>2</sub> according to Fig. 7.101b for a D<sub>1</sub> = P3HT, D<sub>2</sub> = SQ, and A = PC<sub>61</sub>BM blended ternary OPV. In Section 3.8.1 we found that energy transfer is a process that competes with the natural fluorescent decay of the molecule. That is, the radiative decay time is

$$\tau_{tot} = \frac{\tau_{ET}\tau_F}{\tau_{ET} + \tau_F} \quad (7.169)$$

Here,  $\tau_{ET}$  is the FRET transfer time and  $\tau_F$  is the natural fluorescence decay time. It was found that  $\tau_{tot}$  decreased from 223 ps for 0% SQ in P3HT, to 52.4 ps for 1 wt% SQ, to 9.9 ps for 5 wt% SQ. This was one of several pieces of data suggesting that FRET was the most active process for this particular materials system (Huang et al., 2013).

The ternary open circuit voltage,  $V_{OCT}$ , for the parallel circuit model of Fig. 7.101c is analyzed using the  $j$ - $V$  characteristics in Fig. 7.103. Here, we separately plot the characteristics for the two, independent parallel “sub-cells,” D<sub>1</sub>A and D<sub>2</sub>A, that coexist in the blend. From Kirchoff’s Law, the open circuit voltage of D<sub>1</sub>D<sub>2</sub>A corresponds to the point where the  $j_1 = -j_2$ , such that the total short current is  $j_{SC} = 0$ . The  $V_{OCT}$  of the network is calculated using this condition, along with  $V_1 = V_2$  in Eq. 7.122. The solution is complicated unless we assume that the ideality factors for the two junctions are approximately equal, that is  $n_{ST} = n_{S1} \approx n_{S2}$ . Then, in the approximation that  $k_{PPd}(V) = k_{PPd,eq}$ :

$$V_{OCT} = \frac{n_{ST}k_B T}{q} \log \left( \frac{j_{SC}}{j_{OT}} + 1 \right), \quad (7.170)$$

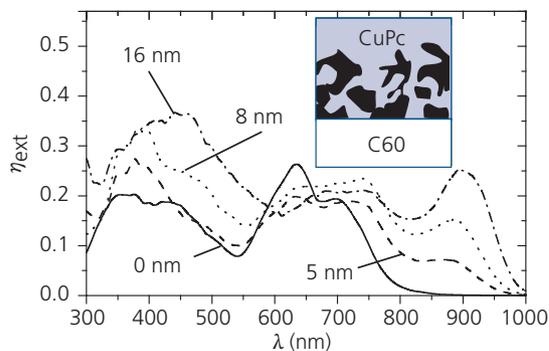

**Figure 7.103** Example  $j$ - $V$  characteristics of two parallel "subcells" in a ternary blend such as in Fig. 7.101c. The open circuit voltage of the ternary blend,  $V_{OC,T}$ , is at the point where the current from subcell 1 (dark blue line) is equal and opposite to that of subcell 2 (light blue line).

where the saturation currents are given by  $j_{0T} = j_{01} + j_{02}$ , and we assume that  $j_{SC} \gg j_0$  for both subcells.

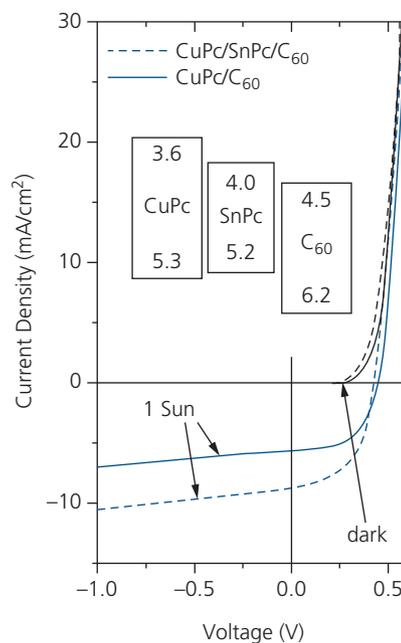

It is apparent from Fig. 7.103 and Eq. 7.170 that  $V_{OC,T}$  must always lie between the upper and lower limits set by  $V_{OC1}$  and  $V_{OC2}$ . This conclusion is consistent with voltage measurements of ternary devices, and is independent of which model in Fig. 7.101 is active. An additional implication of Kirchhoff's law is that the less efficient junction limits the current from the more efficient junction to ensure that voltages from both junctions are equal at the diode terminals.

A ternary cell based on vapor co-deposited  $D_1D_2A$  HJ ( $D_1 = \text{CuPc}$ ,  $D_2 = \text{SnPc}$ ,  $A = \text{C}_{60}$ ) formed a parallel junction similar to that in Fig. 7.101c (Rand et al., 2005b). The parallel network results from incomplete wetting of the CuPc by a thin (5 nm) layer of SnPc, over-coated by the thick (40 nm)  $\text{C}_{60}$  acceptor. In subsequent work, OVPD of the layers in a ITO/SnPc ( $x$  nm)/CuPc (40 nm)/BCP (10 nm)/Ag OPV resulted in formation of a more controlled network of  $D_1$ ,  $D_2$ , and  $A$  (Yang et al., 2008). The solar coverage provided by this ternary combination is significantly expanded by the addition of even a thin SnPc layer due to its strong absorption into the NIR, as shown by the  $\eta_{ext}$  spectra shown in Fig. 7.104. At a SnPc thickness of  $x = 0$  nm (corresponding to  $D_1A$ ), the absorption extends only to 750 nm. However, a peak emerges at 900 nm with the addition of SnPc, providing spectral coverage from 300 nm to 1000 nm for the ternary OPV.

The inset in Fig. 7.104 shows an illustration of the morphology achieved during growth. The SnPc forms

**Figure 7.104** External quantum efficiency spectra for CuPc (15 nm)/SnPc ( $x$  nm indicated)/ $\text{C}_{60}$  ternary OPVs grown by organic vapor phase deposition. Inset: Illustration of the junction showing the discontinuous SnPc (black) and CuPc (light blue) donor regions (Yang et al., 2008).

**Figure 7.105** Current density–voltage characteristics of OPVs grown by OVPD in the dark, and under 1 sun, AM1.5G simulated illumination. The active regions comprise CuPc (15 nm)/ $\text{C}_{60}$  (40 nm) and CuPc (15 nm)/SnPc (16 nm)/ $\text{C}_{60}$  (40 nm) for the binary and ternary cells, respectively. Inset: Energy level diagram of the ternary active region (Yang et al., 2008).

crystalline clusters that segregate into separate junctions with the  $\text{C}_{60}$ . Gaps between the islands allow for parallel, direct contact between the acceptor and the second donor, CuPc. The  $j$ - $V$  characteristics of this device are shown in Fig. 7.105 along with a binary CuPc/ $\text{C}_{60}$  OPV for comparison. The  $j_{SC}$  is increased by approximately 40% in the ternary compared to the binary cell due to the additional NIR absorption of the SnPc. Furthermore, the existence of a parallel conduction network is inferred since  $V_{OC} = 0.44$  V is the same

as that for the binary device. The  $V_{OC}$  of an analogous NPD/CuPc/ $C_{60}$  device was also 0.44 V, whereas  $V_{OC}$  of the NPD/ $C_{60}$  binary was 0.87 V. This suggests that the  $V_{OC}$  is “pinned” to the lowest voltage in the parallel network, although we have seen that this is not always the case. In the junction in Fig. 7.104, the HOMO energies of both SnPc and CuPc are similar, resulting in a similar  $\Delta E_{HL}$ , and hence  $V_{OC}$  should be independent of any a particular network model. The conclusion to be drawn is that in this device,  $V_{OC}$  is determined not by the junction energies, but rather is due to rapid charge recombination at the interface.

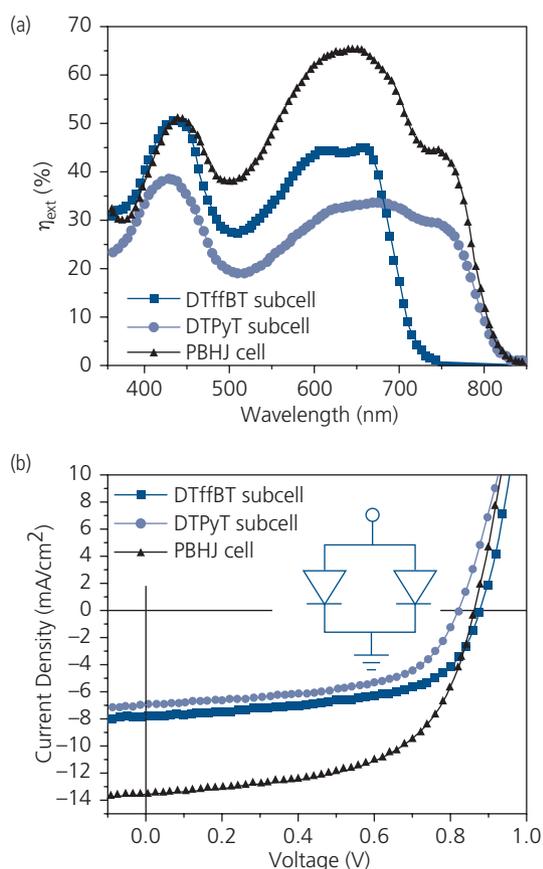

A solution-based system that shows parallel diode-like behavior consists of a blend of DTffBT ( $D_1$ ), DTPyT ( $D_2$ ), and PC<sub>61</sub>BM as the acceptor. The parallel BHJ (PBHJ) results are compared with those of separate diodes comprising only  $D_1A$  and  $D_2A$  “sub-cells” in Fig. 7.106. The absorption spectrum of the PBHJ OPV is the sum of the absorption from the

two constituent subcells. Likewise, the external quantum efficiency spectra in Fig. 7.106a are also a superposition of  $D_1A$  and  $D_2A$  at wavelengths where the spectra from both subcells overlap. At long wavelengths where only DTPyT absorbs, the efficiency is larger than for the DTPyT:PC<sub>61</sub>BM OPV. It is speculated that this is a result of reduced resistance of the hole current due to the presence of additional parallel conductive paths afforded by DTffBT in the ternary blend (Yang et al., 2012a). Increased charge collection due to improved conduction should also result in lower series resistance. Figure 7.106b does indeed show a higher slope in the forward biased characteristics compared with the individual subcell characteristics that support this hypothesis. Direct absorption into the CT state between the two donors (at energy  $\sim 1.6$  eV) may also contribute to the long wavelength quantum efficiency.

It is observed that the  $V_{OC} = 0.87$  V of the PBHJ is close to, but less than the  $V_{OC} = 0.89$  V of the larger energy gap donor, DTffBT ( $E_G = 1.7$  eV), while it is considerably larger than  $V_{OC} = 0.83$  V for the smaller band gap DTPyT ( $E_G = 1.5$  eV).

The alloy model in Fig. 7.101d qualitatively differs from the other models. It suggests the ternary blend forms a molecular alloy between the donors in a  $D_1D_2A$ , or the acceptors in  $DA_1A_2$  blend. In fact, molecular alloys have been proposed over several decades to describe electronic, optical and physical properties of mixtures that are not found in their individual molecular components (Bellows and Prasad, 1977, Engler et al., 1977, Rai and George, 1992, Sturz et al., 2004, Mogeritsch et al., 2009, Murata et al., 2010, Dou et al., 2019). Before one proposes the existence of such a material, however, the concept of an alloy must be clearly defined in the context of organic materials, and what makes such a substance distinct from a simple blend of multiple components commonly found in almost all organic photonic devices.

An alloy is a mixture of two atoms or compounds (most often metals such as brass or stainless steel, or compound semiconductors such as GaAlAs or InGaAsP) that share *chemical* bonds to form a new material whose electronic or physical properties differ from those of the pure substances of which it is comprised. Furthermore, once an alloy is formed, its thermal properties (e.g. the melting temperature of a eutectic) may change substantially from the pure solids of which it is comprised, making recovery of the initial components problematic. In contrast, the constituents in a blend of a small molecule donor and acceptor may be separated by raising the temperature

**Figure 7.106** (a) External quantum efficiency spectra, and (b) current density-voltage characteristics of a  $D_1D_2A$  parallel BHJ ternary OPV consisting of the donors DTffBT and DTPyT with PC<sub>61</sub>BM as acceptor. PBHJ is the parallel BHJ device. *Inset*: Parallel junction equivalent circuit (Yang et al., 2012a).

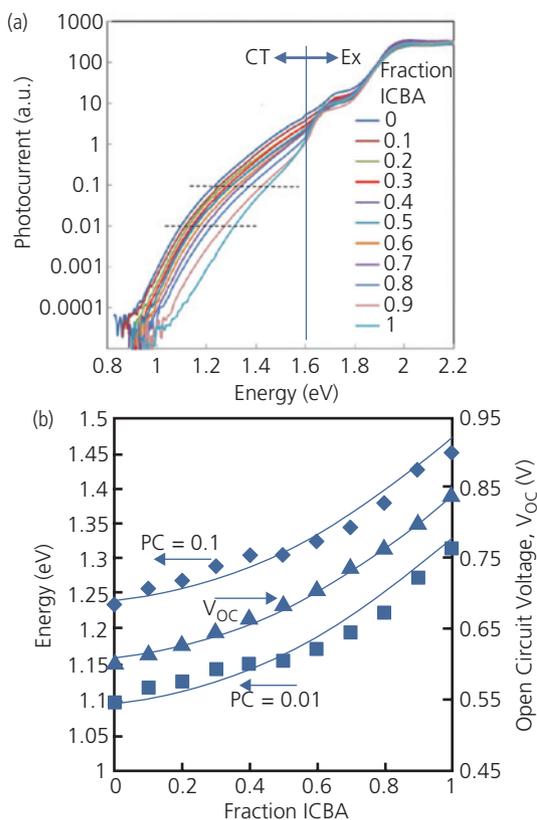

at or near the sublimation point of the lowest temperature constituent. However, a tightly bound charge transfer salt such as TTF:TCNQ may not be so easily separated once the compound solid is formed. Although the individual constituents in this case might not separate on heating, the spectrum of the complex is, nevertheless, only a superposition of the spectra of the cationic and anionic species in the solid.

But what about molecular blends in ternary cells, or even in doped emission layers of OLEDs? Again, one would expect that an alloy formed from a blend would possess emergent properties not found in any of the individual constituents. It is not a simple matter to envision how an alloy would emerge from a mixture of van der Waals bonded materials. Cross-linking between molecules, electronic orbital coordination via hydrogen bonding, etc. may result in the formation of a molecular alloy, or it may simply form a different molecule (e.g. bond linkage between molecules A and B results in a new compound C, corresponding to an oligomer or even a polymer, but not an alloy).

The formation of a molecular alloy for the DA<sub>1</sub>A<sub>2</sub> ternary BHJ comprising P3HT/ICBA/PC<sub>61</sub>BM blend has been proposed based on the photocurrent spectra of the CT and exciton states as functions of ICBA fraction in PC<sub>61</sub>BM shown in Fig. 7.107a (Street et al., 2013). The long wavelength CT photocurrent spectrum (which is proportional to the absorption spectrum) monotonically shifts to larger energies with ICBA fraction. Yet the exciton-induced photocurrent spectra between 1.6 eV and 1.8 eV are a simple linear superposition of the spectra of the two constituent acceptors. This indicates that the exciton energies are unperturbed from those of the individual molecules, even when those molecules are blended. It was argued that changes in the exciton spectrum of an alloy would be small due to their localized nature.

On the other hand, CT states extend across the D-A HJ, and hence are more strongly perturbed when combined into an alloy. The CT energies and  $V_{OC}$  for the P3HT/ICBA/PC<sub>61</sub>BM OPVs measured at two different relative values of photocurrent ( $PC = 0.01$  and  $0.1$ , indicated by the horizontal dashed lines in Fig. 7.107a) are plotted in Fig. 7.107b. The CT energy, which in the ideal case is equal to  $\Delta E_{HL}$ , increases with ICBA fraction. Since  $V_{OC}$  is also a linear function of  $\Delta E_{HL}$  (cf. Eq. 7.123), the open circuit voltage of the alloy,  $V_{OCA}$ , should follow Vegard's law:

$$V_{OCA} = (1-x)V_{OC1} + xV_{OC2} - bx(1-x), \quad (7.171)$$

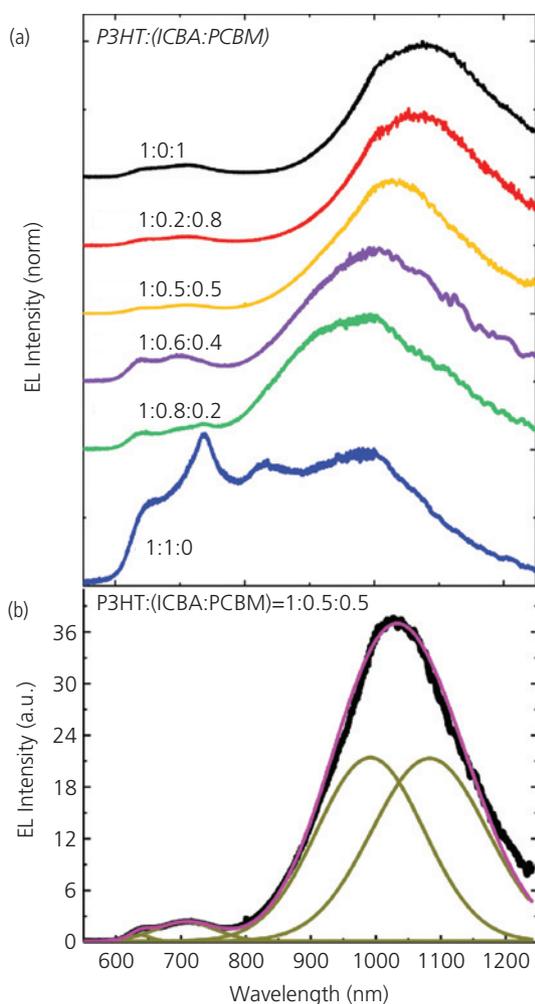

**Figure 7.107** (a) Photocurrent spectrum of the DA<sub>1</sub>A<sub>2</sub> ternary OPV as a function of fraction of A<sub>2</sub> = ICBA mixed with A<sub>1</sub> = PC<sub>61</sub>BM. The ranges of CT and exciton (Ex) response are indicated. (b) CT energy for two different photocurrents ( $PC = 0.01$  and  $0.1$ , corresponding to the dashed lines in (a)). Also shown is the open circuit voltage (Street et al., 2013).

where  $b = 0.18$  is the bowing parameter and  $x$  is the ratio of ICBA to PC<sub>61</sub>BM. The line is a fit to  $V_{OCA}$  and CT spectral peak positions vs.  $x$ , indicating that these two parameters have the same dependence on  $x$ . It is notable that the range spanned by the alloy voltage is  $V_{OC1} < V_{OCA} < V_{OC2}$ , which is similar to that of all the other ternary BHJs discussed, independent of the transport model invoked.

While the trends in Fig. 7.107 may imply the existence of an alloy, they fall short of providing conclusive evidence. Indeed, the nearly linear interpolation of  $V_{OCA}$  in Eq. 7.171 (albeit with a small amount of quadratic bowing) suggests that the photocurrent due to CT states is also a linear superposition of the two independent CT states for DA<sub>1</sub> and DA<sub>2</sub>, much like that found for the exciton spectra. Furthermore, the CT spectra are insufficiently distinct from the excitonic tails to accurately fit their energies. Hence, more convincing evidence should be provided by observation of the transient and photoluminescence spectra of the CT state whose features cannot be

explained by a linear superposition of independent CT states.

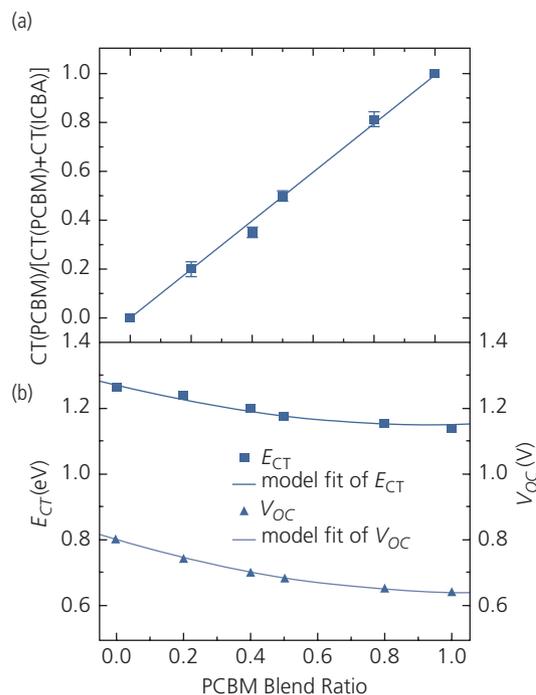

The most direct evidence for electronic interactions could come from the CT state electroluminescence spectra arising from forward current injection into the active regions of the two binary junctions compared to that of the ternary. These spectra are shown in Fig. 7.108a for the same P3HT:ICBA:PC<sub>61</sub>BM system for several different ICBA:PC<sub>61</sub>BM blend ratios. There is a monotonic shift of the EL peak from that of ICBA at 980 nm, to PC<sub>61</sub>BM at 1100 nm as the PC<sub>61</sub>BM fraction is increased from 0 to 1. The peaks at  $\lambda < 850$  nm are excitonic features from the three constituents. The peak positions of the CT spectra are easily resolved compared to the absorption data in

**Figure 7.108** (a) CT state EL intensity spectra for different P3HT:ICBA:PC<sub>61</sub>BM blend ratios. (b) Example fitting procedure to the various excitonic and CT features for the 1:0.5:0.5 blend. The lower (green) curves show the relative heights and widths of the constituent CT states, and the upper (red) curve fit to the data is their sum (Huang et al., 2019).

Fig. 7.107a. The EL features are fit to a series of Gaussians, where only the relative intensities of the two CT states were varied linearly with concentration, that is, all the peak widths and positions remain fixed in each of the blends. An example deconvolution of the spectrum of a P3HT:ICBA:PC<sub>61</sub>BM (1:0.5:0.5) blend into its separate component peaks is shown in Fig. 7.108b.

A plot of the ratio of ICBA to the combined CT peak intensities vs. PC<sub>61</sub>BM fraction is shown in Fig. 7.109a. All blends fit a linear function with a unity slope. This provides clear evidence that the CT feature is a simple linear superposition of the individual CT states of P3HT:ICBA and P3HT:PC<sub>61</sub>BM HJs. Indeed, this linear superposition of Gaussian peaks also accurately replicates the bowing observed in the CT state energy and  $V_{OC}$  of the ternary blends, as shown in Fig. 7.109b. Note that the CT radiative lifetime of 0.95 ns is the same for all the blends, as well as for the individual P3HT:ICBA and P3HT:PC<sub>61</sub>BM junctions. The HOMO energies of the blends were also unaffected by the blend ratio. Photoelectron spectroscopy measurements indicate that the HOMO energies of the blends are pinned to that of ICBA which is slightly higher than for PC<sub>61</sub>BM, thus forming a hole trap (Huang et al., 2019).

**Figure 7.109** (a) Ratio of the ICBA to the total integrated CT state intensity vs. PC<sub>61</sub>BM/ICBA ratio. (b) Charge transfer exciton peak energy and  $V_{OC}$  vs. PC<sub>61</sub>BM/ICBA ratio. Lines are fits to a linear superposition of the CT features in Fig. 7.108 (Huang et al., 2019).

From these data, no new, “alloy” state is found in this particular system. The question remains whether or not alloys are formed in other materials systems. More broadly, there remains little or no conclusive evidence for the existence of an alloy whose optoelectronic properties are not adequately described by a simple blend comprising multiple, independent constituent molecules.

Extensive reviews of device performance and materials used in DA<sub>1</sub>A<sub>2</sub> and D<sub>1</sub>D<sub>2</sub>A ternary BHJs can be found in the literature (Ameri et al., 2013, Fu et al., 2018). Here, we highlight three example high performance ternary OPVs.

A DA<sub>1</sub>A<sub>2</sub> cell comprising a combination of the donor, PBDB-T with the acceptors IT-M, (A<sub>1</sub>) and the bis-adduct of PC<sub>71</sub>BM (A<sub>2</sub>) in the ratio of PBDB-T:IT-M:bis-PC<sub>71</sub>BM (1:1:0.2) is shown in Fig. 7.110. The blend was annealed for 10 min at 100°C prior to the deposition of the PFN-Br exciton blocking layer. A summary of the performances of the ternary as well as the separate binary D-A combination BHJ OPVs is provided in Table 7.10. The ternary device achieves both a higher *FF* and *j*<sub>SC</sub> than either binary device, leading to a maximum power conversion efficiency of 12.2%, compared to 10.8% for the DA<sub>1</sub> and 6.25% for the DA<sub>2</sub> OPVs. Consistent with previous discussions, the open circuit voltage of the ternary device is 0.952 V, lying between *V*<sub>OC1</sub> = 0.937 V and *V*<sub>OC2</sub> = 1.02 V. The higher *FF* suggests improved electron conductivity in the network comprising two acceptors, and hence reduced series resistance. This is supported by the energy level diagram of the materials in Fig. 7.110 where the optical LUMO energies of bis-PC<sub>71</sub>BM and IT-M are nearly aligned to promote barrier-free electron transport to the cathode, consistent with the parallel dissociation model of Fig. 7.101c. The reduced open circuit voltage of the ternary compared to DA<sub>2</sub> is compensated by the increased *FF* and *j*<sub>SC</sub>.

An example D<sub>1</sub>D<sub>2</sub>A OPV comprises the spirobi-fluorene (SF) symmetrically disposed between two 1,3-benzothiazole (BT) units capped with (3-ethylhexyl-4-oxothiazolidine-2-yl)dimalononitrile (RCN) in the acceptor, SFBRCN, combined with the donors PTB7-Th (D<sub>1</sub>) and PBDB-T (D<sub>2</sub>) (see Fig. 7.111). One of the donors (PBDB-T) also serves as the donor in the DA<sub>1</sub>A<sub>2</sub> device in Fig. 7.110. Similar to the device in Fig. 7.92, donors and acceptors can be interchanged since their function is determined by their energy levels relative to the other materials employed in the HJ. The performance of the device along with its separately characterized D and A components are summarized in Table 7.11.

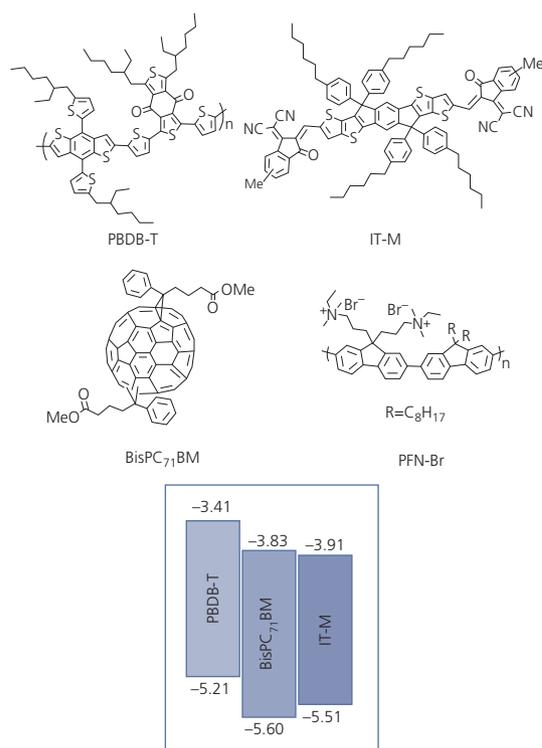

An alternative to the blended and layered multi-junction active region is an amalgamation of the two, whereby two independently fabricated D-A junctions are placed in a series stack. After, attachment, their interface is blended to avoid the use of a CRZ that is otherwise required to interconnect subcells in a tandem architecture. In Fig. 7.112 we show the complementary absorption of the two different HJ OPVs comprising PTB7-Th:PC<sub>71</sub>BM (BHJ1) and PDPP3T:PC<sub>71</sub>BM (BHJ2) employed in the stacked “bi-ternary”

**Table 7.10** Performance characteristics of a ternary DA<sub>1</sub>A<sub>2</sub> OPV and its binary components (Zhao et al., 2017b)

OPV (Huang et al., 2017). The marginal overlap of the absorption spectra between 700–800 nm makes this a nearly ideal combination for efficient coverage of the solar spectrum up to a wavelength of 900 nm.

The two BHJs are combined by physical bonding through the process illustrated in Fig. 7.113. Each active layer is cast from solution onto separate substrates. The 200 nm thick BHJ1 is deposited onto a  $\text{ZnO}_x$  buffer on the surface of the ITO anode from a solution containing 1,8-diiodooctane. The second substrate comprises the 50 nm thick PDPP3T:PC<sub>71</sub>BM BHJ2 active region using a polyurethane-coated polycarbonate (PUA/PC) substrate. When the two BHJs are brought into contact and pressure is applied to the PUA/PC stamp at 75°C for 2 min, the active regions bond. The stamp is peeled away, and methanol is used to remove residual solvent in BHJ1. The device is completed by vacuum deposition of the cathode.

*Time of flight secondary ion mass spectroscopy (TOF-SIMS)* was used to determine the degree of intermixing of the two BHJs at the interface. In TOF-SIMS, the film is slowly removed by sputtering while tracking the relative F, N, and Zn mass spectral intensities to obtain a depth profile of the relative concentrations of PTB7-Th, PDPP3T, and  $\text{ZnO}_x$ , respectively. The spectra in Fig. 7.114a show a 25 nm thick intermixed zone (corresponding to a sputtering time of 100 s). Immediately following contact, the BHJs form a sharp interface (upper left, Fig. 7.114b). Soaking the structure in methanol results in dissolution of the as-deposited layers, forcing some intermixing of the two donor polymers at the junction. When the methanol is removed by

drying, it leaves a continuous, hole conducting path along the blended polymer interface. Due to the nearly spherical symmetry of PC<sub>71</sub>BM, the acceptor regions interconnect by close molecular packing that forms PC<sub>71</sub>BM nanocrystals (Huang et al., 2017). A similar vacuum deposited architecture has also been reported (Li et al., 2019).

The characteristics of the bi-ternary (BHJ1/2) device and its constituent BHJ1 and BHJ2 subcells are provided in Table 7.12. As in the other multilayer cascade and ternary architectures,  $V_{OC}$  of the three-component cell is between the limits set by BHJ1 and BHJ2.

In this section, we have seen that there are several ways to combine three or more molecular constituents into an OPV to increase coverage of the solar spectrum. These active region architectures can either consist of a series of layers, or can form a blend in a ternary (or perhaps higher order) BHJ. Several models have been advanced to describe the photogeneration process in ternary blend cells. The distinction between

these models is sometimes unclear, since multiple processes may be active in such complex blends. Nevertheless, a common feature of the blended junctions is that their open circuit voltages lie within the range bounded by the of the constituent junctions, although the short circuit current can be significantly greater due to the improved coverage of the solar spectrum by three or more constituents vs. conventional binary OPVs.

While the requirements placed on the materials used in such devices are stringent (e.g. alignment of HOMO and/or LUMO levels, overlap of emission and absorption spectra for efficient energy transfer, etc.), the increased efficiency combined with the relative simplicity of the structures has resulted in considerable interest in on both cascade and ternary blend OPVs.

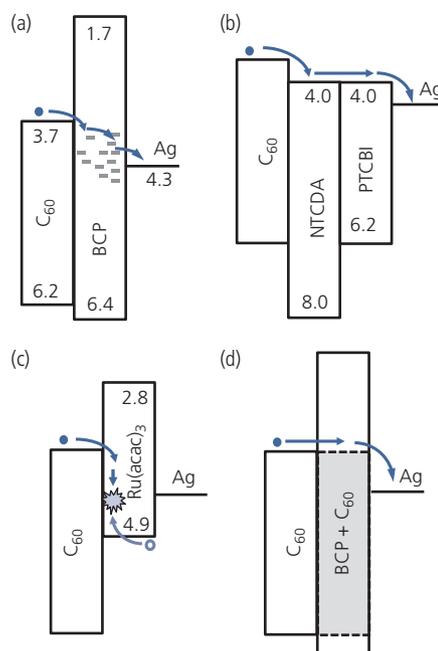

#### 7.4.1.3 Exciton blocking layers

A significant improvement in cell performance was realized by introduction of the *exciton blocking layer* (EBL), also known as the *cathode buffer layer*, interposed between the active region and the cathode (Peumans et al., 2000a, Peumans and Forrest, 2001). The electron-conducting, transparent EBL serves multiple purposes:

- (i) The layer prevents excitons generated in the acceptor layer from migrating to the cathode contact where they are quenched without generating photocurrent. This is particularly important for bilayer and planar-mixed HJ active regions where the exciton diffusion length can exceed that of the layer thickness.
- (ii) The optical field has a node at the metal cathode surface. The wide energy gap EBL, therefore, provides a transparent spacer whose thickness is adjusted to locate the active layers at a distance  $\sim \lambda/4n$  from the cathode. At this position, the optical intensity is maximized, thus maximizing  $\eta_{ext}$ .
- (iii) The layer serves as a buffer between the cathode and acceptor, preventing damage to the active region induced during metal deposition, thus eliminating potential exciton quenching sites or electrical shorts across the junction.

The EBL in an OPV was inspired by, and serves several of the same functions as the hole blocking/exciton blocking layer in OLEDs. In the latter structure, the HBL/EBL prevents triplet exciton quenching at the cathode, as well as providing an optical spacer to minimize optical microcavity effects (Baldo et al., 1998, Baldo et al., 1999).

Since the initial demonstration of a so-called double heterostructure OPV employing a BCP EBL (Peumans

**Figure 7.115** Different exciton blocking layer schemes and the mechanisms for extracting electrons for the example of a  $C_{60}$  acceptor layer. (a) Trap assisted electron transport, (b) transport along the EBL LUMO, (c) e-h recombination at the acceptor interface, and (d) electron filtering along percolating conducting paths in a doped, wide energy gap layer.

et al., 2000a), several other blocking layer concepts shown in Fig. 7.115 have been demonstrated. The illustrations assume a  $C_{60}$  acceptor layer for energy reference, although these configurations are adaptable to all acceptors with the proper choice of blocking layer materials. Each design relies on a large energy gap EBL to ensure its transparency and to avoid exciton transfer from the acceptor. The differences between EBLs are the mechanisms for electron transport. Figure 7.115a shows the wide energy gap BCP that conducts photogenerated electrons from the acceptor via a high density of defect states introduced during cathode deposition (Peumans and Forrest, 2001). Since the defects penetrate only  $\sim 10$  nm into the BCP, the thickness of the buffer may be too small to ensure an optical intensity maximum at the D-A HJ. Nevertheless, EBLs employing defect conduction in wide energy gap buffers are still the most frequently employed in OPVs due to its simplicity.

Figure 7.115b employs a pair of acceptor-like materials whose LUMO energies align with that of the acceptor. The specific bilayer shown is comprised of the wide energy gap NTCDA adjacent to a second electron conducting layer of PTCBI. The PTCBI makes ohmic contact to Ag but absorbs in the red. To

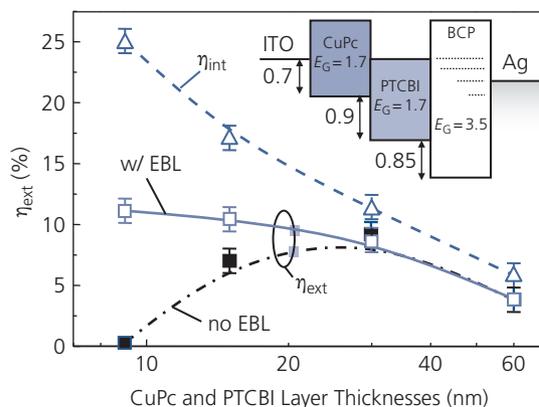

minimize optical losses, the PTCBI layer is kept thin, whereas the wider energy gap NTCDA is used as the transparent optical spacer. The LUMO energy alignments result in low resistance electron conduction to the cathode (Lassiter et al., 2011).

An alternative to employing electron transport is to use a wide energy gap EBL with a small ionization potential, as shown in Fig. 7.115c. Electrons generated in the acceptor recombine at the EBL/acceptor interface with holes conducted via the HOMO level of the EBL. In the figure, we show the mechanism of hole conduction in a Ru(acac)<sub>3</sub> EBL from the cathode to C<sub>60</sub> (Rand et al., 2005a).

Figure 7.115d shows what is perhaps the most effective means for satisfying all of the criteria of a high performance EBL. This so-called electron-filtering exciton blocking layer, comprises a mixture of C<sub>60</sub> in a wide energy gap matrix (Bartynski et al., 2013, Xiao et al., 2014). The spherical symmetry of the C<sub>60</sub> molecules allows them pack into continuous percolating electron conduction paths that completely penetrate the transparent exciton-blocking matrix in which they are blended. The LUMO energy of C<sub>60</sub> aligns with that of the C<sub>60</sub> (or C<sub>70</sub>) acceptor, providing an energy-barrier-free electron conducting path to the cathode. And while C<sub>60</sub> absorbs in the visible, the absorption is due to a charge transfer transition that is largely eliminated at the low concentrations required for conduction. Hence, this composite is both electrically conducting and optically transparent.

We now provide further detail of the conduction mechanisms and optical properties of these four EBL architectures, and the OPV performance enhancements that result from their use.

The defect-based EBL in Fig. 7.115a was first included in a conventional CuPc/PTCBI cell where the 10 nm thick BCP blocking layer was positioned between the Ag cathode and the perylene-based acceptor (inset, Fig. 7.116). The 10 nm thickness is approximately equal to the penetration depth of damage from the cathode deposition; larger thicknesses result in a high cell series resistance due to the lack of conducting paths for electrons extending from acceptor to cathode. A device with 30 nm CuPc lacking an EBL has a peak external efficiency of ~8% at  $\lambda = 540$  nm for a 30 nm PTCBI thick layer (dashed-dotted line, closed squares, Fig. 7.116). The external efficiency drops dramatically for thinner PTCBI layers due to exciton quenching at the cathode, as well as a vanishing optical field within the thin active region placed in such close proximity to the metal contact. For the double heterostructure comprising the EBL,  $\eta_{ext}$  continues to increase with

**Figure 7.116** Quantum efficiency vs. active layer thicknesses for a CuPc donor/PTCBI acceptor double heterostructure OPV employing a 10 nm thick BCP EBL. The closed and open squares are the external efficiencies for devices with a 30 nm thick CuPc, and varying PTCBI thickness. The open triangles are calculated for devices with equal donor and acceptor layer thicknesses. Inset: Energy level diagram for the OPVs. All numbers are in eV. Dashed lines in the BCP represent defect levels that permit electron conduction. After Peumans et al. (2000a).

decreasing PTCBI thickness until it reaches a maximum of  $\eta_{ext} = 11\%$  at approximately 10 nm, due to a higher optical field in the active region and reduced exciton quenching at the cathode.

The device efficiency improves even as the PTCBI thickness is reduced, which in turn reduces the cell series resistance. Hence, devices operated at illumination intensities as high as 6 suns (6 kW/m<sup>2</sup>) without a reduction in efficiency.

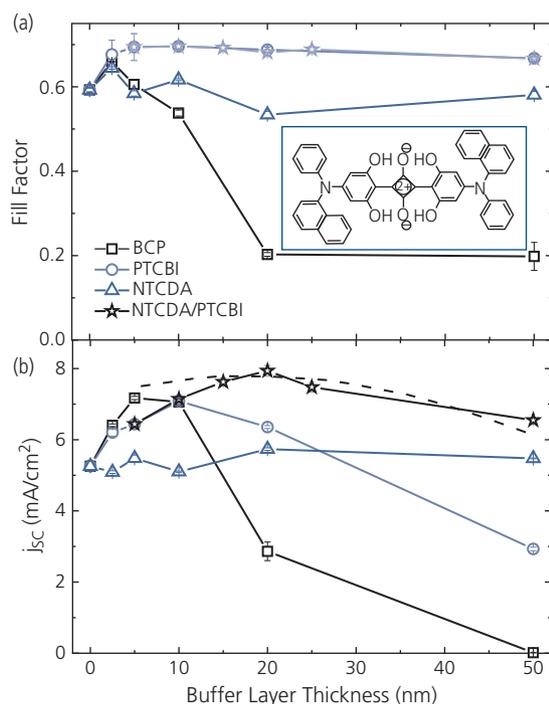

The fullerene C<sub>60</sub> was first introduced in an OPV that employed a 12 nm thick BCP EBL. The large exciton diffusion length of C<sub>60</sub> (~8–10 nm) compared to PTCBI (3 nm) necessitates the use of the blocking layer to prevent exciton quenching at the cathode. The optimized double heterostructure comprised ITO/PEDOT:PSS/20 nm CuPc/40 nm C<sub>60</sub>/12 nm BCP/Ag, achieving  $\eta_p = 3.6\%$  at 1 sun, AM1.5G simulated illumination (Peumans and Forrest, 2001). Contrary to PTCBI-based devices,  $\eta_p$  peaks at 1 sun intensity, and falls off at both higher and lower solar fluence. Due to its higher efficiency, the C<sub>60</sub> cell delivers at least three times the current as the PTCBI-based cell. Hence, the former suffers loss at high intensity due to the cell series resistance. Resistance also leads to a roll-off in *FF*, from a peak of approximately 0.54 at 1 sun, to 0.32 at 10 suns.

Damage-induced defect conduction constrains the thickness of the wide energy gap matrix to the penetration depth of the damage caused by deposition of the metal cathode. The penetration depth is dependent on both the materials and the deposition

processes, but typically the layer thickness can be no greater than 10 nm if high resistance to electron conduction is to be avoided.

Doping the wide energy gap material with a second constituent (e.g. PTCBI) stabilizes its morphology while increasing its conductivity (Peumans et al., 2000a). Alternatively, doping the layer with metal by co-evaporation can also provide a high conductivity even for thick layers. It has been found, for example, that BCP co-evaporated with 20% Yb leads to EBLs as thick as 40 nm without a noticeable loss in  $FF$  and  $j_{SC}$  in CuPc/C<sub>60</sub> OPVs. It is unclear, however, whether the metal doping creates conductive percolating paths, or that it simply extends the depth of damage that ordinarily stops near the surface when induced during cathode deposition. Furthermore, the presence of metal atoms can increase absorption by the EBL, although this was not a particularly significant effect for the Yb:BCP layer (Chan et al., 2006).

The buffer in Fig. 7.115b employs materials whose electron conduction levels align with that of the acceptor. Figure 7.117 compares the performances of several different buffer layer configurations used in conjunction with a 15 nm 1-NPSQ/40 nm C<sub>60</sub> planar

**Figure 7.117** (a) Fill factor and (b) short circuit current density vs. buffer layer thickness for 1-NPSQ/C<sub>60</sub> OPVs. The buffer layers used are indicated in the legends. The dashed line is  $j_{SC}$  calculated for the NTCDA/PTCBI buffer due to the optical field intensity in the active region. Inset in (a): Molecular formula of 1-NPSQ (Lassiter et al., 2011).

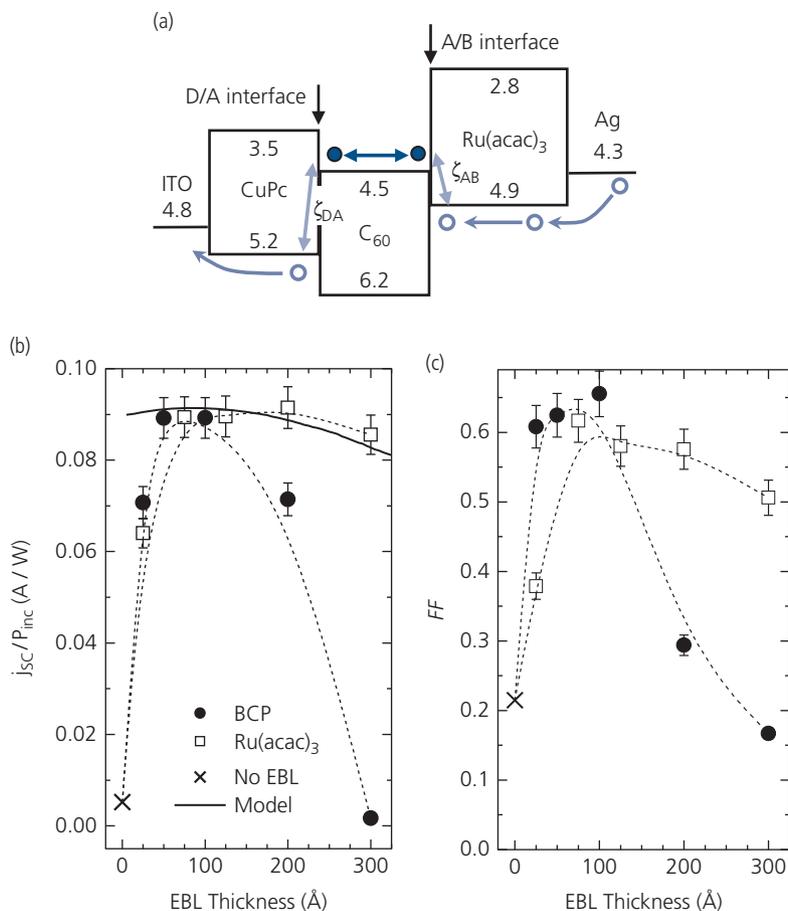

junction. The buffer layer consists of neat BCP, PTCBI or NTCDA, or 15 nm NTCDA/5 nm PTCBI. PTCBI has a low electron injection barrier with Ag, although it absorbs in the red. Furthermore, PTCBI is a robust molecule that is resistant to damage due to cathode deposition, which is not the case for either the wide energy gap (4.0 eV), and therefore transparent NTCDA or BCP. Hence, the combination of a thin PTCBI layer used to absorb damage and to present a low energy barrier to electron injection, and a wide gap NTCDA layer that acts as an optical spacer results in an efficient EBL structure.

In Fig. 7.117a, we see that  $FF$  is maximized between 0.60 and 0.70 for the several buffers tested. As expected,  $FF$  for BCP rapidly decreases at thicknesses greater than 5–10 nm, whereas the other buffers show no such decrease up to 50 nm. However, the  $FF$  of the NTCDA buffer ( $FF = 0.60$ ) does not achieve the high values of either the neat PTCBI buffer ( $FF = 0.70$ ), or the compound NTCDA/PTCBI EBL ( $FF = 0.68$ ).

The highest  $j_{SC}$  (Fig. 7.117b) is achieved for the compound buffer due to its combination of low energy barrier to electron injection, and transparency. The  $j_{SC}$  of the neat PTCBI buffer device decreases with thickness due to its absorption in the red and yellow, and the neat NTCDA layer never reaches the high  $j_{SC}$  of the compound buffer due to the barrier formed with Ag. The dashed line is a calculation of  $j_{SC}$  for the NTCDA/PTCBI buffer that indicates an optimum optical spacer thickness of  $\sim 20$  nm, which is consistent with measurement (Lassiter et al., 2011).

The coupling between layer thickness and conductivity can also be reduced by employing an EBL with a shallow HOMO energy that approximately aligns with the LUMO of the acceptor. This results in so-called reciprocal carrier collection, illustrated in Fig. 7.115c, whereby holes are transported from the cathode to the acceptor/blocking layer (A/B) interface where they recombine with photogenerated electrons. The process was originally demonstrated using a Ru(acac)<sub>3</sub> buffer, which has a  $d^5$  open shell that permits hole transport. The OPV structure: ITO/CuPc (20 nm)/C<sub>60</sub> (40 nm)/Ru(acac)<sub>3</sub> (20 nm)/Ag is shown in Fig. 7.118a.

Comparisons of device performance using the Ru(acac)<sub>3</sub> buffer with that of a device with no EBL, and one using BCP, are shown in Fig. 7.118b and c. The responsivity ( $j_{SC}/P_{inc}$ ) at 1 sun, AM1.5G simulated illumination shows that the thickness dependence of the BCP-based device is eliminated using the Ru(acac)<sub>3</sub> buffer. On the other hand, removing the buffer entirely results in a significant decrease in response. The responsivity of the OPV with the

**Figure 7.118** (a) Energy level diagram of an OPV with a charge reciprocating EBL. Electrons are filled circles, holes are open circles. (b) Solar responsivity and (c) fill factor vs. EBL thickness, comparing device performance for various EBL structures. The solid line in (b) is a fit a model that includes the optical field and exciton diffusion length in the active region. Dashed lines are guides to the eye (Rand et al., 2005a).

$\text{Ru}(\text{acac})_3$  buffer follows the optical absorption/diffusion model (solid line, Fig. 7.118b) of Section 7.1.2. The loss in response with thickness of the device employing BCP is due to its high series resistance, which is supported by a similar sharp drop in  $FF$ , which is absent for the  $\text{Ru}(\text{acac})_3$  buffer (see Fig. 7.118c) (Rand et al., 2005a).

The reciprocal OPV structure has two energy barriers: one at the D/A interface for exciton dissociation, and the second at the acceptor/EBL junction. Hence, the charge density within the acceptor depends on the relative magnitudes of the dissociation rate of PPs at the D/A junction, and the recombination rate at the acceptor/buffer (A/B) junction. Figure 7.100 illustrates that two opposing junctions can be approximately modeled by two, back-to-back rectifiers. This generates in an “S” shaped  $j$ - $V$  characteristic that produces a dramatic loss in efficiency, especially at high illumination intensities where electrons pile up within the acceptor and ultimately

recombine without being collected. The response of the device in Fig. 7.118 thus depends on the magnitude of the A/B HOMO–LUMO offset energy,  $\Delta E_{HL, AB}$ . As this energy increases, the recombination rate also increases, leading to lower efficiency at high intensity.

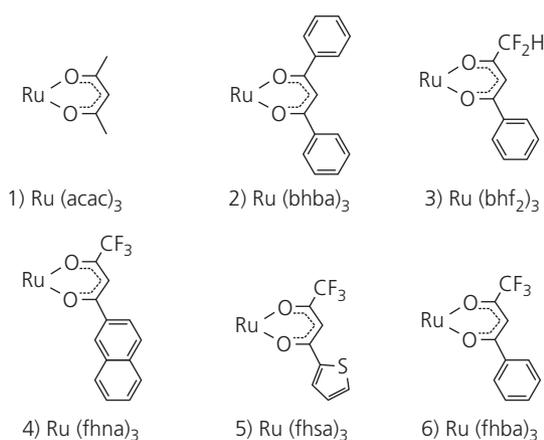

A quantitative analysis can be used as a guide for choosing materials for a reciprocating EBL. The device is a combination of two PP recombination sites at the D/A and A/B interfaces that are coupled by current continuity, that is,  $j_{DA} = j_{AB}$ , and voltage  $V_a = V_{DA} + V_{AB}$ . Then it can be shown that the current for a symmetric D/A junction is (Renshaw et al., 2011)

$$j = \frac{[j_{0S,DA}(\exp(qV_a/n_S k_B T) - k_{PPd,DA}/k_{PPd,eq,DA}) - q\eta_{PPd}j_X]}{[1 + (j_{0S,DA}/j_{0S,AB})\exp(qV_a/n_S k_B T)]} \quad (7.172)$$

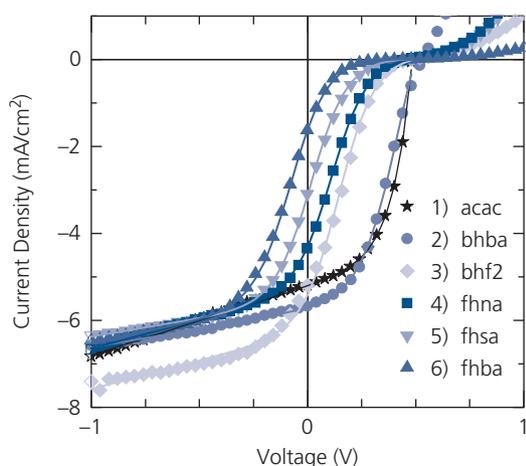

Series and shunt resistances are ignored for simplicity. Also, the subscripts identify the variable associated with either the D/A or A/B junction.

Reciprocal charge collection at the A/B interfaces of ITO/CuPc (40 nm)/C<sub>60</sub> (40 nm)/RuL<sub>3</sub> (20 nm)/Ag OPVs has been studied to determine the dependence of the  $j$ - $V$  characteristics on  $\Delta E_{HL,AB}$ . The family of RuL<sub>3</sub> compounds is shown in Fig. 7.119. In these molecules, L is the ligand in the tridentate complex.

The  $j$ - $V$  characteristics of the RuL<sub>3</sub> buffers OPVs under 1 sun, AM1.5G simulated illumination are provided in the linear and semi-log plots in Figs. 7.120a and b, respectively. With the exception of Ru(acac)<sub>3</sub>,

**Figure 7.119** Molecular structural formulae of RuL<sub>3</sub> complexes used for EBLs in CuPc/C<sub>60</sub> OPVs (Renshaw et al., 2011).

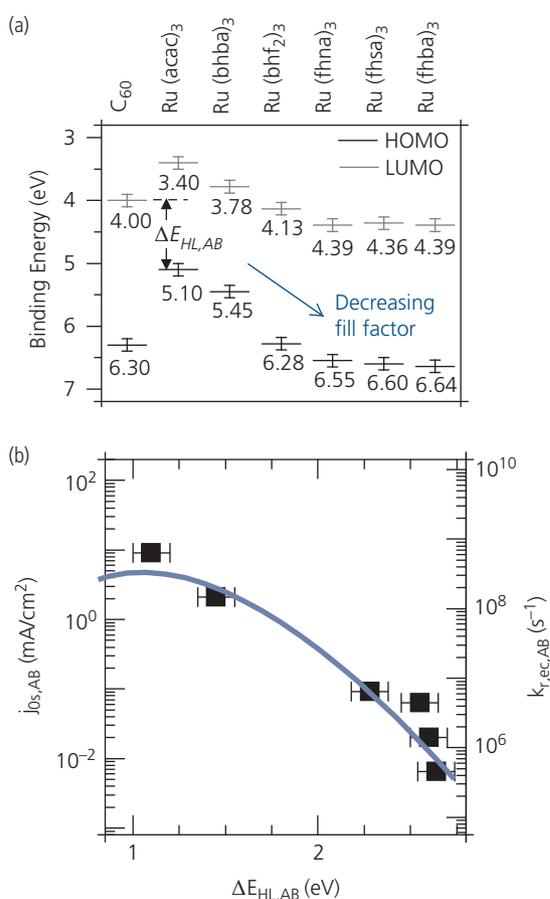

**Figure 7.120** The  $j$ - $V$  characteristics of CuPc/C<sub>60</sub> OPVs using the RuL<sub>3</sub> compounds in Fig. 7.119 as EBLs. The lines are fits to the data (points) using Eq. 7.172 (Renshaw et al., 2011).

Reprinted figure with permission from Renshaw, C. K., Schlenker, C. W., Thompson, M. E. & Forrest, S. R., *Physical Review B*, 84, 045315, 2011. Copyright 2011 by the American Physical Society.

to a greater or lesser extent, all of the characteristics have an “S” shape whereby the current increase falls sharply away from exponential near  $V_{OC}$ . It is presumed that the  $j$ - $V$  characteristics of Ru(acac)<sub>3</sub> also undergo an inflection, but at voltages higher than shown in the figure. The lines in Fig. 7.120 are fits to the data using Eq. 7.172, from which we find that  $j_{0s,AB}$  increases by more than three orders of magnitude, from 6.4  $\mu\text{A}/\text{cm}^2$  for Ru(fhba)<sub>3</sub> to  $\geq 10 \text{ mA}/\text{cm}^2$  for Ru(acac)<sub>3</sub>.

These results can be understood from the energetics of the A/B junction. The frontier orbital energies of C<sub>60</sub> and the various RuL<sub>3</sub> compounds are shown in Fig. 7.121a. The offset energy at the C<sub>60</sub>/RuL<sub>3</sub> A/B interface increases from 1.1 eV for Ru(acac)<sub>3</sub>, to a maximum of 2.64 eV for Ru(fhba)<sub>3</sub>. These

**Figure 7.121** (a) Frontier orbital energies of C<sub>60</sub> and the RuL<sub>3</sub> compounds in Fig. 7.119. The HOMO energies are obtained from ultraviolet photoelectron spectroscopy, and the LUMO energies are the HOMO plus the optical energy gap of the compounds.  $\Delta E_{HL,AB}$  for C<sub>60</sub>/Ru(acac)<sub>3</sub> is shown by example. (b) Saturation current for the A/B junction obtained from the fits to the  $j$ - $V$  data in Fig. 7.120, vs.  $\Delta E_{HL,AB}$  obtained from (a). The right axis is the electron-hole recombination rate at the A/B interface (Renshaw et al., 2011).

energies are then used along with fits to the  $j$ - $V$  characteristics to obtain the saturation current of the A/B junction vs. HOMO-LUMO offset energy in Fig. 7.121b. The  $j_{0s,AB}$  for Ru(acac)<sub>3</sub> is a lower limit due to a lack of deviation from exponential current for this complex.

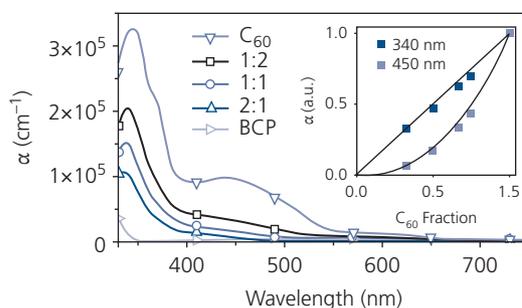

Equation 7.56 shows that  $j_{s0,AB} \propto k_{rec,AB}$ . The recombination rates can thus be calculated from the saturation currents for the various complexes, with results shown on the right axis of Fig. 7.121b. The correspondence between  $k_{rec,AB}$  (and thus  $j_{s0,AB}$ ) and offset energy is described by Marcus theory (cf. Eq. 4.91):

$$k_{rec,AB} = k_{rec0,AB} \exp\left(-(\lambda_{reorg} - \Delta E_{HL,AB})^2 / 4\lambda_{reorg} k_B T\right), \quad (7.173)$$

where  $\lambda_{reorg}$  is the molecular reorganization energy. Reciprocal charge recombination at the acceptor/EBL interface occurs in the inversion regime, in which case  $\Delta E_{HL,AB} > \lambda_{reorg}$ . A fit to the recombination rates is shown in Fig. 7.121b (solid line), using  $\lambda_{reorg} = 0.6$  eV, and  $k_{rec0,AB}$  is chosen for the best correspondence with the data (Closs et al., 1986). The fit shows a slope reversal at  $\Delta E_{HL,AB} \approx 1$  eV as the rate enters the normal Marcus transfer region.

The implication of this analysis is that the energy offset at the A/B interface must be minimized for the EBL to prevent charge pile-up at high illumination intensities. Of the compounds tested, only Ru(acac)<sub>3</sub> with  $\Delta E_{HL,AB} \approx 1.1$  eV is suitable for this purpose. Nevertheless, the benefit of using hole conducting EBLs is their ability to simultaneously achieve high conductivity and high transparency over a large range of thicknesses.

Electron-filtering EBLs (Fig. 7.115d) offer a particularly effective means for achieving the combination of high electron conductivity and transparency. While it was first employed in fullerene-based cells, it can also be applied to OPVs with NFAs since it only relies on the approximate alignment of the LUMO of C<sub>60</sub> to that of the acceptor material (Bartynski et al., 2013, Bergemann et al., 2015). The EBL employs C<sub>60</sub> as a dopant in a wide energy gap matrix. Its spherical symmetry allows it to closely pack, forming extended, high conductivity percolating paths for electrons between the acceptor and cathode when doped even at low concentrations within BCP. Furthermore, the absorption feature of C<sub>60</sub> centered at a wavelength of 450 nm results from a CT state between molecules. As we have shown in Section 3.6.6, the CT state absorption decreases approximately quadratically with dilution. Hence, as the C<sub>60</sub> concentration is reduced, the EBL becomes increasingly transparent, resulting in a buffer

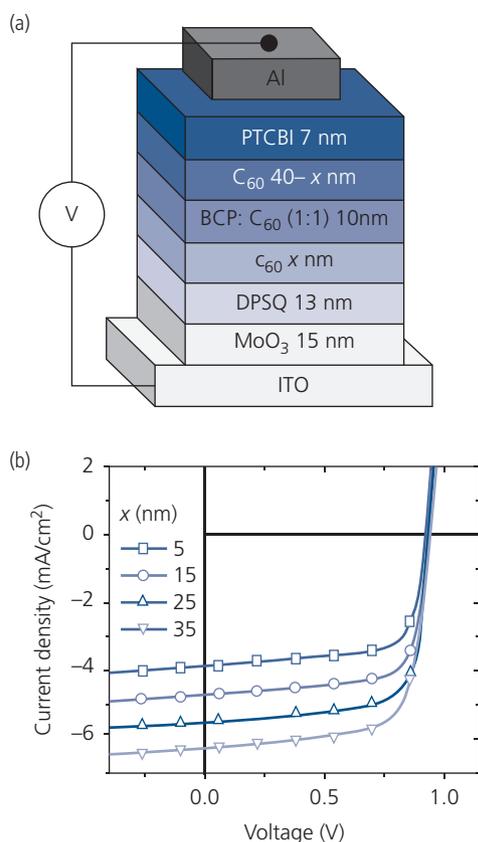

**Figure 7.122** Absorption coefficient of films of BCP mixed with C<sub>60</sub> at the different volume fractions. Inset: The dependence of the absorption coefficient on C<sub>60</sub> fraction at two different wavelengths corresponding to singlet absorption at 340 nm and CT state absorption at 450 nm (Bartynski et al., 2013).

that has the desired combination of high transparency and conductivity over a large range of doped layer thicknesses.

The absorption spectra as functions of C<sub>60</sub> fraction when co-deposited in vacuum with BCP are shown in Fig. 7.122. The CT peak at 450 nm is found to decrease more rapidly than the singlet absorption peak at shorter wavelengths. The dependence of these two absorption features on C<sub>60</sub> volume fraction,  $y$ , is plotted in the inset. The peak at 340 nm decreases linearly with C<sub>60</sub> fraction as expected for an excitation that is confined to a single molecule. However, the long wavelength feature increases as  $y^{2.7}$ , affirming its multi-molecular origin. These data suggest, therefore, that as long as  $y$  is sufficiently small, the EBL absorption is also low. The question remains whether the conductivity at small  $y$  is adequate to support charge conduction at high illumination intensities.

This question is addressed using the device in Fig. 7.123a where a 10 nm thick BCP: C<sub>60</sub> 1:1 blocking layer is sandwiched between two neat C<sub>60</sub> layers, one of thickness  $(40 - x)$  nm adjacent to a PTCBI EBL, and the other of thickness,  $x$ , forming a D-A junction with the donor, DPSQ (Wang et al., 2011). The corresponding  $j$ - $V$  characteristics are shown in Fig. 7.123b. We observe that  $j_{sc}$  increases linearly with  $x$ , as expected for an increasing acceptor layer thickness (for  $x < L_D \sim 40$  nm for C<sub>60</sub>) at the D-A junction. These data also suggest that excitons generated in the C<sub>60</sub> layer adjacent to the cathode do not contribute to the photocurrent, since they lack a D-A junction and are blocked by the intervening BCP:C<sub>60</sub> (1:1) layer. Further,  $FF = 0.72$  for all the devices, independent of  $x$ . Thus, electrons generated at the D-A junction are easily transported to the cathode through the BCP:C<sub>60</sub> layer.

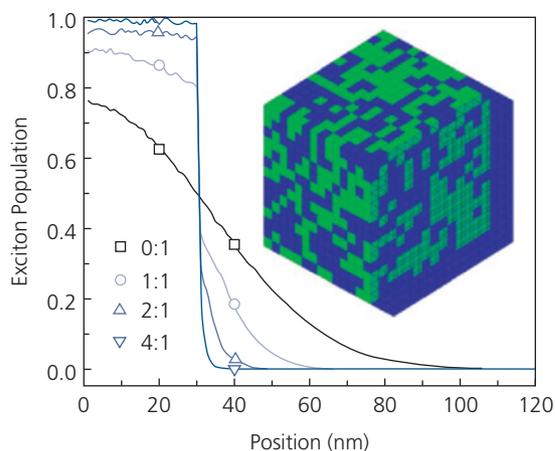

The electron filtering and exciton blocking properties of BCP:C<sub>60</sub> ( $z:y$ ) buffer were analyzed using a

**Figure 7.123** (a) Device used to study the electron conducting and exciton blocking characteristics of a BCP: $C_{60}$  (1:1) EBL. (b) The  $j$ - $V$  characteristics of the device in (a) for varying  $C_{60}$  acceptor layer thicknesses (Bartynski et al., 2013).

combination of simulation and experiment. Monte Carlo simulations of the EBLs are shown in Fig. 7.124. The simulations assume a random distribution of available ( $C_{60}$ ) and unavailable (BCP) sites for exciton transport. The excitons move via hopping on a cubic lattice to nearest-neighbor sites in a random walk. Any exciton that attempts to move onto a BCP site remains stationary for that step. The BCP: $C_{60}$  interface reflects excitons back into the acceptor if no available site exists in the blocking layer. The plot shows that a neat  $C_{60}$  EBL ( $z = 0, y = 1$ ) has no blocking capability, with 50% of the excitons entering the EBL from the acceptor. However, as the BCP fraction increases, the layer becomes increasingly effective at preventing excitons from entering the EBL. The blocking efficiency (i.e. the ratio of excitons reflected back into the acceptor to those entering into the EBL) increases from 81% at  $z/y = 1$ , to 98% at  $z/y = 4$ .

The electron transport properties were also examined by measuring the layer resistivity as a function of  $C_{60}$  concentration in the EBL. The resistivity only

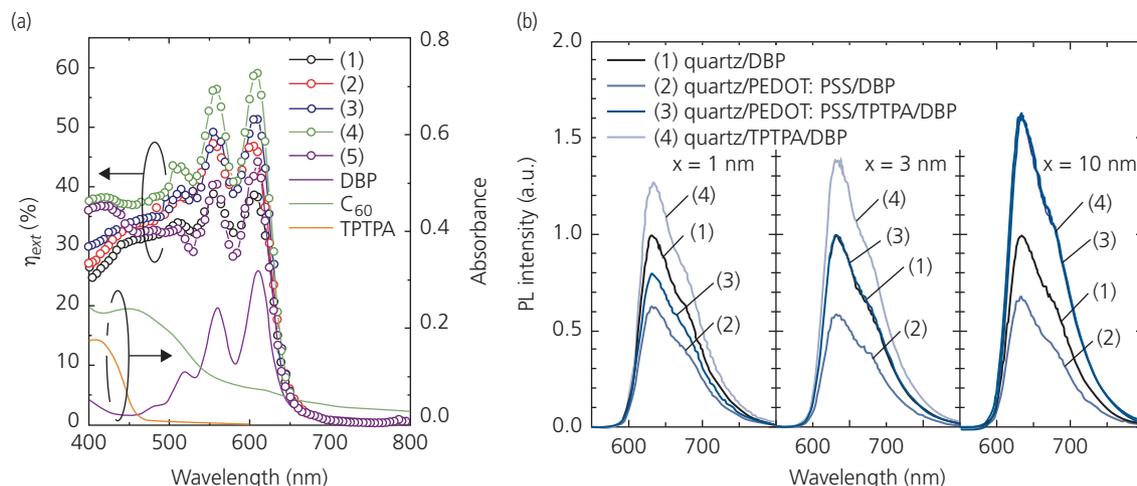

**Figure 7.124** Monte Carlo simulation of the exciton blocking properties of BCP: $C_{60}$  ( $z:y$ ) buffer layers. The cube shows an illustration of a 1:1 mixed layer used, where the different colored blocks correspond to randomly distributed BCP and  $C_{60}$  molecules (Bergemann et al., 2015).

slowly increases from  $z/y = 0.6$  to  $0.9$ , and then increases abruptly to the insulating state at  $z/y = 1$ . Similarly, DBP/ $C_{60}$  OPVs with a 10 nm thick BCP: $C_{60}$  buffer shows an efficiency of 6.6% until  $z/y = 0.9$ , above which  $n_p$  decreased to 5.9%. Phase segregation of  $C_{60}$ , if it is present at all, is not observed using current-sensitive AFM. Hence, conduction occurs along  $C_{60}$  nanowires once the concentration of  $C_{60}$  drops below 50%.

Finally, exciton blockers have been used on the donor side of the junction, although this architecture is uncommon since the exciton diffusion lengths in donors are generally considerably smaller ( $\sim 5$  nm) than for the fullerenes, and the use of mixed or bulk HJs reduces the diffusion lengths even further. Also, positioning a transparent layer near the anode only weakly affects the optical field distribution. Nevertheless, the insertion of a wide energy gap exciton blocker between the anode buffer and the donor can increase cell efficiency in some instances.

Figure 7.125a shows the external quantum efficiency of a ITO/PEDOT:PSS/TPTPA ( $x$  nm)/DBP ( $y$  nm)/ $C_{60}$  (50 nm)/BCP (10 nm)/Al OPV, where a constant thickness of the TPTPA anode blocking layer and DBP donor was  $x + y = 20$  nm. Here, TPTPA is suitable as a blocking layer with an energy gap of 2.7 eV compared to only 1.9 eV for the donor, leading to absorption at  $\lambda < 450$  nm. The  $\eta_{ext}$  spectra are taken for devices with different TPTPA thicknesses, viz. device 1:  $x = 0$  (no blocking layer), 2:  $x = 1$  nm, 3:  $x = 3$  nm, 4:  $x = 10$  nm, and 5:  $x = 15$  nm. The quantum efficiency is primarily affected by DBP absorption, since only excitons absorbed within the donor are impacted by the presence

**Figure 7.125** (a) External quantum efficiency and absorbance spectra of the devices (1–5, see text) and layers employed in OPVs using anode EBLs. The spectra correspond to different TPTPA EBL thicknesses,  $x$ . (b) Photoluminescence intensity spectra of DBP films used in the layers shown in the legend (Hirade and Adachi, 2011).

of the donor-side EBL. In fact, the largest enhancement is achieved for device 4, where  $x = y = 10$  nm. The efficiency decreases for thinner EBLs that are less effective in confining excitons within the donor. For thicker TPTPA, the donor absorption decreases (Hirade and Adachi, 2011).

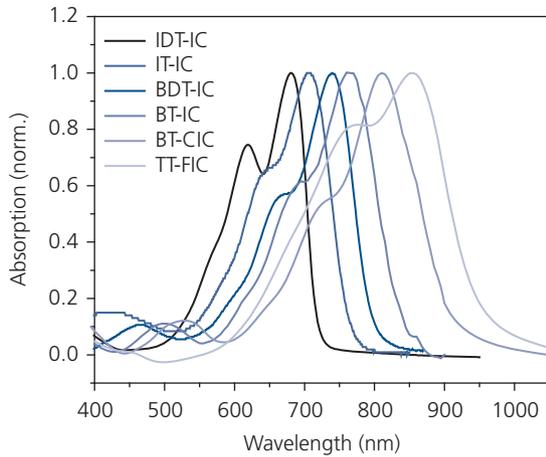

The DBP thin film PL intensity spectra in Fig. 7.125b provide evidence for the blocking properties of the EBL. The spectra from four structures are compared for different TPTPA thicknesses. In film 1, the DBP was deposited directly on quartz, which provides a blocking, non-quenching surface. Film 2 is quartz/PEDOT:PSS/DBP, film 3 is quartz/PEDOT:PSS/TPTPA/DBP, and film 4 is quartz/TPTPA/DBP. The highest intensity for all TPTPA thicknesses is film 4, indicating that TPTPA forms an interface with DBP that exhibits even less quenching than the nominally non-quenching quartz substrate. On the other hand, the lowest intensity is observed for film 2 where DBP is deposited directly on PEDOT:PSS which forms an efficient quenching interface. Film 3, which is the structure employed in the OPV cells, is as effective as film 4 in blocking excitons in the absence of quenching, but only when the TPTPA is 10 nm thick as is necessary to completely block exciton transport to the anode buffer.

An OPV with  $x = 0$  nm showed  $\eta_p = 3.9\%$ , whereas it increased to 5.0% for  $x = 10$  nm. Also, the FF increased from 0.72 to 0.77 over this same range of thicknesses. As noted previously, the absorption in the donor layer decreases with increasing  $x$ , resulting in a concomitant decrease in device performance (Hirade and Adachi, 2011).

#### 7.4.2 OPV transparency and flexibility, and the role of contacts

The narrow excitonic absorption bands of organics compared to the very broad absorption of inorganic semiconductors requires the inclusion of three or even more organic materials to achieve full spectral coverage across the visible and into the NIR. For example, in Fig. 7.126 we show the absorption spectra of six homologous NFA molecules used in high efficiency OPVs. Each of the spectra is rigidochromically shifted by approximately 80 meV, with a half width of  $\sim 150$ –250 nm. The complexity inherent in requiring several molecules to cover the solar spectrum is offset by an opportunity to employ OPVs as power generating windows in building applied or building integrated photovoltaic applications. The examples in Fig. 7.126 indicate that this collection of molecular species leaves transparency windows across broad swatches of the visible and NIR spectra. By choosing organic materials that selectively absorb in the NIR, one can create a cell that has a tint, or even a neutral density semitransparent window while also providing an efficient power source, provided that the anode and cathode contacts are also semitransparent.

To quantify the appearance and efficiency of power generating windows, we introduce two parameters: the *average photopic transmission*, APT (or variously the *average visible transmission*, AVT) and the *light utilization efficiency*, LUE (Traverse et al., 2017). Using the same approach for windows as taken to quantify illumination sources, the perceived color of sunlight

**Figure 7.126** Absorption spectra from six NFAs used in high efficiency OPVs. The molecular formulae and other details of these compounds are provided in Section 7.4.4.

through a window (which during daytime hours is an illumination source) is expressed by the window's chromaticity coordinates (cf. Section 6.2.3). The *APT* is the integrated transmission spectrum,  $T(\lambda)$ , weighted by the *photopic response* of the human eye,  $V(\lambda)$ , and is given by

$$APT = \frac{\int_{\text{visible}} T(\lambda) E_{REF}(\lambda) V(\lambda) d\lambda}{\int_{\text{visible}} E_{REF}(\lambda) V(\lambda) d\lambda}, \quad (7.174)$$

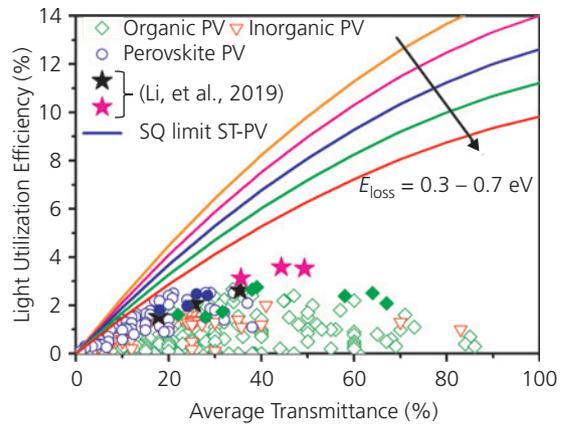

where  $E_{REF}(\lambda)$  is the reference solar spectrum.

The power conversion efficiency is also needed to fully quantify the performance of a window. For this purpose, we define the *LUE*:

$$LUE = APT \times \eta_p. \quad (7.175)$$

Thus,  $LUE = 0$  for a totally opaque cell (where  $APT = 0$ ), although it can be as high as 20% for a cell that is 100% transparent to the human eye. For example, with  $\eta_p = 15\%$  and  $APT = 50\%$ , then  $LUE = 7.5\%$ .

Transparency can be achieved by two approaches. Opaque cells based on inorganic semiconductors such as Si and GaAs can be separated into thin strips or sections, thus admitting light through the gaps between the individual cells. This provides an optical neutral density appearance. However, the fabrication process of such a window that entails precise placement and interconnection of the cell segments can be costly. An attractive and far less complex approach is offered by organic cells that can be transparent across the visible, yet highly absorbing in the NIR using

**Figure 7.127** Light utilization efficiencies (*LUE*) vs. *APT* for several inorganic, perovskite, and OPV cells. The lines are the thermodynamically limited *LUE* curves for a range of energy losses found in OPVs. The stars refer to OPVs from Li et al. (2019). Adapted from (Traverse et al., 2017).

appropriate materials and device structures. The window color can also be selected simply by changing the optical coatings of the OPVs, or selecting materials that remove desired spectral regions.

A compilation of *LUE* values for inorganic, perovskite and OPVs are provided by the data points in Fig. 7.127. Devices with the highest *LUE* are based on organic thin film cells, even though the absolute efficiencies of many inorganic cells are higher. The maximum  $LUE = 3.5\%$  in this compilation is expected to increase as new device architectures, optical filtering schemes and organic materials are developed. One note of caution in reading these data is that not all cells are neutral density. That is, the light transmitted may have its color coordinates significantly shifted away from a standard solar illuminant with  $CCT = 5800$  K. Hence, objects illuminated by the sun through such a window may not appear in their true colors (i.e.  $CRI < 1$ ). This is particularly true for the organic and perovskite cells that can have noticeable tints. If the coloration is too strong, the cells no longer perform as windows, but rather as power generating optical filters that do not serve the purpose of building integrated appliances.

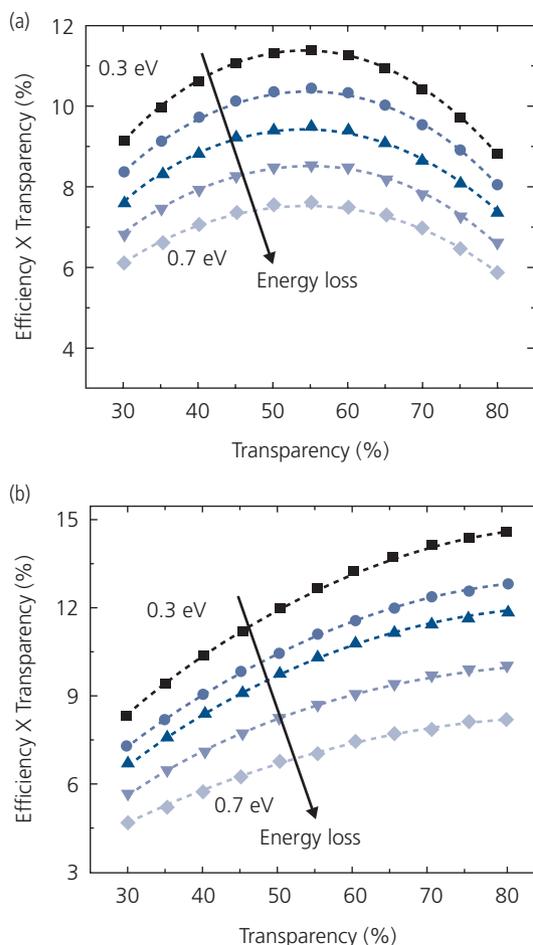

The lines in Fig. 7.127 are calculations based on the thermodynamically limited response of OPVs according to the theory in Section 7.3.2. The curves correspond to different values of energy loss typical of OPVs, assuming that the devices absorb in the UV and NIR (with energy gaps that yield the thermodynamically limited output power), yet are semitransparent in the visible. We observe that the *LUE* increases with *AVT* as a greater fraction of energy is harvested from the UV and NIR. These curves have a

maximum at  $LUE = \eta_p \rightarrow \eta_p^{\max}$  and  $AVT = 100\%$ , where  $\eta_p^{\max}$  is the thermodynamically limited power conversion efficiency in the absence of contributions from the visible spectrum.

We can use the same analysis to estimate the limits to the power conversion efficiency attainable by semitransparent, multijunction OPVs. The efficiency limit for a series, and a series-parallel connection of three subcell devices is shown in Fig. 7.129a and b, respectively. The series-connected triple junction cell comprises a visible absorbing subcell whose external quantum efficiency is  $\eta_{ext,vis} = [1 - VT]$ , where we assume that the transparency window lies between 350 nm <  $\lambda$  < 625 nm. Here,  $VT$  is the visible transmission, which differs from  $AVT$  in that it is the arithmetic mean of the transmission within a specified optical domain. This is unrelated to the perceived appearance of the solar cell. A  $VT = 50\%$ , therefore, does not necessarily have a neutral color. The NIR and IR subcells in Fig. 7.128 assume  $\eta_{ext,IR} = 90\%$ . The subcell absorption bandwidths are adjusted such that the current along the stack is balanced. For  $E_{loss} = 0.5$  eV, we calculate  $\eta_p = 19\%$  and  $LUE = 9.5\%$ . That is, the triple junction design achieves nearly the same high efficiency when it is 50% transparent in the visible, with that of completely absorbing single junction cell in Fig. 7.74.

An alternative multijunction architecture is the series/parallel connection of Fig. 7.129b. Parallel circuits require voltage balance between sources. However, the operational voltage of NIR absorbing subcells is lower than from visible absorbing cells due to their smaller energy gaps. Voltage balance can be achieved by placing two long wavelength series-connected subcells in parallel with a visible absorbing cell. The series subcell stack must be current matched, whereas the MPP voltage optimally follows  $V_{M,IR} = V_{M,IR1} + V_{M,IR2} = V_{M,vis}$ . Here,  $V_{M,IR}$  is the total IR tandem voltage, equal to the sum of the two IR subcells,  $V_{M,IR1}$  and  $V_{M,IR2}$ , which in turn is assumed to equal the voltage of the visible absorbing subcell,  $V_{M,vis}$ .

The matched, multijunction cell efficiency *vs.* transparency is provided in Fig. 7.128b. Again, taking  $VT = 50\%$  and  $E_{loss} = 0.5$  eV, we obtain  $\eta_p = 19\%$  which is approximately that of the series stacked cell. Importantly, the dependence of the efficiency on transparency is less pronounced for the series-parallel OPV. Presumably, this results since the visible absorbing cell voltage is only weakly dependent on intensity. Voltage balance is maintained even though the current generated is significantly reduced by the increased transparency. In contrast, a fully series-connected cell is current-limited by the visible

**Figure 7.128** Power conversion efficiency–average transparency product *vs.* cell transparency for (a) series and (b) series/parallel connected triple junction OPVs. Adapted from Che (2018).

absorbing subcell that is made increasingly transparent via thinning of its active region, yielding its stronger dependence on  $VT$ .

Semitransparent cells require optically transmissive and low resistance contacts. To ensure low injection barriers to electrons into the acceptor, the cathode metals must have low work functions. Similarly, anodes have high work functions. Furthermore, since solar cells cover large surface areas, the contacts must have low sheet resistance. A requirement of all materials used in solar cells including the contacts, is low cost and the ability to be applied over very large substrate areas. Typically, thermally evaporated Al (with a work function of  $q\phi_m = 4.3$  eV) and Ag (4.2 eV) are preferred, although Ag readily diffuses into the organics, creating damage and even shorts across the cell. Indium tin oxide and other metal oxides are almost universally used as anode materials due to their high work functions, relatively low resistance

and high transparency. However, the sheet resistance of ITO is several orders of magnitude higher than metals of comparable thickness, and the sputtering process and materials costs used in their manufacture can be prohibitively high. Lastly, metal oxide films are brittle, preventing them from flexing during use or manufacture.

A straightforward approach to achieving contact semitransparency is to use a metal whose thickness is less than, or on the order the optical skin depth (see Section 6.2.2),

$$\delta = \sqrt{2/\omega\mu_r\mu_0\sigma_{dc}}. \quad (7.176)$$

Here,  $\delta$  is the characteristic distance for electric field attenuation through the metal, viz.  $\mathbf{F}(\mathbf{r}) \propto \exp(-\hat{\mathbf{n}} \cdot \mathbf{r}/\delta)$ . Also,  $\omega$  is the frequency of the incident radiation,  $\mu_0$  is the magnetic permeability of free space and  $\mu_r$  is its relative permeability,  $\sigma_{dc}$  is its d.c. conductivity,  $\hat{\mathbf{n}}$  is the unit vector normal to the metal surface, and  $\hat{\mathbf{r}}$  is the propagation direction. For most metals,  $\delta \sim 50$  nm which sets an upper limit to electrode thickness when used in semitransparent cells. However, since  $\sigma_{dc}$  for a contact metal is much higher than ITO, the thin metal contact generally has a lower resistance than the anode. Electromagnetic theory gives the dependence of the transmittance of a conductor of thickness,  $d$ , on conductivity via (Dressel and Grüner, 2002)

$$T = \frac{1}{\left(1 + \frac{Z_0\sigma_{ac}d}{2}\right)^2} = \frac{1}{\left(1 + \frac{Z_0\sigma_{ac}}{2R_{\square}\sigma_{dc}}\right)^2}, \quad (7.177)$$

where  $\sigma_{ac}$  is the frequency dependent a.c. conductivity,  $R_{\square} = 1/(\sigma_{dc}d)$  is the contact sheet resistance, and  $Z_0 = \sqrt{\mu_0/\epsilon_0} = 377 \Omega$  is the impedance of free space.

An example of the dependence of the transparency of OPVs on the thicknesses of Ag cathodes on a structure comprising ITO/ZnO (25 nm)/PCE-10:BT-CIC (130 nm)/MoO<sub>3</sub> (15 nm), is provided in Table 7.13 (Li et al., 2017c). The devices show a broad

transparency window between 550 nm to 900 nm, with a bluish tint. The  $VT$  varies from 43% for a Ag thickness of 10 nm, to 26% at 20 nm. As the device becomes increasingly transparent, the reflection from the cathode into the thin active region is decreased, eliminating the double pass of the resulting standing wave. Hence, for a device with a 100 nm thick, reflective cathode,  $\eta_P = 11.2\%$ , decreasing to 7.1% for the device with a 10 nm thick cathode. As expected, the series and sheet resistances also increase with decreasing cathode thickness.

The inverse relationship between transparency and sheet resistance of a flexible PEDOT:PSS anode inferred from Eq. 7.177 is shown in Fig. 7.129. The film thickness is varied by sequentially spin coating layers of PEDOT:PSS containing 6 vol.% ethylene glycol, and annealing at 120°C between each deposition step. The solid line is a fit to  $R_{\square} = 1/(\sigma_{dc}d)$ , with  $\sigma_{dc} = 1200$  S/cm. The film with a sheet resistance of 75  $\Omega$ /sq. has a transmissivity of  $\sim 80\%$ . This is 50–100 times higher than ITO, which itself is unsuitably high for use in large modules (Kim et al., 2011).

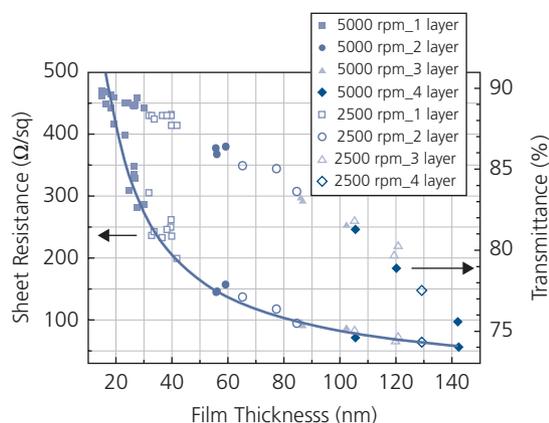

A comparison of the transmissivities weighted by the solar spectrum between 400 nm and 800 nm for several different anode materials is provided in Fig. 7.130. To reduce the sheet resistance of PEDOT:PSS or ITO without significantly affecting transparency, the film can be deposited onto the surface of a thin and widely spaced metal grid. A Ag grid with a period of 400 nm and a gridline width of 40 nm is approximately 90% transparent yet gives a sheet resistance of  $\sim 1 \Omega$ /sq., as shown by the solid line in Fig. 7.130. However, high resolution photolithography required to produce the fine grid features is costly. An alternative is to use a micron-scale, screen-printed grid covered by a thicker layer of PEDOT:PSS, although this configuration is inferior to the transparency and conductivity provided by ITO (Aernouts et al., 2004).

Random, crystalline Ag nanowire meshes may be useful replacements to a patterned grid (Lee et al.,

<sup>a</sup> Obtained at 1 sun, AM1.5G simulated solar illumination.

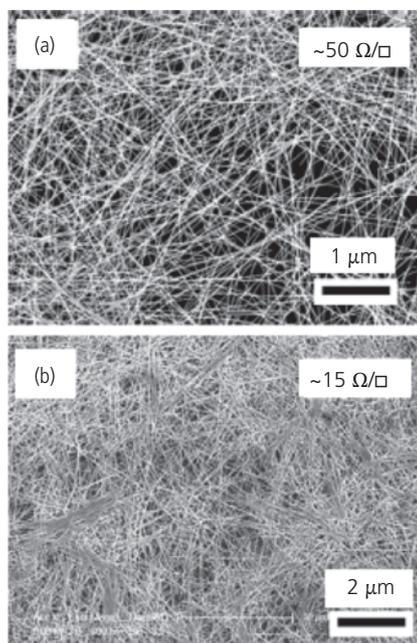

**Figure 7.129** Sheet resistance and transmittance vs. PEDOT:PSS film thickness ( $d$ ), controlled by adjusting the spin velocity and number of layers. The line is a fit to  $R_{\square} = 1/(\sigma_{dc}d)$  (Kim et al., 2011).

**Figure 7.130** Transmissivity weighted by the AM1.5G spectrum vs. sheet resistance for several different OPV anode materials. Very few materials are suitable for use in OPVs, whose preferred properties lie within the shaded box. After Lee et al. (2008). Data for PEDOT:PSS from Kim et al. (2011), carbon nanotubes (CNT) from Rowell et al. (2006) and Van De Lagemaat et al. (2006) (open and filled triangles, respectively), and four-monolayer  $\text{HNO}_3$ -doped graphene from Bae et al. (2010).

2008, Hu et al., 2010). Nanowires that are  $\sim 10 \mu\text{m}$  long by 100 nm in diameter grown from solution are shown in Fig. 7.131. As-deposited wires are coated with a thin insulating barrier that results in a low conductivity mat. Annealing at  $200^\circ\text{C}$  fuses the wires that significantly reduce the film resistance to  $8 \Omega/\text{sq}$ . (filled squares, Fig. 7.131) (Kim et al., 2011).

An increase in nanowire density leads to an increase in conductivity, but also in a loss of transmittance. The transmission ( $T$ ) of the  $50 \Omega/\text{sq}$ . film is  $\sim 85\%$  (Fig. 7.131a) whereas for the  $15 \Omega/\text{sq}$ . sample,  $T \sim$

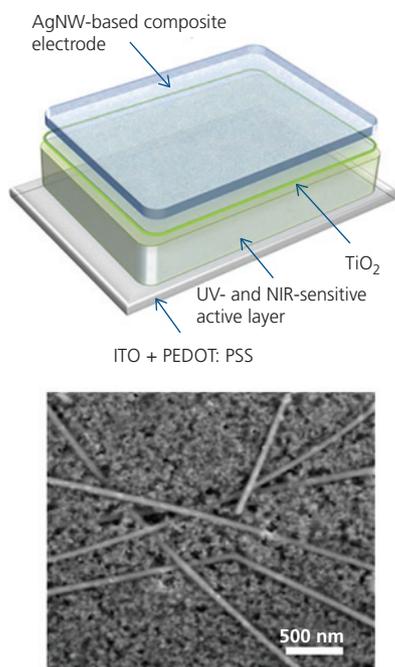

**Figure 7.131** SEM images of Ag nanowire meshes with sheet resistances of (a)  $50 \Omega/\text{sq}$ . and (b)  $15 \Omega/\text{sq}$ . (Hu et al., 2010).

$65\%$  (Fig. 7.131b) (Hu et al., 2010). Prior to fabrication of the OPVs, the rough surface of the meshes is planarized to prevent shorting across the thin device active region. This can be done by coating the mats with a thin PEDOT:PSS layer that also provides a uniformly conductive surface. ZnO nanoparticles with diameters between 3–5 nm synthesized in solution have also been used to fill the gaps between the nanowires, resulting in P3HT:PC<sub>61</sub>BM BHJ OPVs with  $\eta_p = 3.9\%$  and  $FF = 0.68$ ; values that are marginally superior to those achieved using an ITO anode with a ZnO nanoparticle treated surface, where  $\eta_p = 3.5\%$  (Ajuria et al., 2012).

Nanowire mats can also form semitransparent top contacts (Chen et al., 2012a). A Ag nanowire composite cathode was deposited onto the surface of a 20 nm thick  $\text{TiO}_2$  nanoparticle cathode interfacial layer on the OPV structure in Fig. 7.132a. The OPV BHJ consists of the donor, PBDTT-DPP blended with PC<sub>61</sub>BM, on an ITO/PEDOT:PSS anode. The BHJ active region strongly absorbs in the UV and NIR, with only 30–40% absorption in the visible. The nanowires are spray-coated and fused using alcohol-based solvents onto the  $\text{TiO}_2$  interlayer. The last step fills in the gaps between the nanowires by spreading a conducting ITO nanoparticle film suspended in a polymer binder. This creates a relatively low

**Figure 7.132** (a) Schematic illustration of a semitransparent OPV employing a Ag nanowire (Ag NW) composite top cathode and an ITO-PEDOT:PSS anode. (b) Scanning electron microscope image of the underside of the top electrode showing the Ag NWs and the ITO nanoparticle filler. This image was taken after the electrode was peeled off of the organic layers (Chen et al., 2012a).

resistance path between the point of charge injection onto the high conductivity Ag mesh. A micrograph of the underside of the contact in Fig. 7.132b shows that the film exposes nanowires to the underlying layers while creating a continuous film that contacts the OPV layers below. The contact has  $AVT = 87\%$  and a sheet resistance of  $30 \Omega/\text{sq}$  (Chen et al., 2012a). Organic solar cells employing this cathode show  $\eta_P = 4.0\%$  and  $3.8\%$  under 1 sun AM1.5G spectral illumination incident from the anode and cathode sides, respectively. The  $FF$  of the transparent device is 0.57 compared with 0.60 for the conventional device due to increased resistance from the Ag nanowire cathode contact.

CNTs can also form flexible conductive mats. Indeed, Fig. 7.48b shows that its low HOMO energy gives it donor-like characteristics, and thus is suitable as an anode contact. Single walled nanotubes prepared by arc discharge can have transparencies as high as 90% for 30 nm thick films, but with a correspondingly high sheet resistance of  $200 \Omega/\text{sq}$ . (Fig. 7.130). As discussed previously, a random population of nanotubes contains approximately 1/3 metallic and 2/3 semiconducting tubes, but only the

former contribute to the conductivity. This leads to a relatively high sheet resistance that is comparable, or even inferior to that attained by PEDOT:PSS (Hu et al., 2004, Rowell et al., 2006). The resistance is reduced by annealing at  $\sim 100^\circ\text{C}$  to remove surfactant and improve contact between overlapping tubes. Gaps between the tubes can be filled, and the surface planarized by coating with a layer of PEDOT:PSS (Rowell et al., 2006, Van De Lagemaat et al., 2006).

Lastly, graphene has been explored for flexible and transparent electrodes. Due to the delocalized electron wavefunctions along the graphene sheet, its in-plane conductivity and carrier mobility is very high (up to  $200,000 \text{ cm}^2/\text{V s}$ ), and as a monolayer it is transparent. Indeed,  $\text{HNO}_3$ -doped p-type, four monolayer thick graphene sheets have been produced in a continuous R2R process with a sheet resistance of  $30 \Omega/\text{sq}$ . and a transparency of  $\sim 90\%$ . Monolayers are successively transferred to obtain multilayer films with the desired combination of resistance and transparency (Bae et al., 2010).

The performance of graphene anodes adapted for use in OPVs is not quite as high. For example, three monolayers of graphene were successively transferred to a quartz substrate and then coated with a planarizing layer of PEDOT:PSS. The doping process results in an 80% transparent film with a sheet resistance of  $\sim 100 \Omega/\text{sq}$  (Kim et al., 2010). Combining this anode with 21 nm CuPc/40 nm  $\text{C}_{60}$ /9.3 nm BCP double HJ device with a Ag cathode resulted in  $\eta_P = 1.6\%$  and  $FF = 0.42$ , compared to  $\eta_P = 1.8\%$  and  $FF = 0.56$  for an analogous device employing an ITO/PEDOT:PSS anode (Park et al., 2010a). The reduced  $FF$  for the graphene-based OPV is a result of its higher anode injection barrier and sheet resistance. Single monolayers of graphene coated with PEDOT:PSS have been employed as a top, transparent contact on P3HT/ $\text{PC}_{61}\text{BM}$  OPVs employing an ITO/ZnO anode. The sheet resistance was  $\sim 500 \Omega/\text{sq}$ , which results in a low fill factor of  $\sim 0.4$  (Liu et al., 2011).

The recurring theme of the foregoing discussion is that potentially lower cost and flexible contacts can be achieved using metal nanowires, PEDOT:PSS, nanotubes or graphene, although they generally deliver inferior performance compared to those using brittle, transparent metal oxide contacts.

The loss in efficiency that accompanies transparency can be partially recovered by recycling the NIR photons back into the active region, thereby doubling the absorption length, while the visible photons experience only a single pass as they transit across the cell. This is accomplished by appropriate combination

of an ARC and a mirror in the NIR (Koeppel et al., 2009, Lunt and Bulovic, 2011, Betancur et al., 2013). This takes advantage of the narrow spectra of excitonic materials that absorb primarily in the non-visible spectral regions. To selectively transmit multiple spectral regions, a single ARC or *distributed Bragg reflector* (DBR) is insufficient. On the other hand, *aperiodic dielectric reflectors* (ADRs) comprising multiple layers with different thicknesses and indexes of refraction, can achieve this purpose (Sergeant et al., 2009).

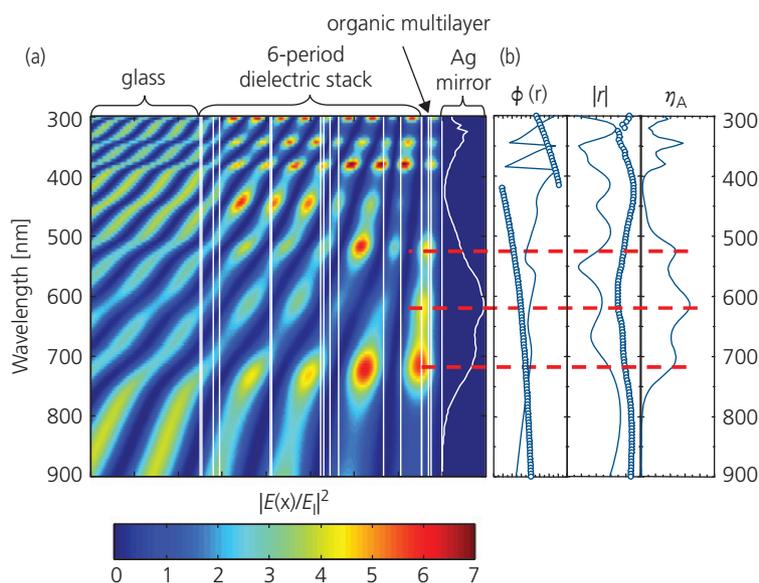

Since the sun is a broad spectral source, the ARCs and ADRs must also have broad spectral transmission or reflection. This is a more complex problem than designing a coating for a relatively narrow spectral source such as an OLED or OPD. Determining the layer thicknesses starts by choosing the number of layers and the refractive indices of the materials to be used in the coating, and the target output spectrum. This is the inverse solution of the conventional design approach that starts with the structure and optical properties of the multilayer stack, and then using transfer matrix formalism (Section 7.1.4) to calculate its transmission, absorption and reflection coefficients. An example of a broad band, aperiodic dielectric stack comprising six periods of  $\text{SiN}_x$  and  $\text{SiO}_2$  of varying thicknesses is shown in Fig. 7.133. The solution is found by using a *genetic algorithm* to iteratively approach the target spectrum (shown at right). The algorithm iteratively varies the thicknesses

of the layers until the output spectrum most closely approaches that of the target. A difficulty inherent in this approach is that the algorithm may become trapped in a local solution that is not optimal. To avoid this possibility, the procedure is attempted multiple times, each with a randomly chosen set of initial conditions.

The absorption efficiency for the aperiodic ARC in Fig. 7.133 is reasonably uniform across the absorption spectrum of the CuPc:PTCBI (1:1) OPV active region for which it is designed. Indeed, the electric field intensity appears to be strongly confined to the organic multilayer, as shown in Fig. 7.133a. The average absorption efficiency is 26.6%, compared with 19.8% without the dielectric stack (Peumans, 2004). A more uniform spectrum may be achieved by increasing the number of layers in the stack.

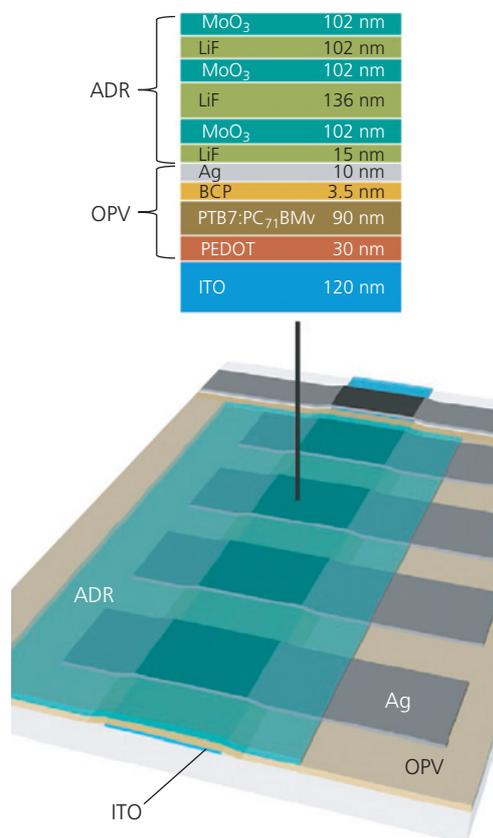

The structure in Fig. 7.134 is an example device employing an ADR designed to reflect UV and NIR radiation to create a standing wave within the PTB7:PC<sub>71</sub>BM active region of an OPV, while being transmissive to visible radiation. The dielectrics employed are LiF ( $n = 1.39$ ) and  $\text{MoO}_3$  ( $n = 2.52$ ) forming a stack on a semitransparent, 10 nm thick Ag cathode.

The calculated  $APT$  and  $j_{SC}$  comparing an OPV with only a thin Ag layer (called Tn-Ag), and one with an ADR on the surface of the Tn-Ag (ADR-Tn-Ag) vs. the number of layers in the dielectric stack is

**Figure 7.133** (a) Optical electric field intensity vs. wavelength ( $y$ -axis) and position in a device with layer structure, glass/ $[\text{SiN}_x/\text{SiO}_2]_6$ /ITO (15 nm)/PEDOT:PSS (32 nm)/CuPc:PTCBI (1:1, 10 nm)/BCP (50 nm)/Ag. (b) Phase ( $\phi(r)$ ) and magnitude ( $|r|$ ) of the complex reflection coefficient,  $r$ , of the coating (solid line), and an ITO/organic/metal cavity (open circles). Also shown is the absorption efficiency,  $\eta_A(\lambda)$  (Peumans, 2004).

shown in Fig. 7.135. This result is compared with that for an optimized, periodic DBR comprising four and six alternating layers (squares). The plot shows that adding layers past four or five has a diminishing impact. The stack used for the OPVs comprises five layers, providing an *APT* only 5% less than for the Tn-Ag sample (open blue circles), but with a short circuit current nearly 20% higher (open black circles). The DBR gives a higher transparency than the ADR, but at the cost of a lower  $j_{SC}$ . The measured performance of the OPVs (solid circles) is close to that obtained via calculation for both Tn-Ag and ADR-Tn-Ag. The inset, Fig. 7.135, shows the appearance of OPVs optimized to transmit different colors, from red to blue to neutral. Generally, building architects favor neutral density coatings on windows, which is accessible via the appropriate dielectric stack designs.

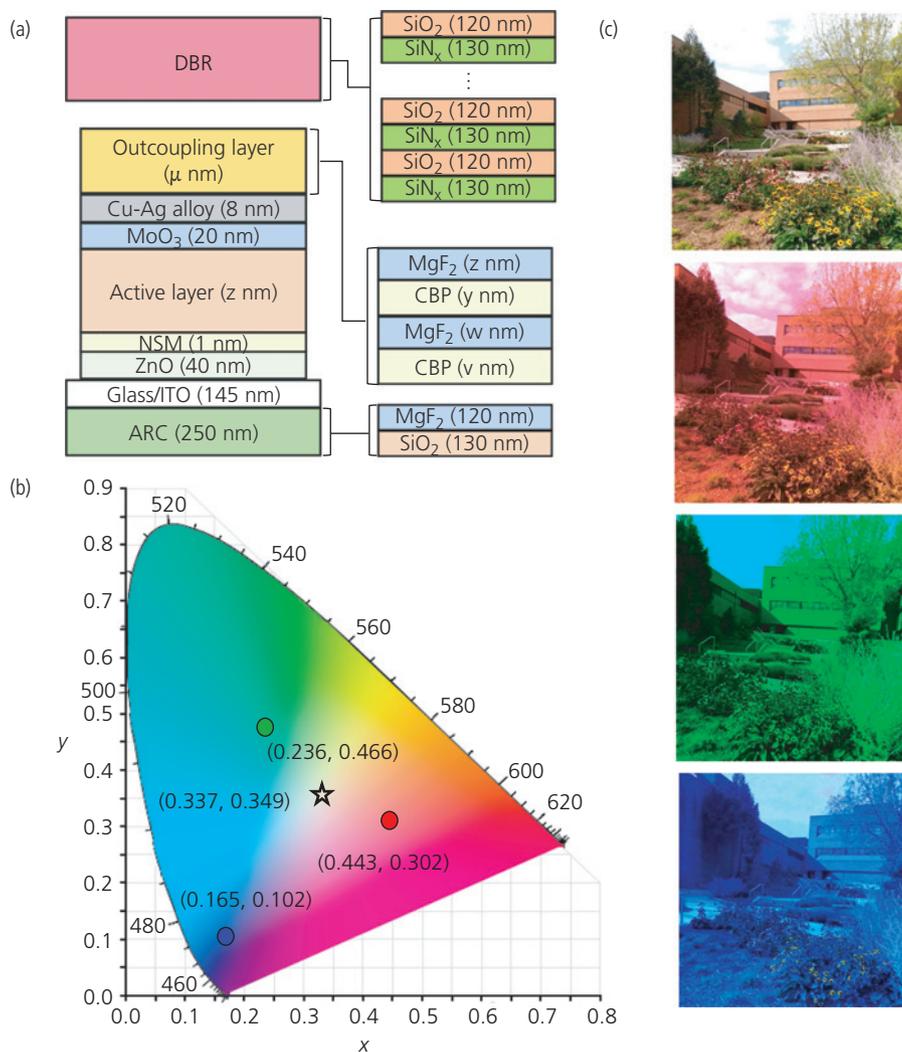

**Figure 7.135** Relative photonic transparency and short circuit current for a PTB7:PC<sub>71</sub>BM OPV vs. the number of layers in the ADR of Fig. 7.134. Comparison of these parameters is between a device with an ADR on a thin Ag electrode (ADR-Tn-Ag), and a similar device lacking the ADR (Tn-Ag). The measured device performances are given by solid circles, and the calculated performances by open circles. Open squares are calculations for an optimal periodic Bragg reflector. Inset: Transparent films optimized for different transmission spectra placed on the logo of the Institut de Ciències Fotoniques (ICFO) (Betancur et al., 2013).

**Table 7.14** Performance of PTB7:PC<sub>71</sub>BM OPVs with different cathode designs (Betancur et al., 2013)

Cathode	$j_{SC}$ (mA/cm <sup>2</sup> )	$\eta_P$ (%)	<i>APT</i> (%)
Tk-Ag	14.0	7.3	0
Tn-Ag	8.5	3.6	32
ADR-Tn-Ag	10.7	5.2	29

The power conversion efficiencies and *APTs* of the variously coated OPVs are summarized in Table 7.14. There are minor differences in *FF* and  $V_{OC}$  attributed to damage incurred during dielectric stack deposition. The largest differences are found in  $j_{SC}$  and  $\eta_P$  where the device with the aperiodic grating has a 20% higher  $j_{SC}$  and a 40% higher  $\eta_P$  compared with the Tn-Ag device, although the visible transparencies are nearly equal (Betancur et al., 2013).

We found in Section 6.2.2 that replacing the semi-transparent metal with ITO can also result in a large *APT*, although there is a possibility that its deposition can damage the underlying organic layers. Furthermore, the large work function of ITO makes it an inefficient electron injecting contact that is overcome, ironically, by the formation of electron-conducting defect states induced by this damage. A buffer layer is often employed between the ITO cathode and the device active regions to eliminate the formation of exciton quenching defects in the light absorbing layers (Parthasarathy et al., 1998).

**Figure 7.136** (a) General structure of the semitransparent OPV with an NIR reflecting DBR, an ARC on the bottom surface, and an optical outcoupling layer on the top surface. (b) Chromaticity coordinates for the four OPVs in (c) with different outcoupling and active layer thicknesses (Li et al., 2019).

While the narrow spectral width of NIR absorbing materials can be exploited to achieve both high efficiency and transparency when combined with a semitransparent cathode, their spectral overlap with the visible spectrum can lead to unwanted coloration of the cells. Hence, it is essential to also engineer the outcoupled spectrum of the devices to achieve the desired hue. In the previous example, most of the attention is directed at improving the coupling of the broad, incident spectrum into the solar cell active region. The appearance and efficiency of the cell can simultaneously be tailored by applying a second coating on the exit surface, called an *outcoupling* (OC) layer. By combining the elements of materials sets featuring narrow absorption spectra with multi-layer ARC and OC films, as well as a DBR used for

NIR light recycling, a high *LUE* is achieved for the device in Fig. 7.136a. Starting from the top surface, a DBR comprising 12.5 alternating layers of plasma enhanced CVD SiN<sub>x</sub> and SiO<sub>2</sub> is deposited on a separate glass substrate. This is attached to the surface of the OPV that is fabricated on a second glass substrate (see also, Lunt and Bulovic, 2011). The device itself has several innovations. The anode buffer consists of a ZnO film coated with a 1 nm thick NSM hole injection layer that minimizes charge trapping at the ZnO surface. The active region comprises a solution-deposited PCE-10:BT-CIC:TT-FIC (1:1.25:0.5) ternary blend that is capped with a MoO<sub>3</sub> cathode buffer and a semitransparent, sputtered 8 nm thick 2% Cu-Ag alloy film (Cho et al., 2017). The alloy has a resistance of 11.3 Ω/sq., which is comparable to a vacuum

deposited Ag film of equal thickness, although the 2% Cu-Ag is >20% more transmissive across the visible. Most importantly, the very thin alloy film is continuous and smooth compared to Ag, which tends to form clusters that results in a rough surface. The final layer is a two period, CBP/MgF<sub>2</sub> light out-coupling layer that reduces trapping of visible radiation within the cell. Unlike the ARC, the outcoupling layer has a narrower spectral bandwidth, and thus controls the tint of the cell. Images of an outdoor scene in daylight taken through several different cells with OC and active layer thicknesses tuned to transmit different wavelengths are shown in Fig. 7.136c. The CIE coordinates of light from an AM1.5G simulator viewed through the cells are indicated by the data points in Fig. 7.136b. The neutral density cell (top image) has coordinates of (0.337, 0.349), that is, it lies close to the isoenergetic chromaticity point of (0.33, 0.33) at 5000 K (see Fig. 6.13). Similar to a light source, the window appearance is defined by its color temperature (here approximately 5000 K), and its color rendering index. In this case,  $CRI = 87$ , indicating that objects illuminated through the OPV will appear in approximately their natural colors. The other cells in Fig. 7.136 strongly filter the light, and as a result have a deeply colored appearance.

The performance characteristics of these cells are summarized in Table 7.15. Included in this compilation is a second neutral density cell with CIE coordinates of (0.280, 0.335), exhibiting a slightly green cast. Importantly, the highest performance neutral density OPV has  $LUE = 3.56\%$  and  $\eta_p = 8.0\%$ , giving photopic transparency of nearly 50%. From Fig. 7.127, this is nearly double the  $LUE$  of inorganic and perovskite cells, suggesting that transparent windows provide a unique opportunity for OPV applications, particularly when coupled to their ability to be deployed on flexible

thin films that can be easily attached within the pocket between the outer and inner panes of insulated windows commonly found in commercial and residential buildings.

### 7.4.3 Bulk and mixed heterojunction morphologies

Bulk and mixed HJs are nanostructured aggregates of donor and acceptor molecules that present a large interface area where excitons can dissociate without having to diffuse long distances from their origin. This structure eliminates the trade-off between the relatively short exciton diffusion length and the long optical absorption length that limits the efficiency of planar HJ devices. However, the inherent disorganization of these random structures can impede charge conduction to the contacts due to the circuitous and often discontinuous paths between the charge point of origin to its respective contact. To maximize the probability of exciton dissociation and minimize resistance to charge transport, the morphology of the mixed regions must be controlled with nanoscale precision. We have seen in Chapter 5 that morphology is determined by numerous factors, including the method of deposition, post-deposition annealing, the ratio of donor to acceptor molecules in the blended junction, and by the steric properties of the donor and acceptor molecules. All of these factors become increasingly complex to manage as the number of constituent molecules forming the active region is increased. It is no surprise, then, that controlling and understanding the morphologies of ternary active regions is considerably more difficult than for binary OPVs.

In this section we discuss a few of the frequently used methods for controlling morphologies to maximize OPV efficiencies. We start by considering guidance provided by the ideal diode theory of Section 4.7.2 to understand the optimal morphologies needed for high efficiency. Then we provide examples of how to achieve those structures based on discussions in Section 5.5 on solvent and thermal annealing of both small molecule and polymer blends.

#### 7.4.3.1 Dependence of efficiency on morphology: theoretical perspectives

The ideal diode equation for excitonic HJs provides insights into how morphology impacts efficiency. The external efficiency in Eq. 7.48 depends on the product of the efficiencies of processes leading to charge generation. The objective of the BHJ is to reduce the distance between the point of photon

absorption to the site of exciton dissociation at the D-A interface, such that the exciton diffusion efficiency,  $\eta_{ED} \rightarrow 1$ . The blended active region, unfortunately, also creates a long and tortuous route for the charges generated at the heterointerface that increases the probability for Langevin or bimolecular recombination. This results in a charge collection efficiency,  $\eta_{CC} < 1$ . The optimal morphology, therefore, must simultaneously maximize both  $\eta_{ED}$  and  $\eta_{CC}$ .

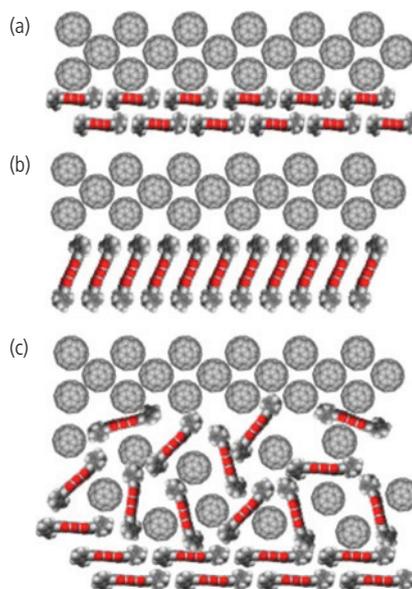

The morphology also controls the ability for the PP to dissociate into free charges. The complex process of free charge generation at the heterointerface discussed in Section 4.7.2 is folded into the charge transfer efficiency,  $\eta_{CT}$ . Recall that the current of an excitonic HJ given by Eq. 7.55 is a function of two morphology-dependent terms: the saturation current and the photocurrent ( $j_0$  and  $j_{ph}$ , respectively). That is,  $j_0 \propto 1 - \eta_{PPd}$  and  $j_{ph} \propto \eta_{PPd}$ , where  $\eta_{PPd}$  is the PP dissociation efficiency given by  $\eta_{PPd} = k_{PPd}/(k_{PPd} + k_{PPr})$  (cf. Eq. 7.53). Thus, morphologies that lead to  $k_{PPd} \gg k_{PPr}$  maximize  $j_{ph}$  (and hence  $j_{SC}$ ), while simultaneously minimizing the dark current,  $j_0$ , both of which lead to an increase in  $V_{OC}$  (Eq. 7.122). Moreover, Onsager-Braun theory shows that exciton dissociation into free polarons is enhanced by an applied electric field, that is,  $k_{PPd} = k_{PPd}(F)$ . Then, from Eq. 7.123 we find that  $V_{OC} = V_{OC}^0 + \frac{n_s k_B T}{q} \log(\eta_{PPd})$ , where we take  $k_{PPd} \propto k_{rec}$  at low voltage, and  $V_{OC}^0$  is the open circuit voltage in the absence of recombination, that is,  $k_{PPr}$  or  $k_{rec}$  are negligibly small.

A consequence of this analysis is that there is a significant benefit to maximizing the rate of PP dissociation vs. recombination. This is apparent from the plot of the calculated  $j$ - $V$  characteristics of an ideal diode in Fig. 7.71 for various ratios of  $k_{PPd}/k_{PPr}$ . All three critical parameters governing the power conversion efficiency, that is,  $V_{OC}$ ,  $j_{SC}$ , and  $FF$ , are significantly increased as  $k_{PPd}/k_{PPr}$  is increased from 0.01 to  $10^3$ .

The ideal morphology is, therefore, one that minimizes  $k_{PPr}$  by decreasing the electronic coupling between D and A molecules at the HJ. This is achieved by using compounds that are sterically hindered from close packing, thus limiting the orbital overlap with neighboring molecules across the HJ. Unfortunately, steric hindrance can also lead to poor coupling between like molecules. That is, it can reduce either or both of the D-D or A-A molecular couplings. This increases the resistance to charge transport along percolating paths from the point of exciton dissociation to the electrodes, thereby

decreasing  $\eta_{CC}$  and increasing cell series resistance (and thus decreasing  $FF$ ). Hence, the preferred morphology is one that achieves a delicate balance between order needed for low resistance conduction, and disorder that promotes exciton dissociation very near to their point of origin.

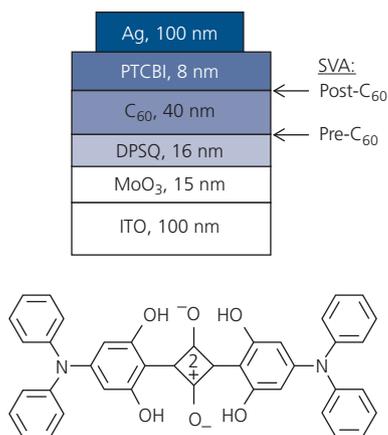

Example HJ morphologies and their potential influence on  $k_{PPr}$  are illustrated in Fig. 7.137 for a model interface between  $C_{60}$  and a planar donor molecule (Wang et al., 2011). Figure 7.137a shows an ordered arrangement of donor molecules with their planar surface adjacent to the  $C_{60}$  layer. Presumably, the  $\pi$ -orbitals are parallel to the planar face and hence overlap with that on the  $C_{60}$  molecules. This leads to strong interactions between electronic systems, thus increasing  $k_{PPr}$  at the expense of  $k_{PPd}$ . Figure 7.137b shows an edge-on arrangement. Here the  $\pi$ -systems extend between adjacent donor molecules, but do not significantly overlap with those of  $C_{60}$ . In this situation, we anticipate that  $k_{PPr}$  is small. However, conduction of photogenerated holes to layers below the interface is problematic given the presumed edge-on relationship of the donor molecules in the underlying bulk layer. The optimal situation is shown in Fig. 7.137c comprising an interface where the D and A molecules interdiffuse, leading to limited

**Figure 7.137** Three morphologies formed at interfaces between  $C_{60}$  and an archetype planar donor molecule. (a) Ordered interface with strong intermolecular coupling. (b) Ordered interface with weak intermolecular coupling. (c) Interdiffusion of D and A molecules at the interface with a combination of couplings. Ordered structures lie beyond the interface region.

disorder. In the bulk, away from the interface, both the D and A molecules form ordered structures that support a high conductivity for both holes and electrons, respectively. While there are pairs of D and A molecules within the interface region that may have strong  $\pi$ - $\pi$  interactions, on average those interactions are considerably smaller than in the ordered structure of Fig. 7.137a. This structure achieves the necessary balance of a high  $k_{ppd}/k_{ppr}$  as well as a high conductivity through the layer bulk (and hence a high  $FF$  and  $j_{sc}$ ).

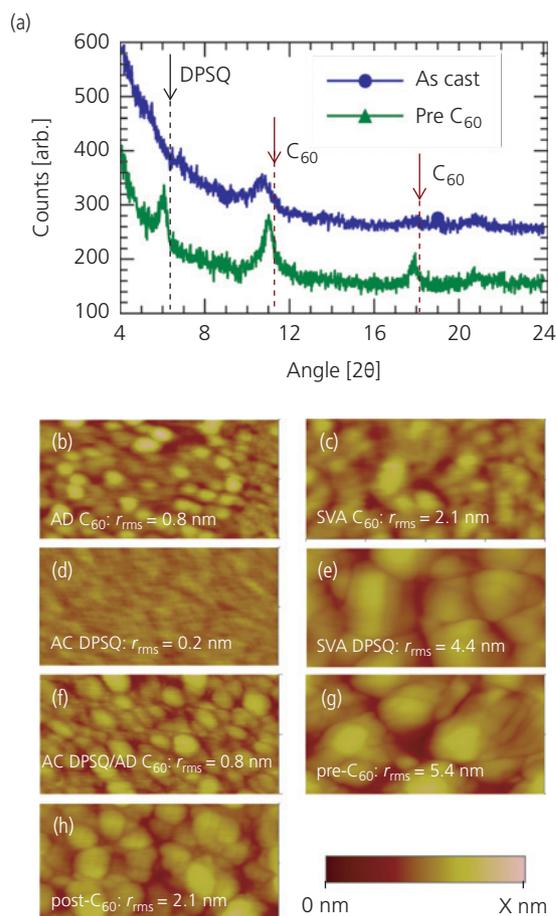

Proposing desired morphologies, that is, disorder at interfaces and order within the bulk, is one thing, but achieving them and showing that they are effective in increasing efficiency is a more daunting challenge. A series of experiments that were directed at independently tailoring the morphologies at the interface and in the bulk of bilayer DPSQ/C<sub>60</sub> HJ OPVs endeavored to directly test the validity of these concepts (Zimmerman et al., 2012). The OPV structure is shown in Fig. 7.138 along with the molecular structural formula for the SQ donor, DPSQ. The donor is spun on a MoO<sub>3</sub> surface from a chloroform (CF) solution. In the “as-cast” (AC) device, the C<sub>60</sub> layer was subsequently thermally evaporated onto the DPSQ surface, followed by the PTCBI EBL and the Ag cathode. In the “pre-C<sub>60</sub>” device, immediately following DPSQ deposition, the donor layer was solvent vapor annealed for 10 min in a sealed vial containing DCM (Wei et al., 2011a). Solvent vapor

**Figure 7.138** The structure used to control interface and bulk film morphologies. Also shown is the molecular structural formula of DPSQ. Three different devices were tested: “as-cast” where the entire device was constructed without annealing, “pre-C<sub>60</sub>” where the DPSQ was solvent vapor annealed prior to deposition of the remaining layers of the device, and “post-C<sub>60</sub>” where the device was completed up to the deposition of C<sub>60</sub> prior to SVA, followed by deposition of the PTCBI exciton blocking layer and cathode.

annealing (SVA) entails the infusion of solvent molecules that re-dissolve the film, allowing the molecules to readjust to a lower energy, crystalline state. Solvent annealing promotes mass transport over large distances, resulting in the growth of nanocrystalline domains. The annealing time is chosen to optimize both efficiency and yield. Subsequent to the annealing step, the remainder of the layers used in the as-cast device in Fig. 7.139 were deposited. The “post-C<sub>60</sub>” process employed SVA after the C<sub>60</sub> deposition but before completing the device.

Morphologies of AC and pre-C<sub>60</sub> films studied using X-ray diffraction data shown in Fig. 7.139a.

**Figure 7.139** (a) X-ray diffraction patterns identifying molecular peaks in both as cast (AC) and pre-C<sub>60</sub> thin films. (b)–(h) AFM images of the surfaces of as deposited (AD) and SVA films of C<sub>60</sub>, AC and SVA films of DPSQ, and AC DPSQ/C<sub>60</sub>, pre- and post-C<sub>60</sub> films. The root mean square roughness,  $r_{rms}$ , is shown in each image. The scale bar at lower right corresponds to (b)  $X=10$  nm, (c, f, h)  $X=20$  nm, (d)  $X=5$  nm, and (e, g)  $X=50$  nm. All fields of view are  $1 \times 0.5 \mu\text{m}$  (Zimmerman et al., 2012).

Independent Control of Bulk and Interfacial Morphologies of Small Molecular Weight Organic Heterojunction Solar Cells. *Nano Letters*, 12, 4366–4371. Copyright 2012 by the American Chemical Society.

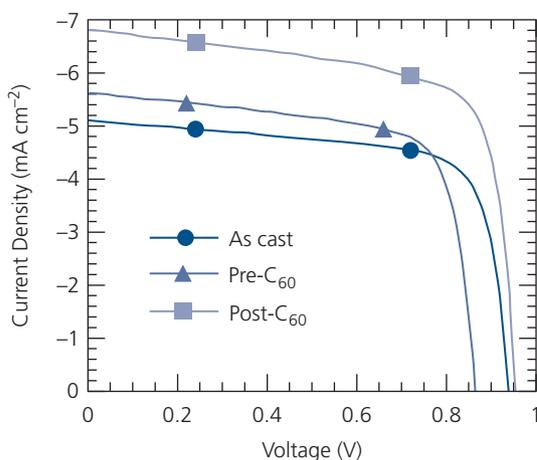

The AC film shows no DPSQ feature, although two weak peaks associated with  $C_{60}$  indicate limited crystallization. In contrast, the pre- $C_{60}$  pattern shows that both DPSQ and  $C_{60}$  exhibit long range order. Apparently, crystallization of DPSQ provides a template on which the  $C_{60}$  can form crystallites on a larger scale than when deposited onto amorphous AC DPSQ films. The post- $C_{60}$  structure also shows  $C_{60}$  crystalline order although there is no corresponding peak for DPSQ. Nevertheless, absorption spectra of the film have a pronounced dimer peak due to DPSQ, indicating the presence of at least small ordered domains arising from this treatment.

Film surface morphologies also show evidence for DPSQ crystallization due to SVA, see Figs. 7.139b–h. As-deposited  $C_{60}$  and AC DPSQ surfaces are smooth, with rms roughnesses of 0.8 nm and 0.2 nm, respectively, which is indicative (although not proof) of an amorphous film. However, when exposed to SVA, the  $C_{60}$  and DPSQ roughness increases to 2.1 nm and 4.4 nm due to formation of nanocrystallites. This roughness appears in the pre- $C_{60}$  sample, although the post- $C_{60}$  roughness is similar in scale to that of the SVA  $C_{60}$  sample. Thus, it appears that the  $C_{60}$  layer prevents the underlying DPSQ surface from roughening, even though it undergoes a degree of internal crystallization. The  $C_{60}$  cap layer preserves the interface disorder while allowing the molecules within the film bulk to adjust during annealing (Peumans et al., 2003a).

The morphological studies indicate that the AC sample is completely amorphous, both at the interface and within the bulk. The pre- $C_{60}$  sample is ordered in both the D and A layers, and at their interface. The post- $C_{60}$  film most likely has ordered bulk layers, but the presence of the  $C_{60}$  cap locks in disorder at its interface with DPSQ. These conclusions are supported by the  $j$ - $V$  characteristics in Fig. 7.140. We make the following observations. (i) The AC sample has a high  $V_{OC} = 0.94$  V, but  $j_{SC} = 5.3$  mA/cm<sup>2</sup> is relatively low. The high  $V_{OC}$  suggests that  $k_{PPd}/k_{PPr}$  is large (cf. Eq. 7.123) due to disorder, but it is difficult to extract charge through the amorphous bulk. (ii) The pre- $C_{60}$  has a high degree of order in the bulk, leading to an increase in  $j_{SC}$ , but the order at the interface increases molecular coupling between  $C_{60}$  and DPSQ, reducing  $k_{PPd}/k_{PPr}$ , and hence  $V_{OC} = 0.86$  V. (iii) The ordered bulk of post- $C_{60}$  results in the highest  $j_{SC} = 7.0$  mA/cm<sup>2</sup>, while disorder locked in at the as-grown interface maintains a high  $k_{PPd}/k_{PPr}$ , resulting in  $V_{OC}$  similar to the disordered AC device.

The interplay between interface and bulk morphologies is summarized in Fig. 7.141. The results

provide compelling evidence that disorder at the interface leads to reduced intermolecular electronic coupling, and thus an increased  $V_{OC}$ , but the disorder in the bulk leads to a decreased charge extraction, and hence a low  $j_{SC}$ . The ideal diode analysis in Section 4.7.2, points to the essential role of morphology in determining OPV performance. While these results are obtained for a bilayer, small molecule diode comprising both solution and vapor deposited molecular species, the conclusions also apply to polymer-based devices. In the following section, we will show several approaches for achieving optimized morphologies in both solution and vapor processed cells. The precise control exhibited for the DPSQ/ $C_{60}$  system is by no means easy to achieve with other

**Figure 7.140** Current density–voltage characteristics of the OPVs in Fig. 7.138 (Zimmerman et al., 2012).

materials or processes, although it is necessary for reaching a high OPV efficiency.

In addition to influencing charge transfer, the degree of interface order impacts the energy loss associated with charge transfer. Indeed, this is implied in the foregoing experiments, where we have seen that  $k_{ppr}$  increases with order, suggesting that the CT energy is lower (and consequently the energy loss larger) for more ordered interfaces due to stronger intermolecular interactions across the HJ. The relationship between interface order and the CT energy is illustrated in Fig. 7.142a. The D-A junction comprising, in this example, a donor polymer and a fullerene acceptor, can assume several morphologies

whose CT energies are, in descending order: (i) fully disordered, (ii) ordered on the donor side, disordered on the other, (iii) disordered on the donor side, ordered on the other, and (iv) ordered on both sides of the D-A junction. This picture is strikingly similar to Fig. 7.141 used to describe CT at small molecule HJs.

The CT state energies in ternary blend OPVs comprising a mixture of amorphous (AnE-PV**ba**) and semicrystalline (AnE-PV**ab**) donor polymers with PC<sub>61</sub>BM were analyzed to understand whether the energy loss picture in Fig. 7.142a is valid. Here, AnE-PV**ab** is an anthracene-containing poly(*p*-phenyleneethynylene)-*alt*-poly(*p*-phenylenevinylene) copolymer (AnE-PV), with octyloxy side-chains at the

**Figure 7.142** (a) Illustration of the relationship between interface morphology and the CT energy for (from left) fully disordered interface; order on one side, disorder on the other; disorder/order; and a fully ordered interface. For this example, the donor is a polymer (lines) and the acceptor is PC<sub>61</sub>BM. (b) CT electroluminescence spectra obtained by fitting the full EL data to a Gaussian-Lorentzian function for different concentrations of an amorphous donor polymer (AnE-PV**ba**) in a ternary blend also comprising the semicrystalline donor, AnE-PV**ab**, and PC<sub>61</sub>BM. After Kästner et al. (2017).

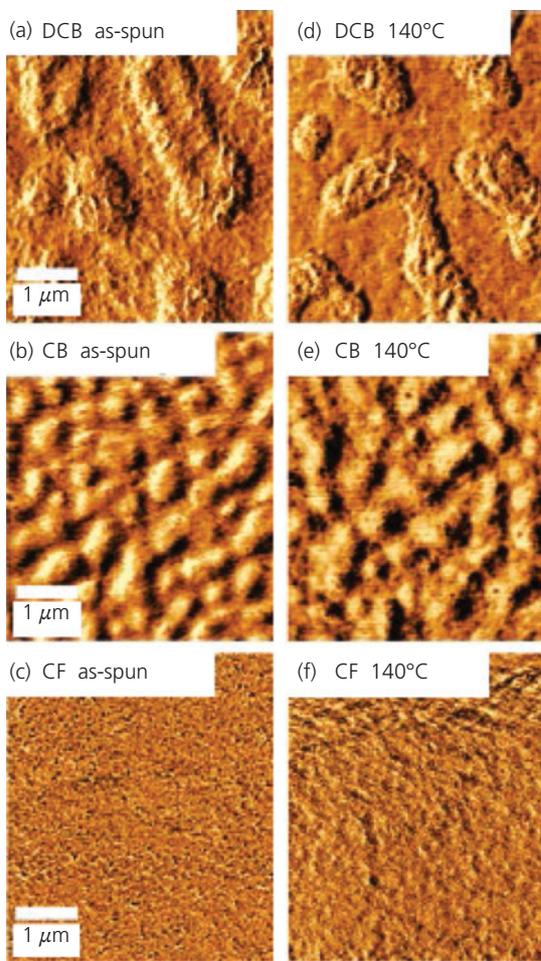

PPE side, and 2-ethylhexyloxy side-chains at the PPV-side. Amorphous AnE-PVba comprises AnE-PV with 2-ethylhexyloxy side-chains at the PPE side and octyloxy side-chains at the PPV. The CT EL spectra obtained by current injection, vs. concentration of the amorphous phase of the donor polymer were measured and fit to a Gaussian–Lorentzian line shape function to extract the EL peak energies. The results of the fits are shown in Fig. 7.142b. The highest energy CT state,  $CT_1$  is at  $E_{CT1} = 1.513$  eV, and is found in the fully disordered OPV. As the ratio of the disordered phase, AnEPVba, to the ordered AnEPVab, donor is increased, the CT state energies decrease from  $E_{CT1} = 1.513$  eV to  $E_{CT3} = 1.386$  eV to  $E_{CT2} = 1.308$  eV to  $E_{CT4} = 1.233$  eV, consistent with the picture in Fig. 7.142a. This is similar to the DPSQ/ $C_{60}$  system in Fig. 7.141, and consistent with predictions from theory in Section 4.7.2.

#### 7.4.3.2 Optimizing morphology during deposition and processing

Here we provide a few examples where morphological control leads to high performance. The following discussion is not meant to be an exhaustive treatment of a very large field, but rather an introduction to those morphologies that are beneficial, and some of the characteristics that they introduce into the active regions of OPVs.

**Structural annealing.** Annealing an as-deposited film adds energy to the system, allowing molecules that are in a metastable configuration (e.g. in an amorphous structure) to reorganize into a more stable, lower energy state. This creates nano- or microcrystalline domains, driving towards a large surface area D-A junction. The domains themselves have low resistance due to high charge mobilities compared to amorphous regions. Intimate packing of the crystalline and amorphous phases can lead to a higher optical density, and hence higher external quantum efficiency. These effects ultimately increase  $j_{SC}$  and  $FF$ , although increased interfacial order can have the unintended consequence of a reduced  $V_{OC}$ .

The solvents used in casting the materials into films, as well as the duration and temperature used, have a significant impact on BHJ morphology (Li et al., 2005, Mori et al., 2011, Mori et al., 2015). An example of such effects is observed in the AFM images Fig. 7.143 of non-fullerene P3HT:PF12TBT (1:1) BHJs that are solution cast from three solvents with widely differing boiling points (BP), *o*-dichlorobenzene (DCB, BP = 180°C), chlorobenzene (CB, BP = 131°C), and CF (BP = 61.2°C). The large-scale surface morphology depends on solvent, with

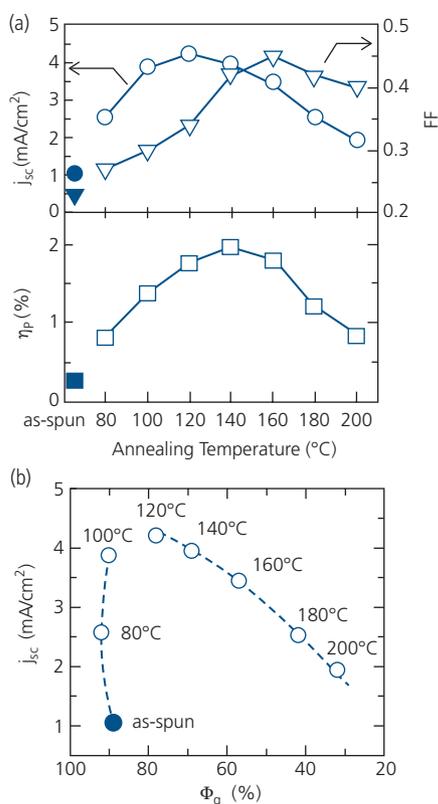

**Figure 7.143** AFM images of both (a–c) as-spin-cast, and (d–f) thermally annealed P3HT:PF12TBT film surfaces using different solvents (DCB, CB, CF) during casting. Annealing conditions are 140°C for 10 min (Mori et al., 2011).

Polymer/Polymer Blend Solar Cells with 2.0% Efficiency Developed by Thermal Purification of Nanoscale-Phase-Separated Morphology. *ACS Applied Materials & Interfaces*, 3, 2924–2927. Copyright 2011 by the American Chemical Society.

the largest phase separation of the donor and acceptors occurring for the highest BP solvents. Spin-casting in the low boiling point CF, results in an apparently homogeneous blend without evidence for phase separation. Hence, there is a monotonic dependence of domain size on solvent boiling point temperature. Thermal annealing does not noticeably change the surface morphology of the as-cast films. The high BP solvents take longer to evaporate, giving the D and A molecular species more time to phase separate.

A qualitatively different picture emerges when we examine the performance of OPVs comprising these same active regions after thermal annealing in

**Figure 7.144** The dependence of (a) performance of P3HT/PF12TBT BHJ OPVs vs. thermal annealing temperature for 10 min in N<sub>2</sub>. All devices are spin-cast from a CF solution. (b)  $j_{sc}$  vs. the PL quenching efficiency,  $\Phi_q$ , vs. annealing temperature (Mori et al., 2011).

N<sub>2</sub> at various temperatures. The devices were spin-cast from CF with the structure: ITO/PEDOT:PSS (40 nm)/P3HT:PF12TBT (1:1, 70 nm)/LiF (1 nm)/Al. Figure 7.144a shows  $j_{sc}$ , FF, and  $\eta_p$  of the devices vs. annealing temperature,  $T_{anneal}$ . Figure 7.144b shows  $j_{sc}$  vs. the PL quenching efficiency,  $\Phi_q = 1 - PL_{blend}/PL_{neat}$ , and  $T_{anneal}$ . Here,  $PL_{neat}$  is the PL intensity of a neat film of PF12TBT, and  $PL_{blend}$  is the intensity of the P3HT:PF12TBT blend. We expect that excitons are immediately dissociated followed their generation, leading to  $\Phi_q \rightarrow 1$ , in a perfectly homogeneous mixture of D and A molecules. On the other hand, the excitons radiatively recombine prior to dissociation in domains whose size is much greater than the diffusion length, leading to  $\Phi_q \rightarrow 0$ . Thus,  $\Phi_q$  gives a qualitative measure of the ratio of grain size to  $L_D$ , the latter of which is on the order of a few tens of nanometers.

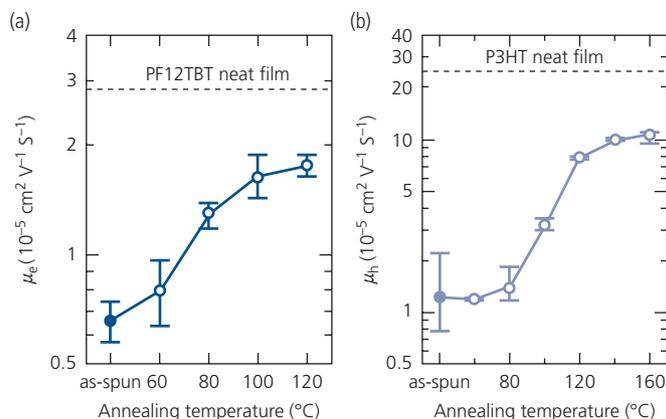

From Fig. 7.144b, we find that  $j_{sc}$  is at a minimum for the as-spun device, increasing to a peak at  $T_{anneal} = 120^\circ\text{C}$ , and decreasing as temperature is further increased. This suggests that the as-spun film is

homogeneous with very small, or nonexistent PF12TBT domains, resulting in  $\Phi_q \approx 1$ . The donor and acceptor components are so thoroughly intermixed that there are few continuous paths to extract charges once the excitons dissociate at the domain boundaries. This is confirmed by the small  $j_{sc}$  and FF for the as-spun films. As  $T_{anneal}$  is increased, the molecules reorganize into larger domains that form a *bicontinuous network* that extends to the OPV electrodes, yet the domain sizes are still less than  $L_D$ . At  $T_{anneal} = 120^\circ\text{C}$ , the domains are  $\sim L_D$ , leading to a maximum  $j_{sc}$ . Interestingly, FF continues to increase as  $T_{anneal}$  is further increased. Thus, the PF12TBT domains continue to grow, leading to improved electron conduction (and presumably better hole conduction on P3HT). However, the excitons may not have an equally large probability to dissociate before recombining in the larger domains, and hence  $j_{sc}$  decreases. This results in a peak power conversion efficiency and quenching ratio at  $T_{anneal} = 140^\circ\text{C}$ .

The electron mobility in PF12TBT and the hole mobility in neat P3HT, and in P3HT:PF12TBT (1:1) blends are plotted vs.  $T_{anneal}$  in Fig. 7.145. The mobilities are extracted from the  $j$ - $V$  characteristics in the space-charge limited conduction regimes of hole- and electron-only devices (Section 4.4.2). The neat films have significantly higher mobilities than the blends. However, as the films are annealed, both electron and hole mobilities increase significantly, reaching a maximum at  $T_{anneal}$  between 120–140°C. These trends track those of the FF in Fig. 7.144, due to the interrelationships between mobility, FF, and  $R_{ser}$ .

This study clarifies the different effects that film deposition and post-deposition annealing have on film morphology, and consequently device performance. The choice of solvents and other deposition conditions creates a global morphology that may, or may not be optimized for both exciton dissociation and charge collection. On the other hand, annealing can provide additional energy that allows the molecules to seek a configuration closer to equilibrium, forming nanodomains of D and A molecules whose size is controlled by the annealing conditions. If the process is driven too far, the domains become so extensive that the device performance once more is reduced. This suggests that the optimum BHJ morphology is metastable, with obvious implications concerning the long-term performance of the devices themselves (see Section 7.8).

SVA can also create internal order. The small solvent molecules diffuse into the film, preferentially dissolving one of the components, which is then free to reorganize into phase-separated domains. The

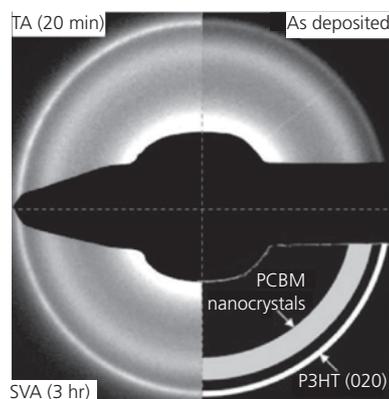

**Figure 7.145** (a) Electron and (b) hole mobilities vs.  $T_{\text{anneal}}$  for P3HT:PC<sub>61</sub>BM (1:1) films (Mori et al., 2015).

archetype polymer-based P3HT:PC<sub>61</sub>BM 1:1 blend morphology was studied by spin casting from a DCB solution onto a glass substrate pre-coated with ITO and 70 nm PEDOT:PSS. The samples were thermally annealed for 20 min at 130°C. Alternatively, the film was solvent annealed by drying at room temperature in a covered container for 3 h. Electron diffraction patterns of 100 nm thick P3HT:PC<sub>61</sub>BM as-deposited films, and films subjected to SVA and TA are shown in Fig. 7.146. The outer ring corresponding to the (020) crystalline plane of as-deposited P3HT is considerably weaker than for either the TA or SVA samples. In contrast, the PC<sub>61</sub>BM ring is broad, suggesting a nanocrystalline morphology. Moreover, the PC<sub>61</sub>BM diffraction intensity is not significantly affected by either annealing procedure. We conclude that annealing tends to organize the P3HT into crystalline domains, but has a much smaller effect on the PC<sub>61</sub>BM morphology. These smaller molecules evidently intercalate between the P3HT fibrils.

The relative influence of thermal vs. solvent annealing on the microstructure of P3HT:PC<sub>61</sub>BM blends was also studied by 3D electron tomography. Electron tomography has been developed primarily for examining biological specimens (Frank, 1992). *Electron tomography*, or *transmission electron microtomography* (TEM), constructs a 3D image of a sample by combining a series of 2D TEM images taken at closely spaced angles relative to the incident electron beam. The images are taken over a large observation angle, preferably the 180° half space above the sample plane. Fourier analysis is then used to construct a volume image from a composite of the 2D images (Jinnai et al., 2004).

The 3D morphologies of the blends in Fig. 7.146 are revealed in the 3D electron tomographs in Fig. 7.147.

**Figure 7.146** Electron diffraction patterns of as-deposited, thermally annealed (TA), and solvent vapor annealed P3HT:PC<sub>61</sub>BM (1:1) BHI thin films. The fourth quadrant is used to identify the diffraction features (van Bavel et al., 2009).

The P3HT fibrils are very short and disorganized in the as-deposited sample. Further, there does not appear to be a significant change in their density as the film thickness is traversed from top to bottom. The volume image shows a relatively featureless film structure throughout. Imaging the TA and SVA samples slice by slice through the film tells a different story. The P3HT crystallites are several microns long, typically ~15 nm wide and only a few nanometers thick. Furthermore, they appear to form a denser network near the bottom of the film vs. toward the top. There are no remarkable differences in the appearance of either the TA or SVA samples. The differences with the as-deposited sample are particularly striking. The P3HT volume fraction increases from ~25% near the top of the sample, to 45% near the bottom. From this we infer that the PC<sub>61</sub>BM had

the opposite concentration gradient, with the film being richer in PC<sub>61</sub>BM near the top. This component segregation is important for OPV performance, since it explains why the cathode and anode are not shorted, as would be expected for a homogeneous, bicontinuous network of D and A regions spanning the entire active layer thickness.

**Solvent additives.** The addition of small molecular weight bipyridine or PC<sub>61</sub>BM increases coupling between porphyrin molecules to form strongly coupled macromolecular assemblies with high conductivity (see Section 7.2.2). Alternatively, additives can be used to selectively dissolve one of the molecular constituents in a blend. If the evaporation rate of the additive is less than that of the primary solvent, the species soluble in the additive reorganizes into a more ordered state. Numerous additive systems have been investigated to improve the nanocrystalline morphology of polymer-based BHJ systems (Peet et al., 2007, Lou et al., 2011, Sharenko et al., 2014).

The morphological evolution of films of a donor copolymer of diketopyrrolopyrrole and

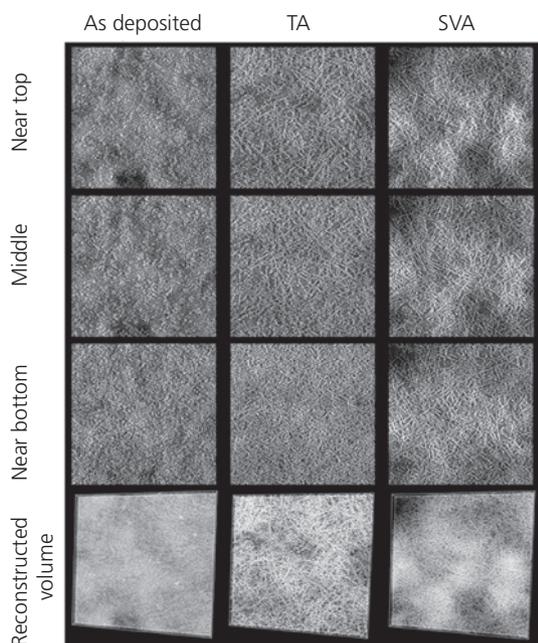

quarterthiophene (pDPP) mixed with PC<sub>71</sub>BM (1:1) has been tracked in real time by *in situ grazing incidence X-ray diffraction* (GIXD), and *grazing incidence small angle X-ray scattering* (GISAXS). Glancing incidence X-ray analysis has proven to be an essential tool for revealing both the molecular as well as the macrostructure of organic thin films, whether they are based on polymer or small molecules. The mixture was dissolved in a solution of CF and DCB. CF is a good solvent for pDPP, which is not the case for the high boiling point, DCB, which therefore selectively solubilizes PC<sub>71</sub>BM. Organic solar cells were fabricated by spin casting the D-A mixture onto an ITO/PEDOT:PSS coated glass substrate to form a 120–140 nm thick BHJ active layer capped with a LiF (1 nm)/Al (100 nm) cathode (Liu et al., 2012). A summary of OPV performance obtained using different CF:DCB additive concentrations is provided in Table 7.16. The additive results in significant improvements in efficiency, primarily a result of short circuit current. The best performance was for the device with a CF:DCB (4:1 vol. ratio), which presumably leads to the optimum nanomorphology.

The GIXD patterns as a function of drying time at room temperature for this system are shown in Fig. 7.148a. The highest peak corresponds to the (100) crystal plane of PC<sub>71</sub>BM. It grows slowly after solvent exposure, then accelerates in intensity, and finally saturates into a stable morphology. The peak intensity is plotted in Fig. 7.148b. As drying proceeds, the film weight decreases rapidly within the first 100 s due to evaporation of CF, and then slowly continues to decrease as the less volatile DCB additive slowly leaves the film.

The size of the crystalline clusters can be estimated from their *radius of gyration* ( $R_g$ ). This quantity is determined by tracking the intensity of the GISAXS diffraction at small scattering angles, that is, small  $q$ , following

$$I(q) \approx I(0) \exp\left(-q^2 R_g^2 / 3\right), \quad (7.178)$$

where  $I(q)$  is the X-ray intensity at  $q$ . Equation 7.178 is known as the *Guinier approximation* that applies to approximately spherical clusters (Guinier and Fournet, 1955, Putnam, 2016). In Fig. 7.148b, we

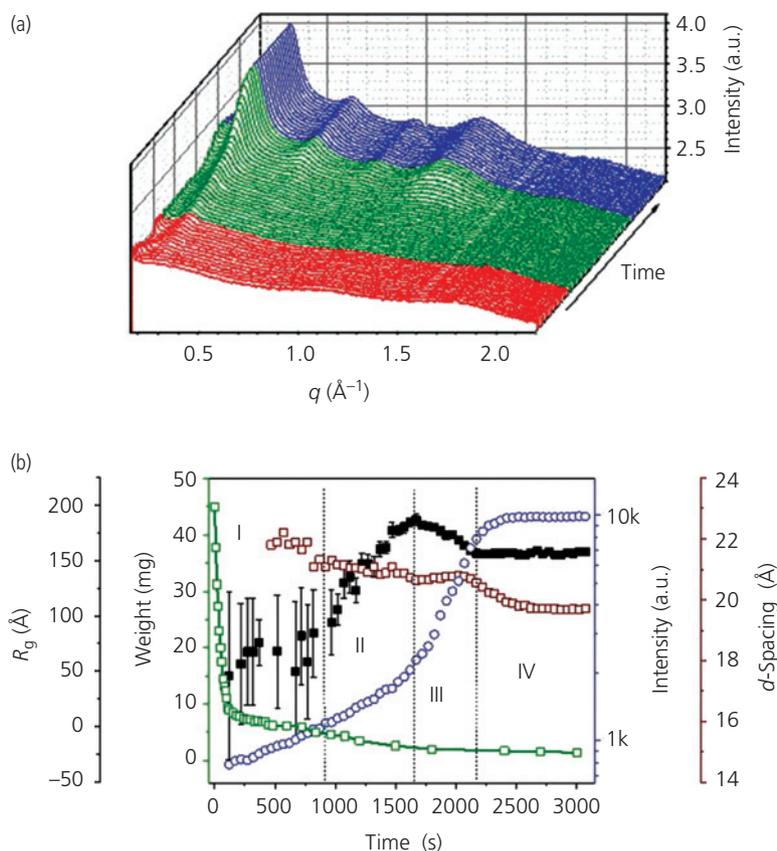

**Figure 7.147** Electron tomographs of P3HT:PC<sub>61</sub>BM (1:1) blends that are freshly deposited, thermally and solvent vapor annealed. The images from electron tomography from near the bottom, in the middle and near the top of the layer are assembled, along with images taken at other angles (and thus depths) to reconstruct the volume images at the bottom. The field of view is 1.7  $\mu\text{m} \times 1.7 \mu\text{m} \times 100 \text{ nm}$  thick (van Bavel et al., 2009).

4:1	0.63	14.8	60	5.6

**Figure 7.148** (a) GIXD diffraction pattern tracking the structural evolution during drying of a pDPP:PC<sub>71</sub>BM BHJ film infused with a CF:DCB (1:4) solvent additive. The highest peak corresponds to the (100) crystal plane of PC<sub>71</sub>BM. The next two adjacent satellite peaks correspond to reflections from the (200) and (300) planes. (b) From X-ray and other data, the domain radius of gyration ( $R_g$ , solid squares), film weight (green open squares), (100) diffraction peak intensity (blue open circles) and crystal  $d$ -spacing (red squares) are obtained as a function of film drying time. The morphological changes are divided into four periods (see Fig. 7.150) (Liu et al., 2012).

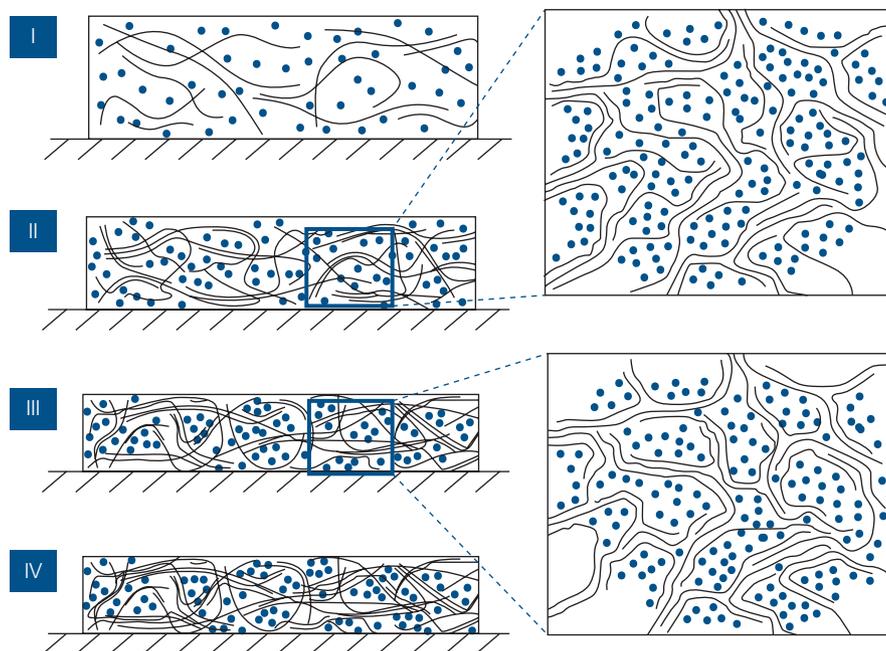

find that  $R_g \approx 50 \text{ \AA}$  for the as-deposited film. As the film dries, the crystallites grow until  $R_g$  peaks at  $200 \text{ \AA}$  after  $1600 \text{ s}$ , and then decreases slightly to a saturation value of  $150 \text{ \AA}$ . The  $d$ -spacing steadily declines by  $\sim 2 \text{ \AA}$  during drying, reaching a steady state value of  $20 \text{ \AA}$ .

These data give a detailed picture of the crystallization process summarized by the illustrations in Fig. 7.149. Initially (zone I, Figs. 7.148 and 7.149), there is considerable solvent infused that creates a nearly homogeneous blend of pDPP and PC<sub>71</sub>BM. As the CF evaporates, the pDPP begins to crystallize, forming fibrils. The loss of solvent volume results in film compaction and a concomitant loss of weight. However, the more slowly evaporating additive, DCB, keeps the PC<sub>71</sub>BM in solution and mobile within the film (zone II), during which pDPP continues to crystallize forming fibrils of increasing length. The remaining additive evaporates during zone III, causing crystalline PC<sub>71</sub>BM domains to form in the regions

between those of pDPP. The decrease in  $d$ -spacing over time results from the evaporation of residual solvent in the interstices between the pDPP chains. Finally, all of the primary solvent and additive has evaporated, leaving a stable, compact and ordered structure that has a higher conductivity and optical density than the as-deposited film (zone IV).

The various solution-based processes such as slow drying, thermal annealing, and the use of additives are qualitatively similar in that they use time and energy to drive a non-equilibrium structure toward a lower energy, and stable morphology.

*Achieving nanocrystalline thin films during vapor deposition.* Thus far we have focused on post-deposition processes to achieve a desired nanocrystalline morphology in solution-based thin films. In Section 5.4.2 we have shown that the morphology of small molecule thin films can be controlled during both VTE and OVPD growth. Here, we focus on the development of nanocrystalline structures during growth in DBP:

**Figure 7.149** Conceptual illustration of the morphological evolution of the pDPP:PC<sub>71</sub>BM BHJ film inferred from the data in Fig. 7.148. Here, I–IV correspond to each of the zones in Fig. 7.148b. Lines = pDPP, dots = PC<sub>71</sub>BM (Liu et al., 2012).

C<sub>70</sub> mixed HJs. This system is of particular interest due to several remarkable properties that lead to high efficiency photon-to-charge conversion. Like the P3HT:PCBM system, DBP:C<sub>70</sub> mixed HJs have been thoroughly studied due both to its high efficiency, and the understanding that it has brought to the relationship between nanostructure, optical absorption properties, and charge generation (Fujishima et al., 2009, Hirade and Adachi, 2011, Yokoyama et al., 2012, Xiao et al., 2013). One particularly notable feature is that when used in a mixed HJ, the optimum fraction of DBP to C<sub>70</sub> is much less than 1:1. In Table 7.17 we show that when 40 nm thick co-deposited DBP:C<sub>70</sub> blends on a ITO/MoO<sub>3</sub>-coated glass substrate are capped with a 8 nm thick Bphen EBL and an Al cathode, the highest power conversion efficiencies and *FF* are achieved at DBP fractions of 10–12%. (Xiao et al., 2013) When the mixed HJ is capped with a neat C<sub>70</sub> layer to form a planar-mixed structure, the power conversion efficiency increases from 4.7%, to 6.4%.

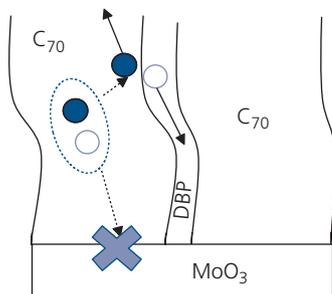

To explain the high efficiencies achieved with such a dilute donor concentration, it was proposed that the DBP and C<sub>70</sub> form separate domains during VTE growth, as illustrated in Fig. 7.150. The domains are sufficiently extensive to allow for conduction of both electrons and holes along uninterrupted paths to their

**Table 7.17** Device performance for various DBP:C<sub>70</sub> blend ratios (Xiao et al., 2013)

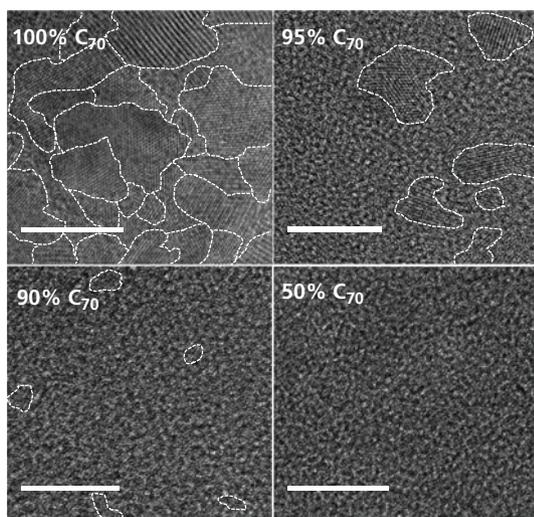

Blend ratio	$V_{OC}$ (V)	$j_{SC}$ (mA/cm <sup>2</sup> )	<i>FF</i>	$\eta_P$ (%)
1:4	0.85	9.1	0.50	3.9
1:6	0.87	9.5	0.53	4.4
1:8	0.89	9.7	0.55	4.7
1:10	0.90	9.3	0.55	4.5

respective electrodes. The microstructure of blends with various C<sub>70</sub> concentrations were examined by TEM, with a sampling of images shown in Fig. 7.151. The nanocrystalline domain size for neat C<sub>70</sub> is 20–50 nm, but it decreases rapidly with increasing DBP concentration. This suggests that C<sub>70</sub> domains are replaced by DBP nanocrystals or by amorphous regions, neither of which are visible in the images.

An interesting feature of the DBP-C<sub>70</sub> CT state noted in Section 4.7.2 is its energy dependence on fullerene concentration. Since photogeneration of charges occurs via the CT state, the dependence of the CT state properties on concentration determines the OPV photogeneration efficiency. The EL spectra of the CT spectra of C<sub>70</sub> in blends with various C<sub>70</sub> concentrations are shown in Fig. 7.152. The

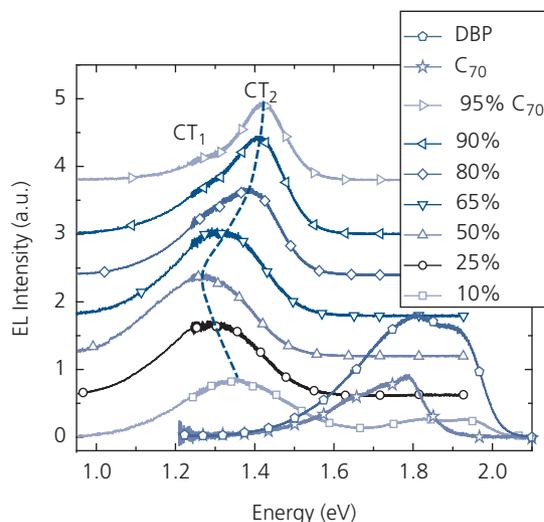

**Figure 7.150** Proposed morphology of a dilute DBP:C<sub>70</sub> mixed HJ in the region of the anode buffer. Due to the strong intramolecular interactions within DBP and C<sub>70</sub>, they segregate into continuous domains. For example, an exciton (dashed oval) generated in C<sub>70</sub> drifts to an interface with DBP where it dissociates into electrons (blue circles) and holes (open circles). The domains provide continuous paths to the electrodes for both carrier types. The "X" indicates that excitons migrating to the MoO<sub>3</sub> buffer are quenched.

**Figure 7.151** TEM images of DBP:C<sub>70</sub> for different C<sub>70</sub> concentrations. The dashed lines indicate the boundaries of C<sub>70</sub> nanocrystalline domains. Scale bars equal 20 nm (Liu et al., 2016c).

EL spectra are obtained by directly forming the CT state via charge injection under forward bias. The PL spectra provided in Fig. 4.108 show a similar dependence of CT peak position on DBP concentration. The singlet emission from DBP and C<sub>70</sub> in both PL and EL are at higher energies, and hence are well resolved from the CT emission. The two CT states (CT<sub>1</sub> and CT<sub>2</sub>) are apparent in both spectra. Interestingly, while CT<sub>1</sub> does not depend on blend ratio, CT<sub>2</sub> is strongly influenced by this parameter, initially

**Figure 7.152** Electroluminescence spectra of DBP:C<sub>70</sub> blends for various C<sub>70</sub> concentrations ranging from 0 (neat DBP) to 100% (neat C<sub>70</sub>). The excitonic spectra of DBP and C<sub>70</sub> are also shown at bottom (Liu et al., 2016c).

decreasing in energy as C<sub>70</sub> concentration is increased from 10% to 50%, and then increasing as the concentration is further increased.

The change of dielectric constant for different blend ratios has typically been invoked to explain the shift in  $E_{CT}$  (Loi et al., 2007, Piersimoni et al., 2011, Bernardo et al., 2014). However, the optical dielectric constant of DBP:C<sub>70</sub> blend increases monotonically with C<sub>70</sub> concentration. This fails to explain the trend of CT<sub>2</sub> that has an energy minimum at 50% C<sub>70</sub>, and a change in slope toward an apparent asymptote at > 80% C<sub>70</sub> concentration.

An alternative explanation is that the exciton binding energy responds to changes in CT state localization that depends on the size of the C<sub>70</sub> nanocrystals or DBP aggregates. As the C<sub>70</sub> concentration increases to > 50%, the electron on a C<sub>70</sub> nanocrystal bound to the hole on a DBP molecule at the domain boundary is delocalized over several C<sub>70</sub> molecules, leading to a decrease in the binding energy and therefore an increase of CT state energy. Similarly, as the C<sub>70</sub> concentration decreases below 50%, the DBP aggregate size increases, resulting in increased hole delocalization on the other side of the boundary.

This scenario has been modeled for CT states in blends with > 50% C<sub>70</sub> where the electron is confined in approximately spherical crystalline domains with average radii,  $\langle r_0 \rangle$ . An electron within the domain is confined by a potential barrier  $\phi_b = 0.5$  eV on its boundary, which corresponds to the difference

between the LUMO energies of DBP and C<sub>70</sub> (Xiao et al., 2013). The electron Hamiltonian is

$$H = -\frac{\hbar}{2m_e^*} \nabla^2 + V(\mathbf{r}),$$

$$V(\mathbf{r}) = \begin{cases} -\frac{q^2}{4\pi\epsilon_0\epsilon_r C_{70} |\mathbf{r} - \mathbf{a}|} & (|\mathbf{r} - \mathbf{r}_0| < r_0) \\ -\frac{q^2}{4\pi\epsilon_0\epsilon_r DBP |\mathbf{r} - \mathbf{a}|} + \phi_b & (|\mathbf{r} - \mathbf{r}_0| > r_0) \end{cases},$$
(7.179)

where  $m_e^*$  is the electron effective mass and  $|\mathbf{r} - \mathbf{a}|$  is the distance between the hole and the electron. The relative dielectric constants are  $\epsilon_{r,C_{70}} = 4.60$  and  $\epsilon_{r,DBP} = 3.92$  at  $\lambda = 900$  nm.

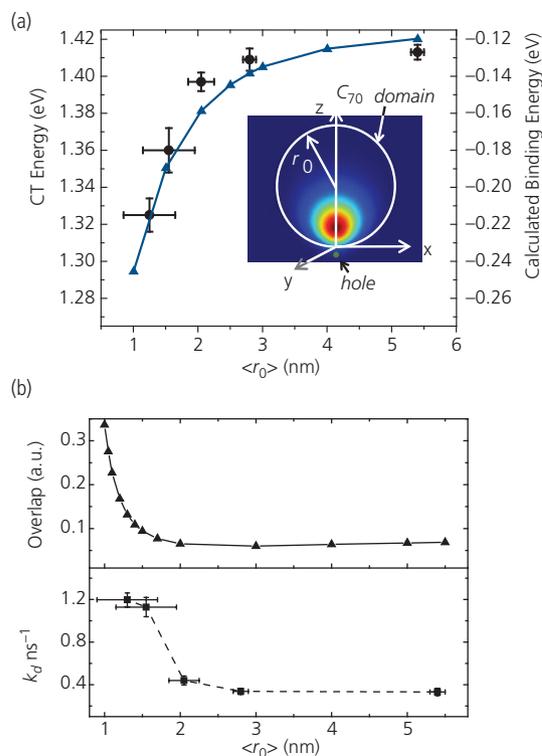

The domain radii are found via x-ray diffraction, where the (111) C<sub>70</sub> peak intensity and width are tracked vs. blend ratio. The mean radius of the domains is obtained from *Scherrer analysis* of the diffraction peak FWHM, given by

$$\langle r_0 \rangle \approx \frac{K\lambda_X}{\Delta\theta \cos\theta},$$
(7.180)

where  $K$  is a constant close to unity that depends on the shape of the crystallites,  $\lambda_X$  is the X-ray wavelength,  $\theta$  is the Bragg diffraction angle, and  $\Delta\theta$  is the FWHM of the diffraction line after removing broadening due to instrumental resolution limits. X-ray data yield mean radii ranging from 1 nm for 50% C<sub>70</sub>, to approximately 6 nm for neat C<sub>70</sub> films.

The energy eigenvalues of the Hamiltonian are obtained from Eq. 7.179, yielding the energy of the Coulombically bound electron states. The energy difference between the bound and unbound ( $V(\mathbf{r}) = 0$ ) states gives the CT binding energy, shown in Fig. 7.153a. The electron density of a Coulombically bound state for a C<sub>70</sub> domain radius  $\langle r_0 \rangle = 2$  nm is shown in the inset. The calculated binding energies fit reasonably well with the measured CT energy,  $E_{CT}$ , after including the 1.52 eV energy difference between the DBP HOMO and the C<sub>70</sub> LUMO.

The CT<sub>2</sub> lifetime is also dependent on the C<sub>70</sub> domain size, with the lifetime increasing with  $\langle r_0 \rangle$ , as shown in Fig. 7.153b. Quantum confinement in the C<sub>70</sub> domains with decreasing  $\langle r_0 \rangle$  leads to an increased overlap of the electron and hole probability densities, resulting in a concomitant increase in the CT<sub>2</sub> recombination rate. To model this dependence, the overlap of the probability density of the excited ( $|\psi_{CT}\rangle$ ) and ground states ( $|\psi_G\rangle$ ), that is,  $J = \int |\psi_{CT}|^2 |\psi_G|^2 dr^3$ , are calculated, where  $\psi_G$  is the electron wavefunction at the DBP HOMO obtained from time dependent density functional theory. The

overlap integral,  $J$ , vs. C<sub>70</sub> domain radius is shown in Fig. 7.153b, upper panel, which qualitatively agrees with the trend observed for the decay rate of CT<sub>2</sub>, in the lower panel.

The model was further tested by measuring the CT energies for nanostructures where the domain sizes were precisely controlled during growth. Transmission electron micrographs of ultrathin layer, alternating layers of DBP and C<sub>70</sub> grown by VTE are shown in Fig. 7.154. To enhance image contrast, the DBP is functionalized by attaching two Br molecules. It is noteworthy that continuous layers as thin as 2 nm are achieved using VTE. The CT<sub>2</sub> energy shift with layer thickness is in quantitative agreement with the data in Fig. 7.152 and 7.153, confirming the confinement of electrons and holes within C<sub>70</sub> and DBP of limited scale and dimension (Ding et al., 2018).

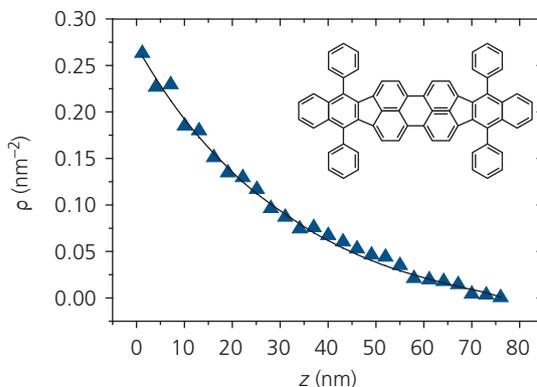

**Figure 7.154** (a) Bright field cross-sectional scanning transmission electron microscopic image of five pairs of 2-nm-thick alternating Br<sub>2</sub>-DBP/C<sub>70</sub> layers capped by a 20-nm-thick C<sub>70</sub> layer and a Ag protection layer. (b) Image of five pairs of 5-nm-thick alternating layers capped by a 20-nm-thick C<sub>70</sub> layer and a Ag layer. The quantum confinement of electrons thus results in a change in the CT state energy and lifetime. This, in turn affects the OPV efficiency due to the competition between the PP dissociation and its recombination rate (see Fig. 7.71). These results once more show the central role played by morphology in OPV active regions, and the necessity for its control either during or after film growth.

Thus far, we have found that details of the nanomorphology affect the energetics of the solid, but we need to clarify why mixtures with the donor diluted to only 10% of the total has the highest  $\eta_p$ . This implies that the absorption and charge collection efficiencies remain high even for such low donor concentrations. Dilute mixtures have also resulted in high efficiencies in polymer blends (Cates Miller et al., 2012). The DMC model in Section 7.1.2 has been used to simulate the morphologies of dilute DBP:C<sub>70</sub> blends to answer this question (Ding et al., 2018). The extended planar core of DBP (see inset, Fig. 7.155) encourages  $\pi$ - $\pi$  stacking between molecules that excludes C<sub>70</sub> molecules to the regions between the stacks. Holes resulting from exciton dissociation are extracted through the resulting contiguous, percolating paths of DBP molecules. The calculated 2D density of percolating paths for hole transport in a simulated solid grown on the anode contact by co-deposition of DBP and C<sub>70</sub> is given by

**Figure 7.155** Simulated 2D density of DBP percolating paths,  $\rho$ , in the substrate plane vs. distance from the anode contact,  $z$  (triangles). The line is an empirical exponential fit to the data following Eq. 7.182. Inset: Molecular structural formula of DBP. After Ding et al. (2018).

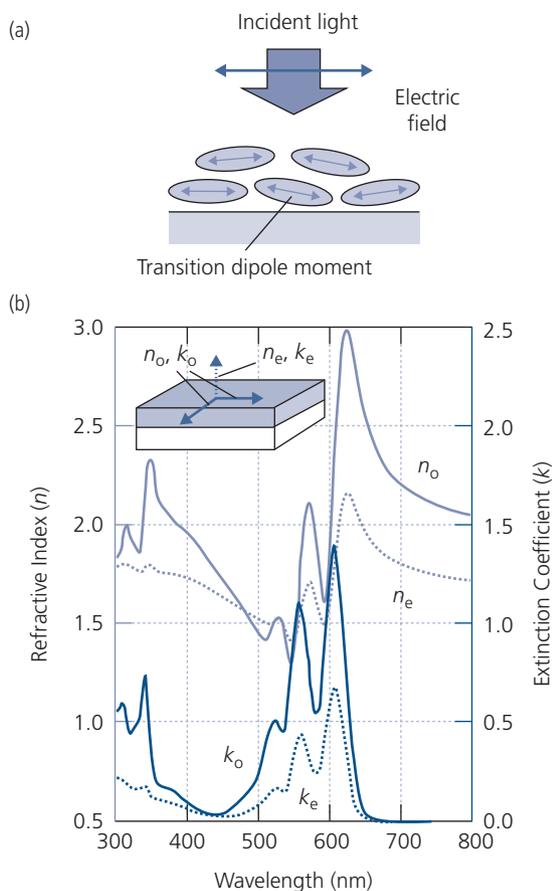

$$\rho(z) = N_p(z)/A. \quad (7.181)$$

Here,  $N_p(z)$  is the number of DBP molecules formed into continuous regions extending a distance  $z$  from the anode, and  $A$  is the anode contact area. Figure 7.155 shows the 2D density of percolating paths in the substrate plane in a blend with 10% DBP versus the distance from the anode. Empirically, the simulation follows

$$\rho(z) = \rho_0(z)e^{-z/\zeta}, \quad (7.182)$$

shown by the line in Fig. 7.155. Here,  $\rho_0$  is the 2D density of percolating paths originating at the anode. From the fit (solid line),  $\zeta = 33$  nm is the characteristic percolation length. At a mixed active region thickness of  $d = 50$  nm that is typical for an efficient OPV cell, then  $\rho \approx 0.05$  nm<sup>-2</sup> which corresponds to a mean distance between percolating paths of 4.5 nm. This is comparable the C<sub>70</sub> exciton diffusion length ( $\sim 4$ -8 nm), suggesting that the holes can be extracted throughout the active layer with a DBP concentration of only 10 mol.%. Thus,  $\pi$ - $\pi$  stacking of DBP results in a high density of continuous paths to the anode from DBP, and the cathode from the C<sub>70</sub> regions. Hence, the crystal packing characteristics of this system lead to  $\eta_{CC} \rightarrow 1$  as long as the thickness of the active region does not exceed the mean percolation length of the comprising molecular species.

A similar situation has been modeled for the packing of PBTTT and PC<sub>71</sub>BM. Molecular mechanics modeling shows that the PC<sub>71</sub>BM intercalates the PBTTT network forming a scaffold comprising the polymer backbone and side chains. These organized structures support electron and hole conduction over long distances from their point of origin, and yet place the

**Figure 7.156** (a) The DBP molecules have a large in-plane transition dipole moment that preferentially aligns parallel to the substrate plane. (b) The index of refraction and extinction coefficients to the extraordinary (e) and ordinary (o) incident wave exhibit a large anisotropy, or film birefringence (Yokoyama et al., 2012).

D and A molecules in intimate proximity that ensures efficient exciton dissociation (Cates Miller et al., 2012).

Finally, we must determine why the external efficiency, and hence  $\eta_A$ , is so high even though only 10% of the DBP molecules contribute to the absorption in the dilute blends. The answer is again found to result from local  $\pi$ - $\pi$  stacking of DBP. The large conjugated electron system in the plane of the molecule results in a transition dipole moment that preferentially orients parallel to the substrate, shown in Fig. 7.156a. Thus, the extinction coefficient for the ordinary wave is nearly triple that of the extraordinary wave (Fig. 7.156b). Since the molecules preferentially orient parallel to the substrates during growth, the species are able to efficiently absorb light even though the material is present in relatively small concentrations. Further, only those percolating paths connected to the anode and oriented perpendicular to the substrate plane are electrically active. This fortuitously creates a

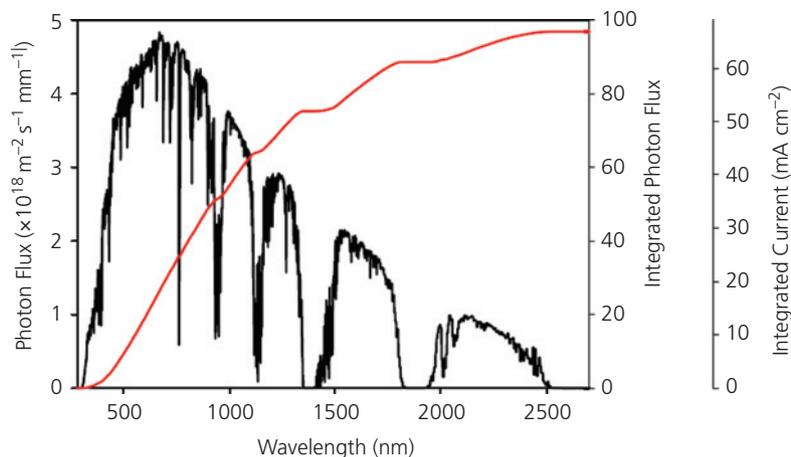

morphology whereby only those molecules in the most favorable orientation for optical absorption participate in the photogeneration process. Indeed, the DBP thin film absorption coefficient is  $\alpha = 3.4 \times 10^5 \text{ cm}^{-1}$  at a wavelength of 560 nm, and  $4.3 \times 10^5 \text{ cm}^{-1}$  at 610 nm. This is compared to the broader but weaker absorption of  $C_{70}$ , with  $\alpha = 6 \times 10^4 \text{ cm}^{-1}$  from 400 nm to 650 nm.

The conclusion from this section is that morphology can be precisely controlled by the steric aspects of the D and A molecules, and conditions used both during and after growth. While each system is different due to different molecular shapes and bonding properties, numerous tools exist for guiding growth to achieve morphologies that can lead to high solar cell power conversion efficiencies. These processing methods are augmented by precise techniques for characterizing structure, ranging from electron microscopy to X-ray diffraction, and by accurate computational tools that connect structure with the microscopic nature of charge and exciton transport. Taken together, the quest for high efficiency OPV materials and structures has vastly improved our understanding and control of organic thin films for a variety of applications, while at the same time providing a detailed view into the fundamental physics underpinning these materials.

#### 7.4.4 Materials optimized for use in OPVs

The range of donor and acceptor materials available for use in both small molecule and polymer cells is enormous, and grows every day. In selecting materials, one needs to focus on those properties that lead to stable, low cost and efficient solar energy harvesting. The properties of an optimal donor-acceptor combination can be summarized as follows:

- (i) A high extinction coefficient across the desired spectrum. For single junction cells, absorption should span the range that leads to thermodynamically limited efficiency (Section 7.3.2). The multijunction cell should have the same property, although, individual D-A subcells should have only moderate spectral overlap with each other to achieve current balance in series-connected architectures. The trade-off between energy gap (and ultimately  $V_{OC}$ ) and power conversion efficiency suggests that the optimal energy gap for a single junction cell needs to be  $\sim 1.4 \text{ eV}$  (or a long wavelength absorption cutoff of 900 nm). But the multijunction cell is not bound by this photon energy thermalization limit. The maximum total, series-

**Figure 7.157** Photon flux from an AM1.5G, 1 sun intensity spectrum (black line) and the integrated photon flux and OPV current (assuming  $\eta_{\text{ext}} = 1$ ) vs. wavelength.

connected cell  $V_{\text{OC}}$  is simply the sum of the voltages of the subcells, whereas the current of the cell is limited by the smallest current generated by a subcell in the stack. To understand the limit to the spectral range that can practically be used in solar energy harvesting, the AM1.5G reference spectrum is plotted in Fig. 7.157 along with the integrated photon flux from  $\lambda = 280$  nm, at 1 sun ( $1 \text{ kW/m}^2$ ) intensity. Also shown is the integrated current density, assuming  $\eta_{\text{ext}} = 1$ . The integrated photon flux at an energy gap cutoff wavelength of 1100 nm is 63% of the total solar emission, and the current is 43% of the possible total. This implies that the subcells in a multijunction OPV must have an increasingly broad spectrum to balance currents generated at shorter wavelengths. But a broader range of wavelengths implies that  $V_{\text{OC}}$  of the long wavelength subcells is also reduced since its energy gap (and hence  $\Delta E_{\text{HL}}$ ) is only as large as the lowest energy photon absorbed. This, in turn, limits the power delivered by the longer wavelength subcells. Hence, there is little to be gained by extending the wavelength range beyond 1200–1400 nm, even in multijunction cells. Also, the energy gap law (Section 3.6.1) implies that non-radiative recombination exponentially increases with decreasing energy gap. Thus, it becomes difficult if not impossible to have high  $\eta_{\text{ext}}$  for long wavelength absorbing cells, placing an additional constraint on finding materials combinations that absorb at  $\lambda > 1400$  nm.

- (ii) A high  $V_{\text{OC}}$  requires a high  $\Delta E_{\text{HL}}$  (see Eq. 7.123). Optimized OPVs maximize this offset, while also maintaining a sufficient LUMO and/or

HOMO energy offset to drive efficient charge transfer while avoiding back transfer. As a rule of thumb, the total energy offset between the D and A frontier orbitals should be  $\Delta E_{\text{LUMO}} + \Delta E_{\text{HOMO}} \sim 0.5$  eV, with neither offset being  $< 0.1$  eV (or approximately  $4k_{\text{B}}T$  at room temperature).

- (iii) The energy loss,  $E_{\text{loss}}$ , which is the energy difference between the energy gap (defined approximately as the exciton low energy cutoff) and  $qV_{\text{OC}}$ , needs to be minimized. It is due to several factors, including the free energy of CT state formation, and the magnitudes of the radiative and non-radiative losses (cf. Section 7.3.2). We find in Section 7.4.4 that NFAs can have significantly smaller  $E_{\text{loss}}$  compared to fullerene-based cells.
- (iv) The materials must be easy to deposit from either the vapor or solution phase, to achieve D-A mixed or BHJ morphologies that lead to high efficiency. That is, deposition and post-processing must result in a nanomorphology that results in  $\eta_{\text{ED}} \approx \eta_{\text{CC}} \rightarrow 1$  while also achieving a low cell series resistance.
- (v) The materials must be inexpensive. This requires the use of low cost precursors, and even more importantly, a simple route to synthesis of bulk quantities of the active materials. The ultimate metric for the value of a solar cell technology is the cost per watt of the modules. A considerable cost of manufacture of large area solar cells is tied up in materials cost, supply and materials use efficiency in cell manufacturing.

We discussed several donor materials and fullerene derivatives in the context of OPDs in Section 7.2.2,

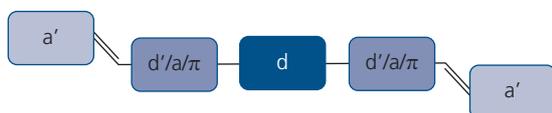

and in subsequent sections. Rather than revisit those molecules, many of which have also found use in efficient OPVs, here we focus on materials that have primarily been optimized for solar energy harvesting applications. As in the chapters concerning light emitting devices and transistors, the discussion is by no means comprehensive. Rather, it provides a sample of archetype materials and the principles used in their design. There are numerous reviews that treat these subjects more comprehensively to which the reader is directed (Dong et al., 2012, Burkhart and Thompson, 2014, Benten et al., 2016, Collins et al., 2017, Fu et al., 2018, Hou et al., 2018).

#### 7.4.4.1 Donors

The design challenge of solution processed donors is to find structures that can readily crystallize, and yet are soluble in solutions also containing the acceptor molecules. These are somewhat conflicting requirements, since the tendency to crystallize requires structures with low solubility. Solubilization generally entails attachment of alkyl groups on the conjugated molecular backbone that sterically hinder  $\pi$ -stacking of neighboring molecules into a nanocrystalline morphology.

The design of most high performance donor and acceptor molecules is to symmetrically position alternating donor (d) and acceptor (a) units along the molecular backbone around a central core. The discussions in this and the following sections use lower case “d” and “a” to connote electron-donating and electron-accepting subgroups within a molecule. Thus the molecular designs typically follow an a-d-a, a-d'-d-d'-a, a- $\pi$ -d- $\pi$ -a, or similar architecture, as schematically illustrated in Fig. 7.158. Here, d' is simply a different electron-donating unit than d, and  $\pi$  is representative of a linkage that extends the conjugation between the functional units comprising the molecule. It is also generally true that the  $\pi$ -linkages may have donor- or acceptor-like properties, but it is their function in creating an extended electron conjugation that dominates.

The advantage of this design is that molecules are combinations of “molecular modules” that simplifies

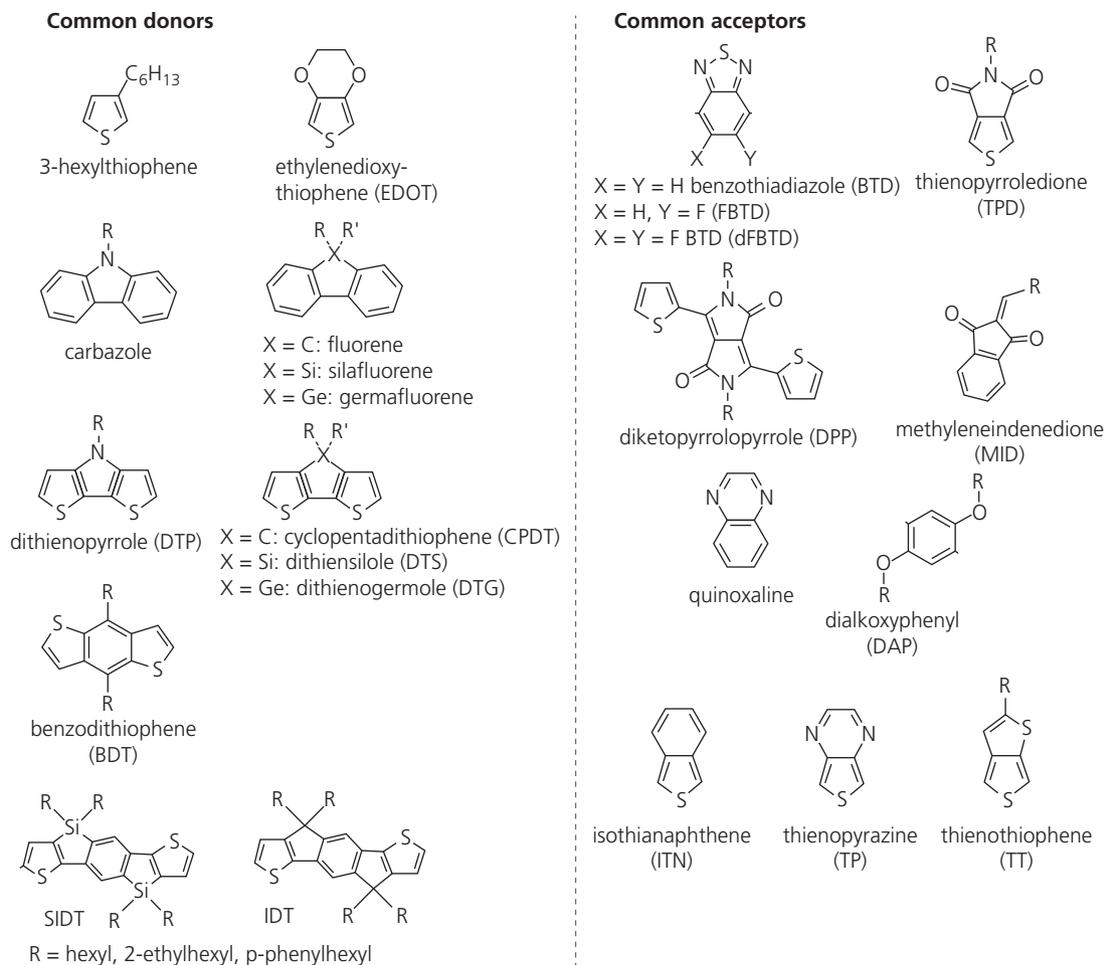

**Figure 7.158** Modular, axisymmetric architecture commonly used in the design of high performance donors and non-fullerene acceptors. Here, “d” and “a” represent donor and acceptor units, and “ $\pi$ ” is a conjugated bridge between units.

both their design and synthesis. Once the backbone structure is fixed, the acceptor end units are attached. This lends itself to an iterative approach to finding the structure best suited to solution processing into the desired morphology, and with the appropriate electronic properties (e.g. its HOMO energy and optical energy gap). The conjugated backbone has other advantages as well. It is generally rigid and planar, which allows the molecules to form closely packed conductive stacks within a BHJ. Furthermore, the extended electron system reduces barriers to intramolecular charge transfer (ICT) between electron rich and electron poor segments along the molecular framework. By distributing the electron density based on principles also used for TADF molecules in OLEDs (Section 6.3.4), the exciton binding energy is reduced. This in turn reduces the energy gap to enable long wavelength absorption. Finally, the extended conjugation reduces the driving force to generate free carriers at the D-A HJ, thus minimizing the energy loss, and hence increasing the  $V_{OC}$ .

Figure 7.159 provides the molecular structural formulae of several polycyclic monomeric d and a units commonly found in donor and acceptor molecules. The planar moieties forming the rigid conjugated backbone lead to ordered  $\pi$ -stacking arrangements. To ensure that the materials are soluble, extended alkane chains or other sterically bulky units are attached to either or both the donor and acceptor groups. The presence of the strategically positioned alkane does not necessarily hinder the ability of the materials to form nanocrystalline domains during deposition or post-annealing of the films.

With rare exception, almost all donor molecules and NFAs comprise a thiophene group. These multi-purpose molecular units are used as connectors between d and a functional groups, and, as illustrated in Fig. 7.159, they serve as constituents in those same groups. They can also aid in planarizing the molecules to encourage  $\pi$ -stacking arrangements. As  $\pi$ -bridges, they can extend the conjugation length within a molecule, and are also helpful in controlling the morphology of the films. Ultimately, inclusion of thiophenes creates the molecular modularity that leads to simplified synthetic approaches to extended d-a structures.

Table 7.18 shows a compilation of several archetype polymer donors combined with fullerenes in BHJ OPVs. With only the exception of P3HT:IC<sub>70</sub>BA and PBnDT-DTffBT:PC<sub>61</sub>BM (1:1), the polymers are blended with PC<sub>71</sub>BM due to its broad absorption spectrum extending into the red. Since all the donors are paired with fullerenes, this table can be used for comparison

**Figure 7.159** Structural formulae of monomer units commonly found in solution processed donor and acceptor compounds.

of their various characteristics, rather than on the specifics of different D-A combinations. With the exception of the homopolymer P3HT, the compounds are copolymers comprising alternating d/a linkages. P3HT is included here since it has found extensive use in OPV and OPD applications due to the relatively high  $V_{OC}$  achieved when combined with fullerenes, and its absorption into the red. Most significant is its ability to form nanocrystalline BHJ networks as discussed previously. The hexyl groups on each segment of the thiophene backbone can alternate regularly in a head-to-tail arrangement, or they can fall in a random head-to-head, tail-to-tail or head-to-tail pattern. We will show in Chapter 8 that the regular head-to-tail arrangements along all segments of the polymer backbone is known as *regioregularity*. This property allows for close and organized packing that leads to a high film mobility, and hence a high  $FF$  and  $j_{SC}$ . In contrast, the random arrangement results in a *regiorandom* polymer that is incapable of crystal formation.

An example of a strong acceptor moiety is benzothiadiazole (BTD) found in PBnDT-DTffBT, as well as in PCDTBT and the naphtho[1,2-c:5,6-c']bis[1,2,5]thiadiazole-containing PBDT-DTNT. Here, PCDTBT combines the BTD unit with a carbazole donor that increases  $E_{HOMO}$  to  $-5.5$  eV compared to  $-5.25$  eV for P3HT. This, in turn, increases  $V_{OC}$  by 40 meV. The PBnDT-DTffBT copolymer employs a difluorinated BTD unit that increases its electron-withdrawing properties to increase  $E_{HOMO}$  even further to  $-5.54$  eV. Also, the film-forming properties of the latter molecule are inferior to PCDTBT as evidenced by the lower  $FF = 0.61$  compared to 0.66 for the non-fluorinated species.

Another BTD-based polymer is PBDT-DTNT, which has the highest efficiency of 8.4%. In this molecule, the BTD is replaced by the fused ring naphthobisthiadiazole unit. This has a slightly stronger electron-withdrawing character than the single ring BTD, and its larger conjugated structure may

rigidify the molecular backbone to some degree. This leads to improved hole conductivity, as well as a decrease in the energy gap. Indeed, the small optical energy gap of 1.6 eV is primarily responsible for the comparatively large  $j_{SC} = 17.4 \text{ mA/cm}^2$  that compensates for the lower  $V_{OC}$  compared to the other BTD-based molecules. This example reinforces the importance of extending the absorption of molecules into the NIR to achieve high power conversion efficiencies.

Substituting thienopyrroledione (TPD) for BTD results in a somewhat weaker electron-withdrawing character in the next molecule in the series, PDTG-

TPD. The molecule has high solubility provided by the alkane chains, while molecular packing is encouraged by the presence of the Ge bridge in the dithienogermole (DTG) unit. We note that a similar silole moiety has been used in place of DTG with similar results (Chu et al., 2012). The energy gap of PDTG-TPD is rather large at 1.69 eV due to the weak acceptor nature of the TPD relative to BTD. This is offset by the deep HOMO of  $-5.6 \text{ eV}$  that leads to a relatively large  $V_{OC}$ . On balance, these several factors lead to a single junction efficiency of 8.5%.

PBDTT-DPP employs a diketopyrrolopyrrole (DPP) acceptor group linked to the benzodithiophene

(BDT) donor. While DPP is a strong electron acceptor, BDT is a comparatively weak donor, both of which act to lower the energy gap while maintaining a deep  $E_{HOMO}$ . In principle, this should result in a high short circuit current and large  $V_{OC}$ . The PDBTT-DPP exhibits a low energy gap of 1.44 eV (corresponding to  $\lambda = 1.16 \mu\text{m}$ ), ultimately achieving an efficiency of 6.6%. Note that the ethylhexyl and butyloctyl groups may hinder the packing, resulting in a  $FF$  of only 0.65.

The next molecule in the family is a representative quinoxaline d/a copolymer, PIDT-phanQ. The quinoxaline is a very strong acceptor that, when copolymerized with the indacenodithiophene group, results in an optical energy gap of 1.65 eV. An alternative approach is to employ thienothiophene (TT) functionalized with a strongly electron-withdrawing fluorine molecule to convert the TT into a strong acceptor group, as found in PTB7. The F atom avoids steric hindrance to packing while at the same time it lowers  $E_{HOMO}$ . The result is the highest  $\eta_P = 9.2\%$  of the compounds listed, which results from a combination of large  $FF = 0.70$  and  $j_{SC} = 17.5 \text{ mA/cm}^2$ , both indicative of a favorable BHJ morphology, and a moderate  $V_{OC} = 0.75 \text{ V}$ .

The last donor polymer is another TT-based copolymer PBDTTT-S-T containing the weak electron-withdrawing potential of TT strengthened by functionalization with a sulfonyl group. Unfortunately, the sulfonyl results in disordered packing, but this deficiency is rectified by including the thiophene side groups to the BDT donor that enforce the  $\pi$ -stacking arrangement needed for a high hole mobility. The resulting OPV has  $\eta_P = 7.81\%$ , along with a moderate energy gap of 1.65 eV that allows for absorption into the NIR.

The molecules in Table 7.18 are representative of classes of some of the most efficient polymer donors reported in OPVs. We have seen that the copolymers share common properties of combining donor and acceptor units along the backbone to reduce exciton binding, thus promoting efficient charge transfer to the acceptor molecule. In addition, the large alkyl chains appended to either one or both of the d and a groups engender a high solubility. A plethora of modifications have been engineered that are analogous to these structures that optimize the film forming or energetic properties to achieve even higher performance than reported here. One of the obvious and recurring benefits of organic electronics exemplified by this list of compounds is the nearly limitless

space available for optimization that is possible by iterative optimization of chemical structures.

The design of small molecules follows that of polymers, with the same combinations of d and a groups defined in Fig. 7.159. A sample of such small molecule donors is provided in Table 7.19. The combination of multiple d, a and  $\pi$  units results in extended molecular structures that cannot be deposited via thermal evaporation, which is unlike the case of many of the donors discussed in the context of OLEDs and OPDs. Nevertheless, solution processed small molecules can also result in high efficiency if the appropriate post-deposition annealing processes are employed.

The first example donor in Table 7.19 is an oligomer comprising five linked thiophenes, DRCN5T. The acceptor groups are based on rhodanine that is made into a strong electron-withdrawing moiety by its CN appendages. Interestingly, it was found that the series of compounds, DRCN $n$ T have improved morphologies when  $n$  is an odd number of thiophenes, presumably due to closer  $\pi$ - $\pi$  stacking of thiophene rings on neighboring molecules (Kan et al., 2015). In addition, the HOMO energies of this series increases monotonically, from  $-5.34 \text{ eV}$  for  $n = 4$  to  $-5.02 \text{ eV}$  for  $n = 8$ . The optimum OPV performance is obtained by creating a nanocrystalline network through thermal annealing followed by SVA in CF. A maximum power conversion efficiency of 10.1% is achieved even though the optical gap is comparatively large at 1.60 eV. Indeed, with only the exception of the porphyrin-based donor, DPPEZnP-TEH, the optical gaps of these molecules lie between 1.6 eV and 1.8 eV, ultimately limiting the efficiencies attained.

The next two molecules, DR3T-SBDT and DR3T-BDTT, contain BDT donor groups, flanked on both sides by three axisymmetric thiophenes, and capped by rhodanine end groups lacking the strong electron-withdrawing cyano moieties of DRCN5T. The difference between the DR3T- structures is the additional thiophene of DR3T-BDTT that replaces the S terminations in DR3T-SBDT to increase the propensity to  $\pi$ -stack. The fill factor of this molecule is 0.76 compared with 0.73 for DR3T-SBDT due to improved hole conductivity. As in the case of DRCN5T, DR3T-SBDT also underwent thermal and solvent annealing to reach its highest efficiency of 9.95%.

The molecule p-DTG(FBT $_2$ Th $_2$ ) $_2$  has a dithienogermole donor flanked by strongly electron-withdrawing fluorinated BTD (FBTD in Fig. 7.159) groups bridged by thiols to form an extended d'-a-

This molecule was spin-coated with PC<sub>71</sub>BM from a CB solution with 5% CF and 0.4% DIO as an additive. The film was thermally annealed to achieve an efficiency of 9.1%. Even with this extended structure, *FF* = 0.73 and *j*<sub>SC</sub> = 15.7 mA/cm<sup>2</sup> are competitive with the more compact structures in Table 7.19.

The remarkably lacey nanostructure formed by films of p-DTG(FBT<sub>2</sub>Th)<sub>2</sub> are shown by the dark field TEM images taken at different angles (60°, 120°, and 180°) in Fig. 7.160a–c, with the composite image shown in Fig. 7.161d. The SAED patterns for these images in the insets indicate an interplanar spacing of 3.5 Å. The composite image shows a mat with fibrils oriented along various preferred directions, depending on their depth from the surface.

An even more extended structure is that of BIT6F, comprising a central difluorobenzothiadiazole (dFBTD) acceptor core symmetrically flanked by Th and indacenodithiophene (IDT) groups to form a molecule with an optical energy gap of nearly 1.8 eV. As in the case of DRCN<sub>x</sub>T, molecules within the series of BIT<sub>x</sub>F exhibited progressively larger HOMO energies

of –5.33 eV for *x* = 4, to –5.28 eV for *x* = 10. Similarly, the optical energy gaps decreased from 1.81 to 1.77 eV for this same range of the number of fluorine atoms. No significant differences in energies were observed for *x* > 10, suggesting that this number of fluorine atoms did not result in a further extension of the conjugation length of the molecule. This may be limited by twists and bends that accumulate with molecular length. By combining thermal annealing and SVA, significant film ordering is achieved.

OPD2FBT2-1-MID has a dFBTD core surrounded by dialkoxyphenyl (DAP) acceptors, and capped by a methyleneidenedione (MID) acceptor unit. Four axisymmetrically disposed thiophene groups provide the donor character along the backbone. Even for such an extended oligomeric backbone, DFT calculations show that the molecule is remarkably flat, allowing for aggregation in closely spaced π–π stacks. Ordered films leading to high efficiency OPVs after SVA in CF are obtained. The use of the 0.8% 2-chlorophenyl additive mitigates the lack of molecular mobility due to its large size, allowing the compounds to organize during annealing.

The most spatially extended oligomer, NDPPFBT, has an axisymmetric *d'*-*a'*-*d*-*a*-*d*-*a'*-*d'* structure, where *d'* = dithiophene, *a'* = dFBTD, *d* = IDT linked by a Th group to *a'*, and the central acceptor *a* = diketopyrrolopyrrole (DPP). Its extensive conjugation length coupled with a strong acceptor core moiety leads to reduced energy loss, and consequently a high *V*<sub>OC</sub> = 0.88 V (Wang et al., 2015). Smooth films are achieved by SVA in tetrahydrofuran for 60 s. It is among the longest wavelength absorbing donors of those in Table 7.19, with a cutoff at λ = 800 nm.

A substantially different approach to achieving ICT is illustrated by DPPEZnP-TEH that employs a Zn porphyrin donor as the *d*-group, linked to two DPP acceptors via alkyne groups in an *a*-*d*-*a* architecture. We have shown in Section 7.2 that porphyrins (and their phthalocyanine analogs) are stable donor molecules used in bilayer and mixed OPDs. In DPPEZnP-TEH, the ZnP unit results in the smallest energy gap (1.37 eV, with a wavelength cutoff of ~900 nm) of the compounds in Table 7.19, making this a candidate for NIR absorption. Use in an OPV gives the highest short circuit current of 16.76 mA/cm<sup>2</sup>. Unfortunately, the molecular design raises the HOMO to –5.14 eV, which in turn, reduces *V*<sub>OC</sub>. Finally, the strong tendency to form aggregates that is promoted by the discotic porphyrin structure may ultimately limit *FF* to 0.62. To achieve the desired morphology, the blend

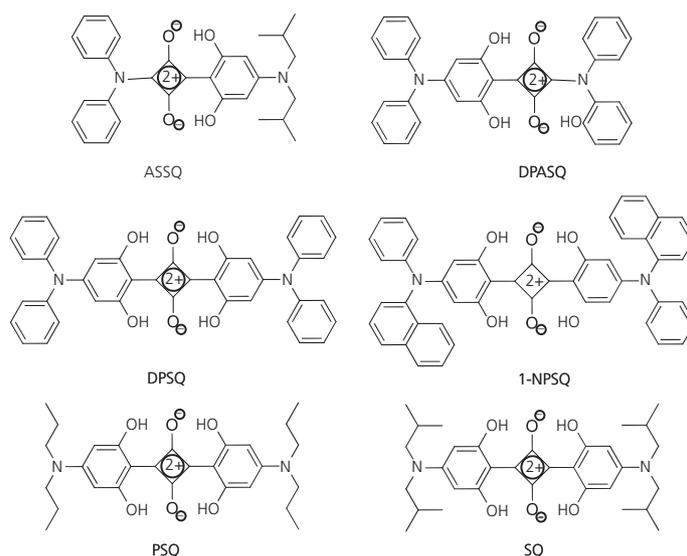

films with PC<sub>71</sub>BM were thermally annealed in the presence of a 1% pyridine additive. In an OPV employing a PFN blocking layer,  $\eta_{max} = 8.08\%$  was achieved using this donor.

Up to this point, we have only considered solution processed small molecule and planar donors that feature ICT between d and a groups using the building blocks in Fig. 7.159. These molecules contain thiophene, or thiol-containing groups to enhance planarity and intermolecular  $\pi$ -stacking. However, we have previously shown that the SQ compound, DPSQ, can also achieve a morphology that leads to nearly ideal structures for charge transfer at the HJ. It is instructive to consider the generalized class of functionalized SQ donors to provide deeper insights into how molecular structure drives thin film morphology, and ultimately device performance.

SQ dyes are intensely fluorescent, and likewise have intense absorption in the red and NIR. They feature a four-membered, electron deficient aromatic ring, and are readily functionalized with aryl and alkane groups to modify their film forming and optical properties. The tendency of the end groups to twist out of the SQ plane sterically hinders the molecules from forming ordered domains. Hence, initial work with SQ-based dyes resulted in low  $\eta_P \sim 1.2$ –2%, which resulted from a low  $FF \sim 0.35$  and  $V_{OC} < 0.6$  V when blended with PC<sub>61</sub>BM (Silvestri et al., 2008, Bagnis

et al., 2010). Nevertheless, their ease of functionalization has led to the development of a series of *N,N*-diarylanilionsquaraine derivatives with end groups that drive their  $\pi$ - $\pi$  stacking, and hence in increase  $FF$  in fullerene-based OPVs (Wang et al., 2011). Example functionalized squaraines (*f*SQs) synthesized to determine the link between molecular structure, film morphology, and OPV performance are shown in Fig. 7.161 (Wei et al., 2011b). There are three species of functionalized molecules: the “parent” SQ that features the sterically limiting butyl groups; three axisymmetric SQs, namely 1-NPSQ with naphthyl plus aryl functional units, DPSQ with an arylamine, and PSQ with symmetric propylamino groups; and the asymmetric molecules, DPASQ and ASSQ, functionalized with either butyl or amine units.

The butyl end-groups of the parent SQ sterically limit close packing with adjacent molecules, that in turn limits the film hole conductivity, and exciton diffusion length to only  $L_D = 1.6$  nm. This is compared with the asymmetric SQs with  $L_D = 11$  nm and the symmetric compounds with  $L_D \sim 3$  nm. Replacement of the end groups with planar aryl moieties exerts control over the crystalline morphology by influencing the intermolecular contact distance while tuning the optical absorption spectrum and energy levels of the films. The arylamine substitutions enhance  $\pi$ -stacking, which results in an increased thin film density. Table 7.20 shows that the film densities

**Figure 7.161** Molecular structural formula of six functionalized squaraines.

vary from 1.45 g/cm<sup>3</sup> for DPASQ, to 1.27 g/cm<sup>3</sup> for ASSQ. The asymmetric compounds also have considerably larger optical energy gaps of 1.9–2.1 eV compared to the symmetric *f*SQs whose energy gaps all lie between 1.5 and 1.6 eV, making the latter suitable for detection into the NIR.

The central SQ unit, combined with the symmetrically disposed functional end groups, creates a tendency for the films to crystallize. With the exception of PSQ, all *f*SQs form amorphous films when cast from CF solutions, yet when they are thermally annealed between 70°C and 90°C, the symmetric *f*SQs readily crystallize, which is apparent from the SAED patterns for 1-NPSQ, DPSQ, and SQ in Fig. 7.162. However, the asymmetric compounds do not crystallize due to their lack of inversion

symmetry, although they may nevertheless form small domains that are not found in the unannealed films. The case of PSQ differs, in that it shows weak crystallinity both before and after annealing (Fig. 7.163b and e), whereas DPSQ shows the most extensive order apparent from by the well-defined diffraction spots in Fig. 7.162d.

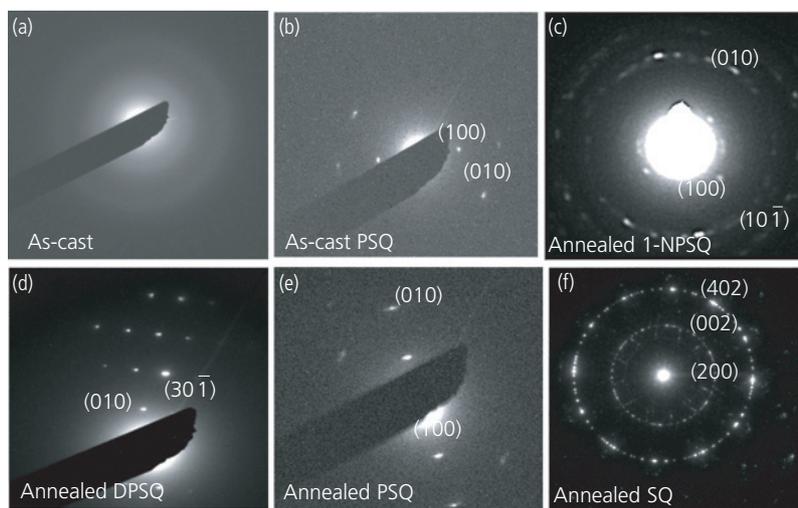

Bilayer HJ OPVs comprising the structure: ITO/MoO<sub>3</sub> (8 nm)/*f*SQ (8.5 nm)/C<sub>60</sub>(40 nm)/PTCBI (8 nm)/Ag (100 nm) were fabricated, with characteristics listed in Table 7.20. The *FF* scales monotonically with film density,  $\rho$ , as shown in Fig. 7.163. The highest *FF* = 0.73 and  $\rho$  = 1.45 g/cm<sup>3</sup> for DPASQ, falls to 0.63 and 1.27 g/cm<sup>3</sup> for ASSQ. This trend indicates that the intermolecular stacking distance is reduced by the arylamine functional appendages, which in turn

results in improved molecular density, and ultimately in a higher hole mobility (which is indirectly inferred from the increased *FF*). The highest performance ( $\eta_P = 4.8\%$ ) is achieved for the symmetric DPSQ with its two phenyls on each end of the SQ core. This is higher than for DPASQ (4.0%) although it has a higher  $\rho$  and *FF*, but at the cost of a lower  $j_{SC}$  arising from a larger optical energy gap.

Currently, there are fewer vapor-deposited small molecular weight donors yielding OPVs with efficiency as high as the solution-processed donors in Tables 7.18 and 7.19. A notable exception are the highly dipolar d-a-a' molecules comprising a strong electron donating ditolylaminothienyl group connected to electron-withdrawing dicyanovinylene via a second acceptor, BTDC (Chen et al., 2012b). These molecules have ground state dipole moments of 10–15 D, causing them to crystallize with  $\pi$ - $\pi$  stacking distances of 3.4–3.5 Å. Their intermolecular dipole attraction is sufficiently strong that annealing does not improve order in the blends comprising d-a-a' structures (Che et al., 2018a). Two isomers of asymmetric heterotetracenes with different thienyl ring arrangements, antiBTDC and synBTDC, are shown in Fig. 7.164a. These molecules employ a terminal benzene ring fused with the electron-donating dithieno[3,2-b:2',3'-d]pyrrole (DTP) donor unit to yield a coplanar structure.

The electronic density plots in Fig. 7.164b show the HOMOs are delocalized over the molecular backbone while the LUMOs are localized on the electron-deficient benzothiadiazole-dicyanovinylene fragments. The lowest energy transitions of antiBTDC

**Figure 7.164** (a) Molecular structural formulae of antiBTDC and synBTDC. The colored paths trace the molecular orbital conjugation. Note the longer conjugation length of antiBTDC compared with synBTDC. (b) Charge densities of the lowest energy singlet excitations,  $S_1 \leftarrow S_0$ . © 2016 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

and synBTDC comprise both  $\pi$ - $\pi^*$  and ICT character that ultimately reduce the energy loss when combined with  $C_{70}$  in a mixed HJ. The MO spatial overlap for  $S_1 \leftarrow S_0$  is calculated using DFT to be 43% and 27% for antiBTDC and synBTDC, respectively. This reflects the longer electron conjugation of antiBTDC, indicated by the colored bonds in Fig. 7.164a. The internal dipole moments of the ground and excited states are  $\mu_g = 15.42 \text{ D}$  and  $\mu_e = 16.48 \text{ D}$ , respectively, for antiBTDC, compared with synBTDC where  $\mu_g = 14.84 \text{ D}$  and  $\mu_e = 13.77 \text{ D}$ .

The large ground state dipole moments lead to an antiparallel molecular arrangement along the long backbone axes, as shown by the crystal packing configurations in Figs. 7.164c. The smaller intermolecular distance, enforced by the larger dipole moment and the longer conjugation length of antiBTDC results in improved characteristics when the isomers are employed

in OPV cells whose structure is shown in Fig. 7.165, inset. The longer conjugation length results in absorption considerably deeper into the NIR, with a cutoff wavelength of 800 nm compared with 750 nm for synBTDC.

The characteristics of the devices employing these isomers in mixed HJs with  $C_{70}$  are provided in Table 7.21, along with the performance of analogous d-a-a' donors, DTDCPB and iBuBTDC. Among this group of compounds, DTDCPB has the highest  $\eta_P = 9.6\%$ , largely as a result of its close interplanar spacing of ca. 3.5 Å (Chen et al., 2012b) that leads to a high fill factor of 0.67 in the blended films. The advantageous performance characteristics of DTDCPB has led to its use in tandem cells discussed in Section 7.5.

**Figure 7.165** External quantum efficiency spectra of OPVs employing two BTDC isomers blended with  $C_{70}$  in the device structure in the inset (Che et al., 2016).

Two-dimensional (2D) GIXD reveals the morphologies of the thin films and provides an understanding the origin of the high  $FF$  of these dipolar donors. In Figs. 7.166a and b, we compare the GIXD diffraction patterns of iBuBTDC, antiBTDC, and  $C_{70}$ . The strongest diffraction signal in the in-plane direction (corresponding to high diffraction intensity shown by the yellow regions at large  $q_{xy}$  and low  $q_z$  scattering parameters) with almost no out-of-plane component (indicated by the low intensity broad blue pattern in  $q_z$  and low  $q_{xy}$ ) is observed for antiBTDC, suggesting a preferred edge-on orientation. In contrast, iBuBTDC shows an intense signal at all  $q_z$ . The higher ratio of face-on  $\pi$ - $\pi$  stacking in the iBuBTDC film leads to efficient charge transport perpendicular to the substrate, resulting in the highest  $FF$  compared to antiBTDC (see Table 7.21). The diffraction patterns of the d-a-a' species differ considerably from  $C_{70}$ , which shows maxima due to scattering from several different molecular planes, consistent with its tendency to crystallize into an organized fcc lattice. The line-cut patterns shown in Fig. 7.166b emphasize the in-plane and out-of-plane stacking habits of these three compounds. The higher intensities correspond to higher organization along a given film axis.

An interesting series of vacuum deposited donors is based on a conjugated backbone comprising oligothiophenes attached at the  $\beta$ -position, and symmetrically capped with strongly electron-withdrawing dicyanovinyl (DCV) groups, shown in the inset, Fig. 7.167b. These DCV $n$ T compounds reveal the relationship between the length of the conjugated thiophene oligomer and the HOMO and LUMO energies. The peak molar extinction

coefficients of compounds  $n = 1-5$  (Fig. 7.167a) monotonically shift to longer wavelengths with an increasing number of thiophenes. The spectra lose their articulated vibronic features with increasing  $n$ , presumably due to increasing torsional disorder with molecular length. This suggests that increasing  $n$  to even larger numbers of thiophene units will result in ever smaller spectral shifts, since bends and kinks in the chains ultimately limit the extent of the excited state supported by the molecules (cf. Section 3.5.3).

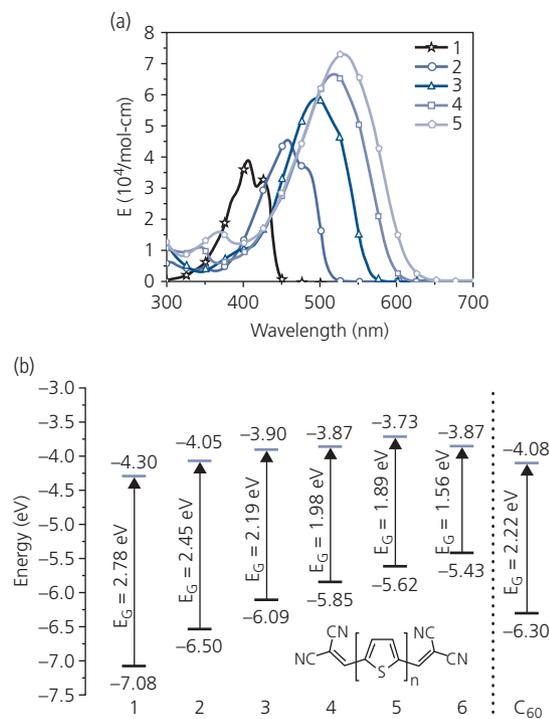

The increased conjugation length with  $n$  is apparent in the HOMO and LUMO energies obtained via cyclic voltammetry, as shown in Fig. 7.167b. The high  $E_{LUMO}$  results from attachment of the strongly electron-withdrawing DCV units, which is advantageous for increasing  $V_{OC}$  in OPVs using a fullerene acceptor. The figure shows a monotonic decrease in  $E_{HOMO}$  with  $n$ , along with a concomitant decrease in  $E_G$  as the conjugation length is increased.

This molecular series illustrates the systematic relationship between molecular structure and energetics.

The highest efficiency p-i-n OPVs employ DCV5T with an active region thickness of 40 nm. The operating characteristics under approximately 1 sun intensity, AM1.5G illumination are  $j_{SC} = 11.1 \text{ mA/cm}^2$ ,  $V_{OC} = 0.97 \text{ V}$ ,  $FF = 0.49$  leading to  $\eta_P = 5.2\%$  (Fitzner et al., 2011).

#### 7.4.4.2 Non-fullerene acceptors

The earliest bilayer cell employed the non-fullerene, perylene-based imidazole, PTCBI, as the acceptor (Tang, 1986). The limited efficiency resulting from  $E_{loss} = E_{opt} - qV_{OC} > 1 \text{ eV}$  (i.e. the difference between the exciton energy and  $qV_{OC}$ ) led to their eventual replacement by fullerenes (Yu et al., 1995, Peumans and Forrest, 2001). Nevertheless, perylenediimides (PDIs) of which PTCBI is an example, have several properties that are advantageous for their use as acceptors. Primarily, their large LUMO energies allow them to be paired with a wide range of donor molecules. Also, their planar, extended conjugated electron systems promote close  $\pi$ -stacking, giving a high electron mobility. Contravening the advantage of

**Figure 7.167** (a) Molar extinction coefficient vs. wavelength for DCV $n$ T donors dissolved in DCM, where  $n = 1-5$ . Compound  $n = 6$  is absent due to its low solubility in DCM. (b) HOMO and LUMO energies for DCV $n$ T donors whose molecular structural formulae are shown in the inset. The energies of C<sub>60</sub> are shown for reference (Fitzner et al., 2011).

stacking is their tendency to aggregate. This prevents high efficiency in mixed or bulk HJ structures, where homogeneous blending with the acceptor molecule is required. Also, as shown in Chapter 3, close packing leads to strong coupling of the excited states with the intermolecular phonon population, which in turn can lead to rapid non-radiative recombination, and hence a reduced diffusion length.

To take advantage of the benefits presented by PDIs while minimizing their disadvantages, a large family of solution-processable PDI-based oligomers have been introduced (Li et al., 2017b), with some of the highest efficiency materials paired with polymer donors listed in Table 7.22. These PDIs have a very low solubility, which can be enhanced by attaching alkanes to the peripheral imide groups.

The energy loss provides a measure of the efficiency for charge transfer from A to D. In the table,  $E_{\text{opt}}$  is listed for the acceptor in the OPV. The  $E_{\text{loss}}$  of these molecules is nearly 1 eV, with the notable exception of SF-PDI<sub>2</sub> comprising two PDIs linked by a spirofluorene-2,7-diyl at the bay positions (Yan et al., 2013). We introduced the P3TEA:SF-

PDI<sub>2</sub> D-A system in Section 4.7.2 due to the apparent absence of energy loss in transferring from the exciton to the CT state. Furthermore, the electroluminescence efficiency of the PDI is  $\sim 0.5 \times 10^{-4}$ , resulting in a voltage loss of 0.26 V. This, combined with 3 ps electron transfer time results in a high  $V_{\text{OC}} = 1.11$  eV (Liu et al., 2016a).

The Se-bridged PDI dimer, SdiPBI-Se, exhibits a maximum power conversion efficiency of 8.42%, which is in part due to the large  $FF = 0.70$ . Including Se in the bay positions of the PDIs has several effects. Selenium is a large atom that allows for facile ionization, thus raising the LUMO of the molecule and enhancing its electron-accepting character. It introduces a twist between the perylene bisimide (PBI) pair, preventing excessive aggregation. It may also enhance the electron mobility due to improved orbital overlap with neighboring molecules, thus leading to a higher  $FF$ .

The next two compounds are the trimers, TPH and TPH-Se. These triperylene hexaimides form tridentate structures with their rylene units severely twisted out of plane, preventing aggregation. Here, rylene generally applies to a dye compound comprising naphthalene units linked at their peri-positions, resulting in compounds such as perylenes, naphthalene diimides, and so forth. The large conjugated systems on the so-called propeller units promote strong  $\pi$ - $\pi$  interactions between molecules that result in a high  $FF$  and  $j_{\text{SC}}$ . As in SdiPDI-Se, the Se-annulated TPH-Se has a higher LUMO energy than TPH, which is inferred from its reduced  $E_{\text{HOMO}}$ , but with a similar energy gap of 1.93 eV. As a result, the efficiency is improved from 8.28% for TPH to 9.28% for TPH-Se.

The last PDI in Table 7.22 is an electron-withdrawing tetramer linked by a benzodithiophene, electron-rich core. The molecule, TPB, has the conventional a-d-a architecture that leads to a reduced exciton binding energy. This is reflected in a low  $E_{\text{loss}} = 0.79$  eV. It also has the lowest optical energy gap of the compounds listed, possibly due to the extended electron conjugation of the tetramer. However, this same attribute leads to a reduced  $FF = 0.58$ , which ultimately leads to a lower  $\eta_{\text{P}} = 8.47\%$ .

Many if not all the compounds in Table 7.22, and in other PDI-based OPVs, lack solubility from the rylene moieties, thus requiring additional annealing or solvent additives to achieve the target morphologies. While the performance of these compounds are remarkably high, they fall short of those achieved with the fullerenes. The large conjugated electron

E		

system on the fullerene periphery results in very rapid (hundreds of femtoseconds) charge transfer, and hence high  $\eta_{CT}$ , and a concomitant reduction in  $E_{loss}$  to 0.6–0.8 eV. Moreover, the near spherical symmetries of both  $C_{60}$  and  $C_{70}$  lead to close packing into nanocrystalline domains. This promotes a high electron conductivity and hence a high  $FF$  and low series resistance. All of these factors have led to the widespread use of fullerenes as acceptors in OPVs.

Fullerenes, however, also have significant disadvantages. For example, while  $E_{loss}$  is less than in the PDIs, its magnitude ultimately limits cell efficiency. Furthermore, as in Section 7.2.2, their absorption spectra are confined to the visible, with absorption coefficients that are often smaller than more tightly  $\pi$ -stacked compounds such as planar donors in Section 7.4.4.1. To avoid these deficiencies, a family of thiophene-based NFAs has emerged with

$E_{loss}$  approaching 0 V in some cases, and with energy gaps that allow for absorption into the NIR. The design flexibility afforded by this molecular family has led to a new generation of OPVs with single junction efficiencies > 15%.

The general architecture of this class of calamitic mesogenic a-d-a NFAs is similar to that followed by donors (Table 7.19), and is illustrated in Fig. 7.168. A *calamitic mesogen* is a molecule that has liquid crystalline properties (i.e. it is *mesogenic* such that, depending on temperature, it can behave as a solid or liquid), and it has a rigid core that allows it to organize into layered stacks (i.e. it is calamitic). The alternation of electron rich thiophene donor units and electron-withdrawing 2-(3-oxo-2,3-dihydroinden-1-ylidene)malononitrile moieties allows for facile ICT. The tendency to  $\pi$ -stack competes with the need for solubility provided by alkane groups attached along its length. All high performance NFAs have

**Figure 7.168** (a) Molecular structure of the NFA, IT-IC, showing its electron push–pull architecture. (b) The packing motif of IT-IC with each molecular sub-unit performing a different function: (1) intermolecular overlap results in efficient electron conduction between members of the stack; (2) the donor backbone is protected by the alkyl groups also used to increase solubility; and (3) the a-unit that lacks shielding by alkyls to promote close  $\pi$ -stacking with neighbors. low energy gaps, and contain thiol groups as  $\pi$ -bridges or donor units.

Figure 7.168 illustrates how the different molecular units are designed to affect both morphology and charge transfer in the archetype NFA, IT-IC (see spectrum, Fig. 7.126). The molecule comprises a seven-ring fused donor core (indacenodithieno[3,2-b]thiophene, IT), terminated with 2-(3-oxo-2,3-dihydroinden-1-ylidene)malononitrile acceptor units. The core is shielded from close packing with other, similar molecules by the alkane chains that afford the needed molecular solubility. However, the alkanes do not impede molecular stacking of the acceptor end groups, whose electron-withdrawing character is enhanced by the CN groups (Fig. 7.168a). This permits intermolecular stacking to within 3–4 Å, and hence a high electron conductivity along the stacks. The rigid, planar backbone (Fig. 7.168b) enables efficient ITC necessary to reduce  $E_{opt}$  and  $E_{loss}$  when IT-IC is employed in OPVs. IT-IC has a long wavelength cutoff of 925 nm corresponding to  $E_{opt} = 1.35$  eV, making it suitable for NIR sensitive OPVs. Thus, the extended backbone with the bulky central donor unit protected by the alkane chains creates the needed delicate balance between solubility and close packing in a slip-stack molecular structure. The OPVs consisting of ITO/PEDOT:PSS/PTB7-Th:ITIC (1:1.3)/Al thermally annealed for 15 min at 150°C exhibited  $\eta_P = 6.8\%$ . While this is still lower than obtained when PTB7-Th is blended with either PC<sub>71</sub>BM ( $\eta_P = 7.5\%$ ) (Lin et al., 2015), or using a ZnO/C<sub>60</sub> cathode buffer with PC<sub>71</sub>BM (9.35%) (Liao et al., 2013), we will show in the ensuing discussion that the calamitic NFAs can lead to exceptionally high single junction efficiencies when combined with the appropriate donor. Importantly, the narrow absorption spectra make these molecules particularly well-suited for visibly transparent OPV applications.

A theme throughout our discussion of OPV materials has been that energy loss sets a fundamental limit to the open circuit voltage and hence the efficiency of OPVs. This loss can be as large as 0.7 eV for fullerene acceptors, although NFAs with the a-d-a motif of the archetype IT-IC, and indeed in the d-a-d donors reduce this to  $\leq 0.6$  eV. Understanding the molecular origins of energy losses can be used to devise design rules that lead to even higher efficiency CT. In the following we describe an analytical framework of Liu and co-workers that connects molecular design to  $E_{loss}$  (Liu et al., 2019).

In Section 7.3.2 we showed that the driving force required to overcome the binding energy is supplied

by the offset of the LUMO and HOMO energies,  $\Delta E_{LUMO}$  and  $\Delta E_{HOMO}$ . As a result, the dissociation process incurs an energy loss during charge transfer:

$$\Delta E_{CT} = E_X - E_{CT} \approx \Delta E_{HOMO(LUMO)} - E_B, \quad (7.183)$$

where, as previously,  $E_X$  is the energy difference between  $S_1$  and  $S_0$ , and  $E_B$  is the exciton binding energy. Additional losses arise from both radiative ( $\Delta E_r$ ) and non-radiative ( $\Delta E_{nr}$ ) recombination at the HJ (Menke et al., 2018):

$$\Delta E_{rec} = E_{CT} - qV_{OC} = \Delta E_r + \Delta E_{nr}. \quad (7.184)$$

Therefore, the total energy loss at the donor–acceptor HJ is (cf. Eq. 7.155)

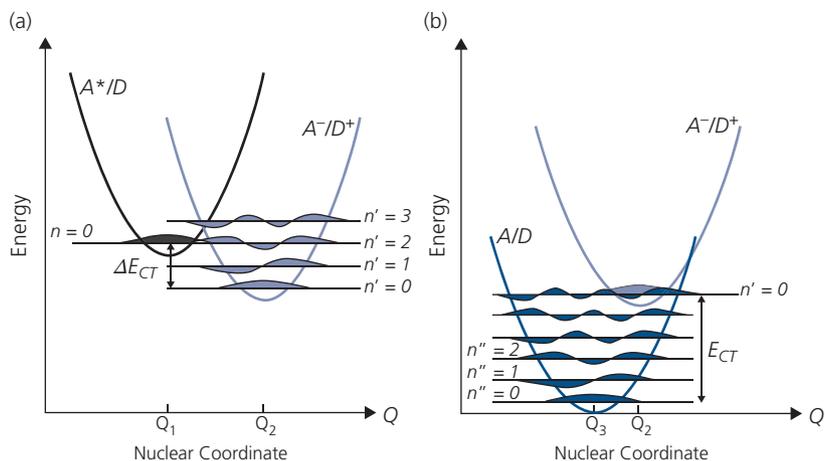

$$E_{loss} = \Delta E_{CT} + \Delta E_{rec} = E_X - qV_{OC}. \quad (7.185)$$

From semi-classical Marcus theory (see Section 4.3.2), the transfer rate from an acceptor exciton ( $A^*$ ) to a CT state ( $A^-/D^+$ ) illustrated in Fig. 7.169a is given by (cf. Eq. 4.89)

$$k_{CT} = \frac{J^2}{\hbar} \left( \frac{\pi}{\lambda_{reorg} k_B T} \right) \sum_{n'} \frac{S^{n'}}{n'!} \exp(-S) \times \exp \left[ \frac{-(\Delta E_{CT} + \lambda_{reorg} + n' \hbar \langle \omega_I \rangle)}{4 \lambda_{reorg} k_B T} \right], \quad (7.186)$$

where, as previously,  $J$  is the electronic coupling between the acceptor excited state ( $\psi_{A^*D}$ ) and CT ( $\psi_{A^-D^+}$ ) wavefunctions,  $\lambda_{reorg}$  is the intermolecular reorganization energy, and  $S$  is the Huang–Rhys factor for intermolecular electron–phonon coupling. The intramolecular phonon modes are replaced by a single mode with mean energy  $\hbar \langle \omega_I \rangle$ , typically corresponding to the dominant (C–C) bond stretch with  $\hbar \langle \omega_I \rangle \approx 0.17$  eV. Also, the Gibbs free energy is given by  $\Delta E_{CT}$ .

The CT process between the initial  $A^*/D$  initial state to the  $A^-/D^+$  final state and the definition of  $\Delta E_{CT}$  are illustrated in Fig. 7.169a. Quantum mechanical tunneling mediates transfer through the barrier separating the initial and final states. Following Kasha’s rule, the transition occurs from the lowest vibrational state ( $n = 0$ ) of the excited acceptor to the  $n'$  vibrational state in the CT ( $A^-/D^+$ ) manifold. The Frank–Condon (FC) integral of the tunneling transition is then simplified to  $\exp(-S) \frac{S^{n'}}{n'!}$ . The reorganization energy,  $\lambda$ , during charge transfer is the sum of *intramolecular* ( $\lambda_I$ ) and *intermolecular* ( $\lambda_0$ ) contributions. Intermolecular reorganization is due to electronic polarization, and consequently lattice

**Figure 7.169** Energy diagrams of (a) charge transfer from the acceptor exciton ( $A^*$ ) to the charge transfer (CT) state ( $A^-/D^+$ ), and (b) non-radiative recombination from the CT state ( $A^-/D^+$ ) to the ground state ( $A/D$ ). The Gibbs free energies are  $\Delta E_{CT}$  in (a) and  $E_{CT}$  in (b). Symmetric parabolic potentials are assumed for the initial and final states. Equilibrium configurations of  $A^*/D$ ,  $A^-/D^+$ , and  $A/D$  manifolds are indicated by  $Q_1$ ,  $Q_2$ , and  $Q_3$ , respectively (Liu et al., 2019).

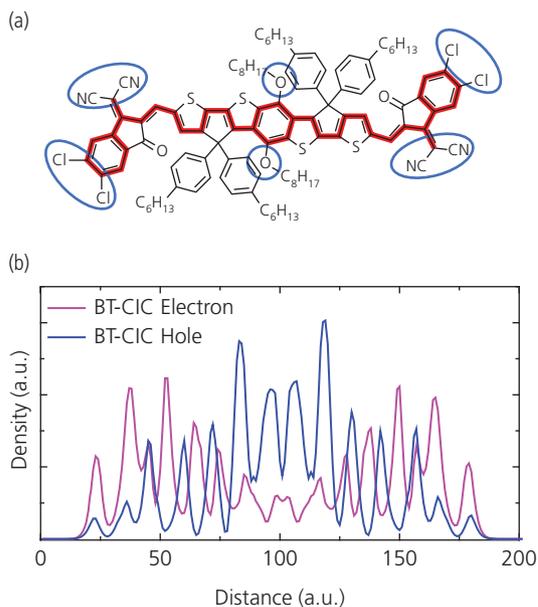

relaxation of the surrounding medium. Assuming a spherically symmetric charge distribution on the donor and acceptor, and treating the medium as an isotropic dielectric continuum,  $\lambda_0$  is found from Eq. 4.61.

Non-radiative recombination energy losses ( $\Delta E_{nr}$ ) occur through coupling from CT ( $A^-/D^+$ ) to the ground state ( $A/D$ ), as illustrated in Fig. 7.169b. The transition rate,  $k_{nr}$ , can be described by Eq. 7.186 after making the following substitutions. The Gibbs free energy is now  $E_{CT}$  instead of  $\Delta E_{CT}$ , and  $J \rightarrow J'$ ,  $S \rightarrow S'$ , and  $\lambda_{reorg} \rightarrow \lambda'_{reorg}$  to account for the electronic coupling between the CT and the ground state, which may or may not differ from those in Eq. 7.186 that describes coupling between  $A^*$  and CT (cf. Fig. 7.169). Clearly,  $k_{nr}$  increases with decreasing  $E_{CT}$  in accordance with the energy gap law. For non-radiative recombination, the energy loss is (cf. Eq. 7.153) (Rau, 2007)

$$\Delta E_{nr} = -mk_B T \ln \left( \frac{1}{\eta_{CT}} \right) = -mk_B T \ln \left( \frac{k_r + k_{nr}}{k_r} \right). \quad (7.187)$$

To achieve low energy loss yet efficient charge transfer,  $E_B$  and  $\Delta E_{HOMO}$  must be minimized simultaneously (cf. Eq. 7.183). Secondly, decreasing both intra- and intermolecular electron-phonon coupling leads to an increased  $k_{CT}$  at a minimum cost to  $\Delta E_{CT}$ , as well as a decrease in  $k_{nr}$ , and consequently,  $\Delta E_{nr}$ .

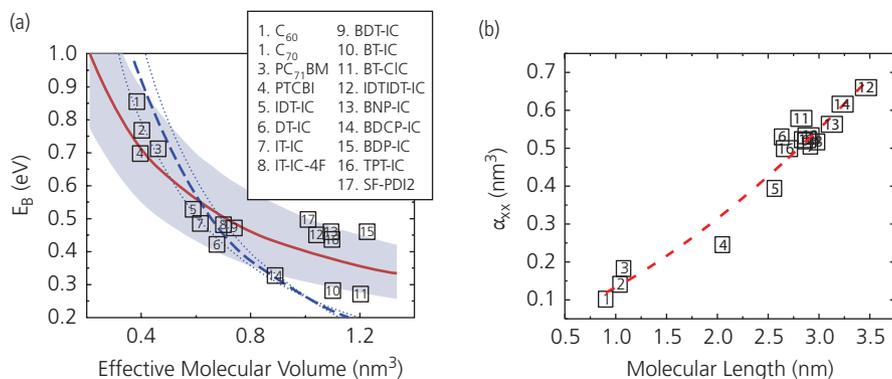

Energy loss is a function of  $E_B$ ,  $S$ , and  $\lambda_{reorg}$ , which in turn are specific to a particular molecular structure. The exciton binding energies have been calculated using DFT for both fullerenes and NFAs. The exciton binding energy is  $E_B = (E_- + E_+) - (E_0 + E_X)$ , where

**Figure 7.170** (a) Molecular structure of BT-CIC. The red bold line traces the electron conjugation path comprising alternating C—C single and double bonds. Blue circles indicate the electron-rich (i.e. oxy-) and deficient (i.e. chloro- and cyano-) moieties. (b) The electron and hole density distributions along the molecular length of BT-CIC calculated using DFT (Liu et al., 2019).

Reprinted figure with permission from Liu, X., Li, Y., Ding, K. & Forrest, S. R., *Physics Review Applied*, 11, 024060, 2019. Copyright 2019 by the American Physical Society.

$E_-$  and  $E_+$  are the optimized energies of radical anions and cations of the molecule, respectively, and  $E_0$  is the ground state energy. Figure 7.170a shows the molecular structure of the example NFA, BT-CIC. The electron and hole distributions along the molecular backbone of the excited state are shown in

**Figure 7.171** (a) Exciton binding energy calculated via DFT vs. effective molecular volume for several acceptor molecules indicated in legend. The solid line is a fit assuming electron confinement within the effective molecular volume for each molecule. The calculation assumes a dielectric parameter,  $f = 5.4$ . The shaded area is the 95% confidence band. The dashed line assumes  $f$  depends on molecular polarizability from (b). The confidence limits of the calculations are shown by dotted lines. (b) Calculated molecular polarizability along the molecular longitudinal axis,  $\alpha_{xx}$  vs. the effective molecular length  $l$ . The dashed line is the fit using the empirical power-law described in text (Liu et al., 2019).

Fig. 7.170b. The conjugated electron system is indicated by the bold red line bridging the electron-donating thiophene chain to the electron deficient cyano and Cl groups. This results in symmetric ICT from the middle to the two ends of the optically excited molecule, which features electron rich regions near the end caps, and an increased hole concentration toward the center of the backbone. The relative segregation of electron and hole densities results in the reduced  $E_B$  characteristic of a-d-a acceptors and d-a-d donors, resulting in their reduced energy loss according to Eq. 7.185 compared to the more compact fullerenes. The rigid coplanar structure of a-d-a NFAs ensures that the electron wavefunction is delocalized over the entire molecular backbone, unlike polymers that can twist at C–C single bonds that ultimately terminates the extent of the excited state (see Section 3.6).

For a given offset of the donor and acceptor frontier orbital energies,  $\Delta E_{CT}$ , is maximized by minimizing the acceptor or donor exciton binding energy, which in turn increases  $k_{CT}$  in the Marcus non-inverted regime. The combined influences of molecular size, conjugation length, and strength of the electron donating and withdrawing groups determines the magnitude of ICT in the acceptors (or donors), and this ultimately determines  $E_B$ . The effects of molecular size on  $E_B$  can be quantitatively estimated assuming that the electron wavefunction for a particle in a three dimensional “molecular box” is bounded by the extent of the electron and hole distributions (see Fig. 7.170b). The wavefunctions are  $\Psi_{n_x, n_y, n_z} = \sqrt{\frac{8}{v}} \sin\left(\frac{n_x \pi x}{l}\right) \sin\left(\frac{n_y \pi y}{w}\right) \sin\left(\frac{n_z \pi z}{h}\right)$ , where  $n_x, n_y, n_z$  are quantum numbers. This can be used to calculate

$E_B$  vs. effective molecular volume  $v = lwh$ . The effective molecular length  $l$ , width  $w$ , and height  $h$  are defined by a box whose boundaries are set at the point that the electron density falls to  $0.02 \text{ au}^{-3}$ , a metric commonly used to define the iso-surface of electron distributions and the size of a molecule (Frisch et al., 2009).

Figure 7.171 shows the calculated  $E_B$  for a population of fullerenes and NFAs vs.  $v$ . For this analysis, an average molecular height of  $h = 0.3 \text{ nm}$  and width of  $w = 0.8 \text{ nm}$  was assumed, with  $l$  varied according to the linear dimension of the molecule. The binding energy monotonically decreases, with  $v$  independent of the details of the molecular structure due to increased separation between the electron and hole densities (Fig. 7.170b). The solid line is the binding energy obtained from the hole and electron wavefunctions,  $\Psi_{0,0,0}$  and  $\Psi_{1,0,0}$ , respectively, found from solutions to Schrödinger’s equation. Thus,

$$E_B = q^2 \int \frac{|\Psi_{0,0,0}(\mathbf{r}_h)|^2 |\Psi_{1,0,0}(\mathbf{r}_e)|^2}{4\pi\epsilon_0 f |\mathbf{r}_h - \mathbf{r}_e|} d^3\mathbf{r}_h d^3\mathbf{r}_e, \quad (7.188)$$

where the  $\mathbf{r}_h$  and  $\mathbf{r}_e$  are the position vectors of the hole and electron, respectively, and  $f$  is a parameter that accounts for the relative dielectric constant of the molecule and the relaxation energy of the ionic species. Remarkably, the solid line corresponds to only a single value of  $f = 5.4$  that approximately fits the entire population of acceptors, ranging from highly symmetric fullerenes to extended and planar NFAs. The deviations of the data from the solid line are due to details of the molecular structures that impact the molecular polarizabilities and relative dielectric constants in the solid.

Since the dielectric constant is related to the polarizability,  $\alpha_{xx}$ , we can interpret the analysis leading to Eq. 7.188 by calculating the polarizability vs. molecular length  $l$ . The polarizability follows an empirical power-law dependence (Van Dyck et al., 2017):

$$\alpha_{xx} = \alpha_0 + \alpha_1 l^n, \quad (7.189)$$

where  $\alpha_0$  is the polarizability of terminal bonds such as C–H, and  $\alpha_1$  is related to the polarizability of conjugated or non-conjugated chains of length  $l$ . A fit to the data in Fig. 7.171b gives  $\alpha_0 = 0.035 \text{ nm}^3$ ,  $\alpha_1 = 0.098 \text{ nm}^{3-n}$ , and  $n = 1.51$ . The weak, superlinear increase of polarizability ( $n > 1$ ) is due to the contributions of conjugation and ICT. The relationship between the dielectric constant of the medium and the polarizabilities of each constituent,  $\alpha_i$ , is given by the *Clausius–Mossotti relationship*:

$$\frac{\epsilon - 1}{\epsilon + 2} = \frac{4\pi}{3} \sum_i N_i \alpha_i, \quad (7.190)$$

where the molecular packing density is  $N_i$ . The effect of the dielectric constant change on  $E_B$  is estimated using Eqs. 7.189 and 7.190 to replace constant  $f$  of Eq. 7.188, and assuming an isotropically polarizable medium comprising randomly oriented molecules with  $N = 1.3 \text{ nm}^{-3}$ . This yields the blue dashed line in Fig. 7.171a. The fit closely follows the data for molecules **1** to **11** compared to that using a constant  $f$ , although there are noticeable departures from the data arising from approximations made to the molecular structure and the relaxation of ionic species. The less accurate fits to molecules **12**, **13**, and **15–17** are attributed to molecular bends that disturb the electron conjugation, thereby increasing  $E_B$ .

Achieving a small  $\Delta E_{CT}$  and  $\Delta E_{nr}$  requires simultaneously reducing both intra- and intermolecular electron–phonon coupling. According to Eq. 4.61, the increased dielectric constant of NFAs reduces the intermolecular coupling,  $\lambda_0$ . The intramolecular coupling constant,  $S'$ , also changes with the size and rigidity of the molecules, that is, they scale with the increased FC shift that is twice the total reorganization energy,  $E_{FC} \approx 2 \lambda_{CT}$ . This yields  $\lambda_{CT} = 0.11 \text{ eV}$  for IT-IC/PBDB-T HJs compared to  $\lambda_{CT} = 0.24 \text{ eV}$  for PC<sub>71</sub>BM/PBDB-T, resulting in a higher  $k_{nr}$  for the latter system. Thus,  $\eta_{CT} = \frac{k_r}{k_r + k_{nr}}$  is higher in the IT-IC/PBDB-T HJ. Indeed, the non-radiative recombination loss using Eq. 7.188 and  $\eta_{EL}$  of IT-IC/PBDB-T and PC<sub>71</sub>BM/PBDB-T HJs result in a  $0.05 \pm 0.01 \text{ eV}$  smaller  $\Delta E_{nr}$  in the IT-IC system, leading to the generally higher power conversion efficiencies observed for NFA vs. fullerene based OPVs. The presence of nonbonding

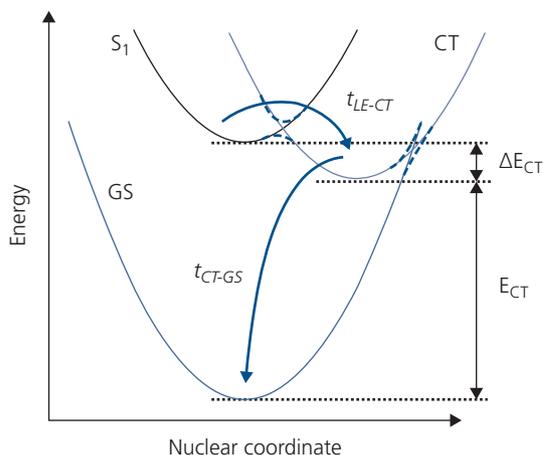

orbitals in the cyano, chloro or oxy groups introduce lone pair electrons that do not participate in bonding, and thus avoid electron–phonon coupling. At the same time, the cyano and chloro groups attract electrons and reduce the charge density along the backbones, effectively reducing electron–phonon coupling.

Finally, it is worth noting that the treatment assumed thus far is based on semi-classical Marcus transfer, where only direct coupling of the CT to the ground state is assumed. A more complete theory must take into consideration coupling of all the excited states, and most importantly, the coupling of the lowest excited ( $S_1$ ) state to the CT manifold. This is illustrated in Fig. 7.172, that explicitly includes the strength of the coupling of the  $S_1$  to the CT state ( $t_{LE-CT}$ ) in addition to the coupling of CT to the ground state ( $t_{CT-G}$ ) considered above. These multiple contributions can be quantified using Marcus–Jortner electron transfer theory (Marcus and Sutin, 1985, Bixon and Jortner, 1999). The potential energy surface of the transition from  $S_1$  to a CT state is illustrated in Fig. 7.172 assuming a simple harmonic oscillator model. The dashed lines at the crossing points present the adiabatic surface, while solid lines are non-adiabatic. In the case of non-adiabatic transitions within the Born–Oppenheimer approximation, the CT rate constant from Fermi’s golden rule is (Bixon and Jortner, 1999)

$$k_{CT} = \frac{2\pi}{\hbar} |\langle \psi_{S_1} | H | \psi_{CT} \rangle|^2 |\langle v_{S_1} | v_{CT} \rangle| \rho(E_{CT}) \quad (7.191)$$

$$= \frac{2\pi}{\hbar} t_{LE-CT}^2 (FCWD).$$

Here,  $t_{LE-CT} = \langle \psi_{S_1} | H | \psi_{CT} \rangle$  is the matrix element that mixes the wavefunctions of CT ( $\psi_{CT}$ ) and local excited

**Figure 7.172** Coupling of the CT state to both the ground (GS) and lowest excited state ( $S_1$ ). These transition and their corresponding strengths (denoted  $t_{CT-GS}$  and  $t_{LE-CT}$ , respectively) must be considered to fully account for energy losses in the charge generation process.

state ( $\psi_{S_1}$ ) of acceptor or donor,  $H$  is the interaction Hamiltonian,  $\rho(E_{CT})$  is the density of CT states, and  $FCWD$  denotes the Franck–Condon factor weighted density of states. In a semi-classical approximation at room temperature, Eq. 7.191 gives

$$k_{CT} = \frac{2\pi}{\hbar} t_{LE-CT}^2 FCWD(-\Delta G_{LE-CT}) = \frac{2\pi}{\hbar} t_{LE-CT}^2 \frac{1}{\sqrt{4\pi\lambda_0 k_B T}} \times \left[ \sum_{n'} \exp(-S) \frac{S^{n'}}{n'!} \exp\left(-\frac{(-\Delta G_{LE-CT} + \lambda_0 + n'\hbar\langle\omega_l\rangle)^2}{4\lambda_0 k_B T}\right) \right], \quad (7.192)$$

where the Gibbs free energy change  $\Delta G_{LE-CT}$  is the sum of energy offset,  $\Delta E_{CT}$ , and the entropy change. The  $FCWD$  factor is assumed to be the sum of vibrational overlap integrals between the lowest ( $n = 0$ ) vibrational state of  $S_1$  and the state  $n'$  of the CT manifold. Each transition from  $n = 0$  to  $n'$  in the sum, contributed by low frequency intermolecular modes ( $\hbar\omega_0 \ll k_B T$ ) in the medium, is adequately described by the classical picture by an Arrhenius-type exponential term.

Recently, derivations of the matrix element between  $S_0$  and hybridized CT- $S_1$  states have been developed (Chen et al., 2018, Eisner et al., 2019). That analysis finds that  $k_{rad}$  decreases with decreasing energy offset, while  $k_{nr}$  stays approximately constant when hybridization is absent. Hybridization increases both  $k_{rad}$  and  $k_{nr}$ , but has a stronger impact on  $k_{rad}$  than on  $k_{nr}$ , giving rise to the decrease in  $\Delta V_{OC,nr}$ . While this approach is formally correct, its application depends on knowing the coupling strengths between the states involved. However, the experimental evidence thus far is insufficiently detailed to justify invoking the more complex interactions involved in the three-state formalism.

The foregoing analysis suggests molecular design strategies that can further reduce energy loss. Currently, a-d-a-type NFAs are inherently symmetric, and hence possess a nearly zero dipole moment. However, asymmetric electron-withdrawing end groups in a-d-a molecules provide freedom to tune the dipole moment and further reduce  $E_B$ ,  $S$ , and  $\lambda_0$  by changing the effective intramolecular electron–hole separation and the molecular packing in bulk HJs. Additionally, the relationship between molecular dimension, rigidity and energy loss points to the benefits of increasing the molecular volume. However, there is a limit to the extent to which the length of the molecular backbone can be increased without bending, and hence terminating the effective conjugation length. Extending the conjugation into two and three dimensions can further reduce  $E_B$ ,  $S$ , and  $\lambda_0$ , as compared to 1D conjugation used up to now. This may also enhance intermolecular  $\pi$ - $\pi$  interactions along all directions, leading to

increased charge carrier mobilities. Indeed, early demonstrations of increasing the molecular volume in two dimensions based on dithienopicenocarbazole-based a-d-a-type (Yao et al., 2018) or spiro-fused PDI NFAs (Gao et al., 2017) provide an illustration of the benefit of this strategy.

Table 7.23 lists several different solution-processed a-d-a NFAs that are chosen to demonstrate the facility with which the modular design of molecules in Fig. 7.168 can lead to systematic variations in electronic properties. The first six entries in the table, namely IDT-IC, IT-IC, BDT-IC, BT-IC, BT-CIC, and TT-FIC, correspond to the materials whose absorption spectra are found in Fig. 7.127. While some of the molecules have efficiencies exceeding 11%, the most interesting aspect is the nearly rigidochromic shift of the spectra, with optical energy gaps monotonically increasing from 1.28 eV for TT-FIC, to 1.73 eV for IDT-IC. This is accompanied by a concomitant, near monotonic decrease in  $E_{HOMO}$  from  $-5.43$  eV to  $-5.61$  eV, respectively. This trend is depicted in the energy level diagram in Fig. 7.173. The energy losses, which are determined using the  $E_{opt}$  of the acceptors, depend on the specific choice of donor. The minimum value of  $E_{loss} = 0.56$  eV is found for the J71:BT-IC blends, which is smaller than obtained with any of the PDI-based acceptors in Table 7.22.

We can qualitatively understand the source of the decreasing energy by examining the structures of the six NFAs themselves. The planar, electron-donating backbone of each molecule comprises a series of fused rings, each contributing to the conjugation length of the electron system. The d-unit is capped at each end by a 2-(3-oxo-2,3-dihydroinden-1-ylidene) malononitrile a-unit, and in the case of BT-CIC and TT-FIC, the a-units are functionalized with Cl and F, which further increases their electron-withdrawing ability. Then, starting with the smallest energy gap IDT-IC comprising five fused rings (containing two Th), we progress to lower  $E_{opt}$  with IT-IC (6 rings, 4 Th), BDT-IC (7 rings, 4 Th), BT-IC (3 fused rings disposed on opposite sides of a alkoxy group), BT-CIC (as in BT-IC but with strongly electron-withdrawing Cl functionalized a-units), and TT-FIC with eight rings having an even more electron deficient F-functionalization. The strong donating ability of the alkoxy group in BDT-IC also results in a somewhat higher  $E_{HOMO}$ , evident in Fig. 7.173. Hence, this series shows a progressively increasing conjugation length leading to decreasing energy gaps. These modifications tend to lower the  $E_{HOMO}$ , and thus  $E_{LUMO}$ . Finally, the planar donor core of the molecules promotes ordered  $\pi$ -stacking, giving  $FF > 0.7$  in almost all cases.

**Figure 7.173** Progression in the optical energy gap and HOMO energy for the series of NFAs in Fig. 7.126.  $E_{opt}$  is the energy for the  $S_1 \leftarrow S_0$  transition.

**Figure 7.174** External efficiency spectra of BHJ OPVs employing a PCE-10 donor and a BT-IC (circles), BT-CIC (triangles), or PC<sub>71</sub>BM (squares) (Li et al., 2017c).

The absorption of these molecules is quite strong, with  $\alpha \sim 10^5 \text{ cm}^{-1}$ . However, since their absorption is narrow and generally centered in the NIR, a donor with absorption in the visible is needed to achieve more complete coverage of the solar spectrum when visible transparency is not required. Examples of the external quantum efficiency spectra of BT-CIC and BT-CIC OPVs with the structure ITO/ZnO(25 nm)/PCE-10:NFA (1:1.5, 130 nm)/MoO<sub>3</sub> (15 nm)/Ag are shown in Fig. 7.174. For comparison,  $\eta_{ext}$  for a PCE-10:PC<sub>71</sub>BM OPV with the same blend proportion and thickness is also provided. Remarkably, the OPVs based on the NFAs have  $\eta_{ext}$  approaching 80% over much of the NIR, with the longest wavelength response, and highest  $\eta_p = 11.2\%$  observed for BT-CIC. The short wavelength response of the PC<sub>71</sub>BM-based OPV is the highest of the group, since the fullerene has a higher absorption coefficient than either of the NFAs, and the donor PCE-10 also has limited absorption in the blue spectral region.

The next four NFAs all have  $\eta_p > 13\%$ . The acceptor, C<sub>8</sub>-IT-IC, is a modified IT-IC whose hexyl side chains are replaced by octyl units. Given the marginal differences in the energetics of these two compounds, the improved morphology obtained by the extended octyl chains apparently leads to the higher efficiency of C<sub>8</sub>-IT-IC. In fact, the highest efficiency achieved for both materials employed a PFBDB-T donor blend that was annealed at 160°C to improve its nanocrystalline morphology.

The IT-4F acceptor has a strongly electron-withdrawing F-functionalized a-capping unit. This increases both the HOMO and LUMO energies compared to its non-fluorinated analog, IT-IC. While this reduces the CT energy somewhat, and hence reduces  $V_{OC}$  (0.88 V vs. 0.94 V for IT-IC), the smaller optical energy gap leads to a higher current of  $j_{SC} = 20.5 \text{ mA/cm}^2$  compared with  $17.32 \text{ mA/cm}^2$ . Taken together,  $\eta_p = 13.1\%$  is obtained in a D-A BHJ device comprising the fluorinated donor, PBDB-T. An analogous fluorinated acceptor, INPIC-4F achieves a similarly high power conversion efficiency, indicating the effectiveness of employing strongly electron-withdrawing a-groups along with an extended, electron-rich 5,5,12,12-tetrakis (4-hexylphenyl)-indacenobis(dithieno[3,2-b:2',3'-d]pyrrol) (INP) donor core.

The highest efficiency is obtained with the NFA, Y6 used in combination with the donor, PM6 (Zhang et al., 2015) in a 1:1.2 (w/w) D:A ratio. This molecule is also built around a BT core, with strong electron-withdrawing F-functionalized acceptor capping groups. The low optical energy gap of 1.33 eV coupled with the exceptionally low energy loss of 0.5 eV leads to a relatively high  $V_{OC}$ . The low energy loss may be a result of a twist about the molecular core enforced by avoidance of the alkyl groups attached to the central N-atoms. This, in turn further

separates the electron and hole densities, leading to a reduced  $E_B$ . The efficiency reported is 15.7% for both conventional and inverted OPVs.

#### 7.4.4.3 Materials used in non-fullerene ternary OPVs

In Section 7.4.1, we introduced the concept of the ternary OPV where the active region consists of either a donor and two acceptors or vice versa. Adding a third component into the BHJ can increase the solar coverage, which often leads to higher single junction OPV efficiencies. In Table 7.24 we summarize the char-

acteristics of several high efficiency ternary solar cells. Each of these devices comprises at least one NFA, often combined with a fullerene acceptor. Since all a-d-a NFAs require solution processing, both the donor and secondary acceptor additions to the blend are also solution-processed. Furthermore, the ternary OPVs in Table 7.24 have a  $DA_1A_2$  architecture. The structural formulae of compounds listed in the table and not referred to elsewhere in this chapter are provided in Fig. 7.175.

Ternary device performance is particularly sensitive to details in film morphology due to the need to sim-

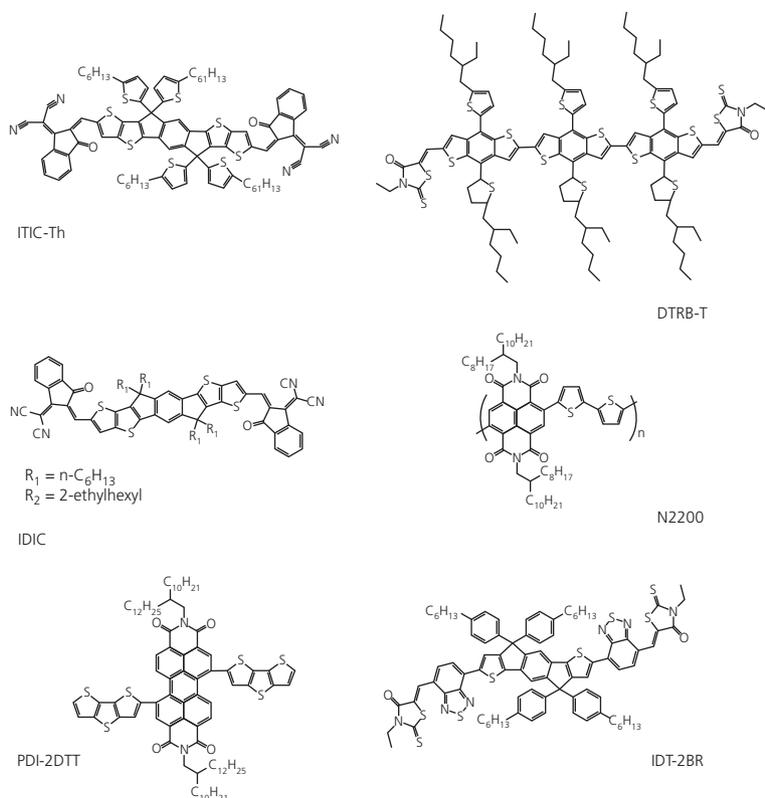

**Table 7.24** Performance characteristics of selected  $DA_1A_2$  OPV cells

Materials	Blend ratio	$j_{sc}$ (mA/cm <sup>2</sup> )	$V_{OC1}$ (V)	$V_{OC2}$ (V)	$V_{OCT}$ (V)	FF	$\eta_{max}$ (%)	Ref.

Notes: (i) The materials and blend ratio sequences follow the order D:A<sub>1</sub>:A<sub>2</sub>.

(ii)  $V_{OC1}$ ,  $V_{OC2}$ , and  $V_{OCT}$  correspond to the open circuit voltages of DA<sub>1</sub>, DA<sub>2</sub>, and DA<sub>1</sub>A<sub>2</sub>, respectively.

(iii) Performance characteristics are obtained at 1 sun, AM1.5G simulated illumination.

**Figure 7.175** Molecular structural formulae of several donor and acceptor compounds used in ternary OPVs in Table 7.24.

ultaneously balance the local concentrations of the three molecular components. With one exception (PTB7-Th:IDT-2BR:PDI-2DTT), the ternary mixtures consist of high concentrations of both acceptors, which in total equal the concentration of the donor. A second observation is that the open circuit voltage of the ternary OPV,  $V_{OC}$ , falls within the limits set by the individual binary devices,  $V_{OC1}$  and  $V_{OC2}$ . Although the PBDB-T:ITIC:N2200 appears to violate this “rule,”  $V_{OC}$  exceeds  $V_{OC1}$  by just slightly more than 10 meV, and  $V_{OC2}$  is also close to  $V_{OC1}$ . This apparent anomaly has been attributed to the improved morphology of the ternary, which also resulted in a significantly increased  $FF = 0.73$  and decreased series resistance  $R_{ser} = 3.5 \Omega \text{ cm}^2$  for the blend containing 10% of the poly(naphthalene bithiophene), N2200, compared to the binary DA<sub>1</sub> (0.68,  $3.8 \Omega \text{ cm}^2$ ) and DA<sub>2</sub> (0.73,  $5.3 \Omega \text{ cm}^2$ ) devices (An et al., 2018). We showed in Section 7.4.1 that this finding is consistent with all four models used to describe ternary device operation, absent other extrinsic factors such as morphology, junction non-idealities, etc.

An interesting exception to the devices in Table 7.24 employs a PTB7-Th:IDT-2BR:PDI-2DTT active region. The highest efficiency device using this blend was reached when only 1% of the acceptor, PDI-2DTT, is included. Such a low concentration should not be thought of as a third ternary component, but rather as a dopant in a binary BHJ (Cheng et al., 2017). The rationale for the addition of PDI-2DTT is that the HOMO and LUMO offset energies between PTB7-Th and the primary a-d-a NFA, IDT-2BR, of 32 meV and 10 meV, respectively, are too small to efficiently drive charge transfer at the HJ. Doping with PDI-2DTT increases the offset energies with the donor to 40 meV and 31 meV, respectively, which is sufficient to prevent back transfer of dissociated charges into a bound CT state. At concentrations of  $\leq 1\%$ , the films show a powder texture with the molecular lamellar spacing consistent with that of PTB7-Th:IDT-2BR. However, at higher PDI-2DTT concentrations, numerous new distinct crystalline rings are observed in the GISAXS diffraction patterns. Apparently, this more crystalline morphology decreases the hole and electron mobilities by a factor of three from the undoped DA<sub>1</sub> film, and the  $FF$  is also reduced. Clearly, only a small addition of A<sub>2</sub> is advantageous for device performance.

## 7.5 Multijunction cells

The multijunction cell offers several advantages over single junction OPVs, many of which were touched on in Section 7.1.2 and subsequent sections. Briefly, these advantages include:

- (i) *Increased coverage of the solar spectrum by combining subcells whose absorption spectra do not entirely overlap.* Given the narrow absorption spectra characteristic of excitonic materials, the case for employing multijunction cells for achieving high efficiency is compelling.
- (ii) *Reduced thermalization losses in series-connected stacks.* The energy difference between the incident photon and the single junction cell energy gap is lost to heat, thus setting a thermodynamic limit to the maximum power that the cell can generate (see Section 7.3.2). By combining cells of different energy gaps, thermalization losses due to high energy photons absorbed by large energy gap subcells are reduced. Similarly, low energy photons are absorbed by subcells with smaller energy gaps. Thus, a multijunction cell can, in principle, exceed the thermodynamically limited efficiency of the single junction cell.
- (iii) *Increased terminal voltage.* The  $V_{OC}$  of a series-connected multijunction cell is the sum of the  $V_{OC}$  of the subcells in the stack. Additionally, the multijunction cell current is limited by the subcell generating the lowest current. As a result, the series-connected stack is a “high voltage, low current” OPV. Consequently, tandem cells are less vulnerable to resistive losses that equal  $I^2 R_{ser}$ .
- (iv) *Reduced current increases cell efficiency.* Due to the generally high internal resistance of an OPV, the  $FF$  of a stacked cell can be higher than that of its constituent subcells under an equivalent illumination intensity. The  $FF$  is a function of  $R_{ser}$  (see Fig. 7.70). When the incident light is absorbed in different subcells in the stack, the resulting reduction in cell current results in an increased  $FF$ , and hence  $\eta_P$ .
- (v) *Reduced current reduces the cell vulnerability to current-induced failure mechanisms.*

Subcells connected in parallel were also considered in Section 7.1.2. While parallel-connected multijunction cells do not require current balance, they nevertheless require matched operating voltages for each parallel element. In contrast to a series cell, parallel-connected cells can be “high current, low voltage” devices. For this reason, they lack many of the advantages of the series multijunction OPV, and hence will not be a focus of further discussion.

The ease of combining numerous materials and multiple layers in organic devices, and the benefits accrued by stacking subcells absorbing in different spectral regions, makes the series-connected multijunction architecture suited for achieving high efficiency and reliable OPVs. In this section we focus

on three topics: (i) the design principles leading to cell optimization, (ii) the design of optically and electrically lossless CRZs between subcells, and (iii) examples of multijunction cell architectures used to understand how materials and processing problems are solved to achieve high efficiency.

### 7.5.1 Design principles of optimized multijunction OPVs

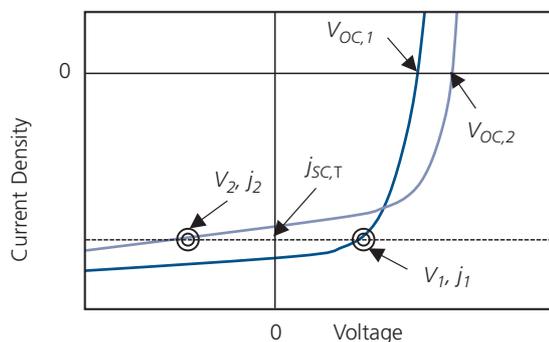

To develop a systematic approach to multijunction cell design, we consider the operating point of a series tandem (i.e. dual junction) cell, and then generalize the method to  $N$  junctions. Figure 7.176 illustrates the  $j$ - $V$  characteristics of two cells comprising a tandem. Since the central terminals of tandems cannot be accessed, these characteristics correspond to single junction OPVs whose characteristics are close, but not identical to those expected when similar devices are used as subcells in the completed device. Subcell 1 has a low  $V_{OC,1}$ , whereas subcell 2 has the smaller  $j_{SC,2}$  and lower fill factor. Presuming that the CRZ connecting the subcells is lossless, then the tandem meets two conditions:

$$V_{OC,T} = V_{OC,1} + V_{OC,2} \quad (7.193a)$$

and

$$j_{SC,T} = j_1 = j_2. \quad (7.193b)$$

This second condition corresponds to the horizontal dashed line in Fig. 7.176 where the current in a series-connected cell is balanced, that is, the current delivered by each subcell is equal. This requires that the voltage across the two subcells at short circuit meet the condition:  $V_T = V_1 + V_2 = 0 \Rightarrow V_1 = -V_2$ .

**Figure 7.176** Current–voltage characteristics of two subcells and the operating current of a series-connected tandem solar cell comprising these subcells.

A similar analysis for a parallel tandem is provided in Fig. 7.103 in the context of the operation of a ternary BHJ. For a parallel diode connection, the operating points lie along vertical, constant voltage lines, and the currents are additive (the converse of Eq. 7.193).

The performance of the multijunction cell is modelled by constructing its  $j$ - $V$  characteristics from those of the discrete devices, with the goal of finding  $j_M$ ,  $V_M$  at the MPP, and hence  $\eta_p$ . This must be done using numerical methods along with the conditions of Eq. 7.193 at each  $(V, j)$  coordinate. Care must be taken such that the spacer and active layers in the discrete cells result in an optical field that is close to that experienced when they are placed in the stack. We start by defining  $\Delta\eta_p$  as the power conversion efficiency penalty at the  $N$ -junction cell MPP relative to its value if each individual subcell in the stack were operating at its own MPP. That is,

$$\Delta\eta_p = 1 - \frac{j_{M,T} V_{M,T}}{\sum_{i=1}^N j_{M,i} V_{M,i}}, \quad (7.194)$$

where  $j_{M,i}$  is the current density at MPP of subcell  $i = 1, 2 \dots N$  (as numbered from the reflective contact), and  $V_{M,i}$  is the voltage at the MPP of the  $i$ th subcell, which is defined as

$$MPP_i = j_{M,i} V_{M,i} = FF j_{SC,i} V_{OC,i}. \quad (7.195)$$

Setting  $\Delta\eta_p = 0$ , we obtain  $j_{M,T} V_{M,T} = j_{M,i} \sum_{i=1}^N V_{M,i}$ .

Thus, if all subcells operate near to their individual  $(V_{M,i}, j_{M,i})$ , then  $\Delta\eta_p$  is minimized. Thus, a criterion to achieve the maximum power conversion efficiency,  $\eta_{p,T}$ , for a multijunction cell is to match  $j_{M,i}$  for each subcell.

The foregoing analysis has been used to project the performance of a series tandem OPV comprised of two different sets of subcells whose single junction performances are listed in Table 7.25. One tandem (T1), combines cells  $i$  and  $ii$  with nearly equal fill factors, while the second tandem (T2) is comprised of cells  $iii$  and  $iv$  with widely different FFs. The different situations should lead to different MPPs and introduce significantly different power efficiency penalties when used in the tandem cells. Note that these data are obtained from four different, small molecule OPVs whose  $j$ - $V$  characteristics and solar spectral responses were measured and fit to the diode theory in Section 7.1.2. Furthermore, the optical properties of the various compounds were

measured to determine the response of the tandem cells in which they were placed. For reference, the cells used in the models are (i) DBP/C<sub>70</sub> PM-HJ, (ii) DPASQ:DPASQ (4:6)/C<sub>70</sub> bilayer, (iii) SubPc/C<sub>70</sub> graded HJ, and (iv) DPSQ/C<sub>70</sub> bilayer HJ (Lassiter et al., 2013a).

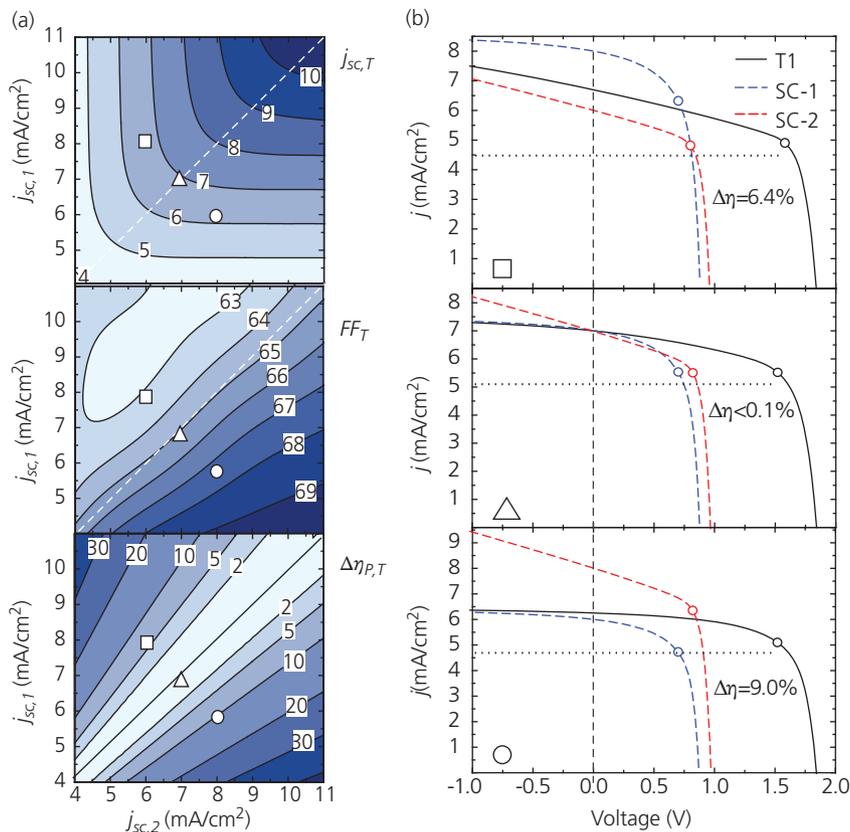

Figure 7.177a shows contour plots of the performance calculated for T1 whose front subcell, that is, SC-2 in Fig. 7.9, is cell *i*. When the *FF* of the two subcells are approximately matched, we see that  $FF_T$  is closer to the higher of the two individual fill factors ( $FF_b =$

**Table 7.25** Example discrete cell characteristics used in Fig. 7.178 (Lassiter et al., 2013a)

Parameter	Cell <i>i</i>	Cell <i>ii</i>	Cell <i>iii</i>	Cell <i>iv</i>
$V_{oc}$ (V)	0.89	0.96	1.04	0.94
<i>FF</i>	0.61	0.66	0.48	0.71
$j_{sc}$ (mA/cm <sup>2</sup> )	9.4	7.7	8.5	6.1
$\eta_p$ (%)	5.0	4.9	4.3	4.1

0.66) when the subcell  $j_{sc}$  are matched. Also, the power penalty is very small if the individual subcells operate at approximately the same  $j_{sc}$  when used in the tandem. The relationship between  $\Delta\eta_p$  and  $j_{sc,1}$  and  $j_{sc,2}$  becomes apparent for T1 in Fig. 7.177b. Here, the differences between cell *i* and SC-2, for example, are due to the position of cell *i* in the stack, the overlap of its spectrum with SC-1 (using the materials in cell *ii*), and the thicknesses and other parameters chosen for all of the layers comprising the tandem OPV. Thus, for devices in Fig. 7.177b (top and bottom panels) with very different  $j_{sc}$ , a power penalty of > 6% is incurred compared to the situation where  $j_{sc,1} = j_{sc,2}$ , which is approximately achieved for the scenario in Fig. 7.177b, center panel. As predicted above, when  $P_M = j_M V_M$  is approximately equal for each subcell, then the power delivered by the tandem is given by  $P_{M,T} = j_M (V_{M,1} + V_{M,2})$ .

The penalties incurred by using significantly mismatched subcells *iii* and *iv* in T2, are considerably larger. In this case,  $FF_T$  trends towards that of the

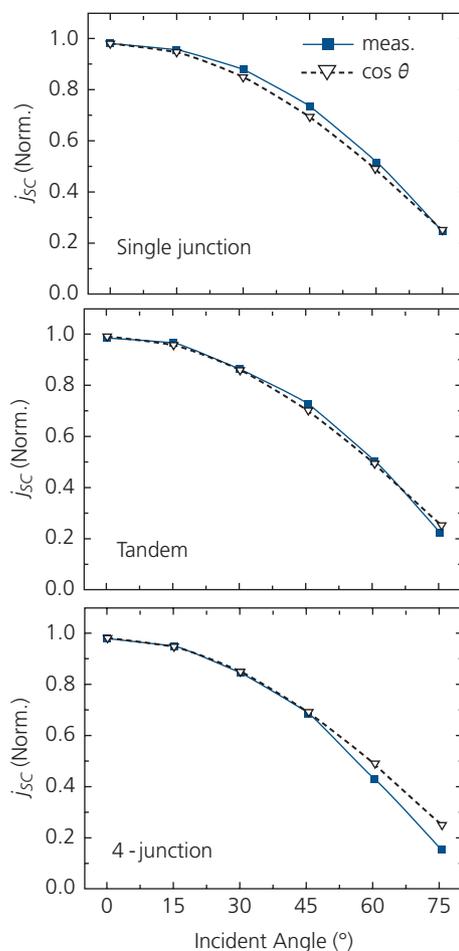

**Figure 7.177** (a) From top to bottom:  $j_{sc,T}$ ,  $FF_T$ , and  $\Delta\eta_{p,T}$  for tandem T1 comprising cells *i* and *ii* in Table 7.25. The diagonal lines are for the optimal case of  $j_{sc,2} = j_{sc,1}$ . (b) Three  $j$ - $V$  characteristics for the tandem T1 modelled in (a) employing front and back cells SC-2 and SC-1, respectively. The small circles on the characteristics indicate the MPPs of each device. The symbols in the lower left correspond to those shown in (a). After Lassiter et al. (2013a).

subcell with the lowest current, that is, when  $j_{SC,1} \gg j_{SC,2}$ , then  $FF_T \rightarrow FF_{SC,2}$ , and when  $j_{SC,2} \gg j_{SC,1}$ , then  $FF_T \rightarrow FF_{SC,1}$ . When the short circuit currents of the two subcells are equal, then  $FF_T = (FF_{SC,1} + FF_{SC,2})/2$ . Finally, the power penalties are also more severe when the individual fill factors and currents are increasingly asymmetric. The power penalty is then no longer centered along the diagonal in Fig. 7.177a, but rather  $\Delta\eta_p$  it is larger when  $j_{SC,2} > j_{SC,1}$ . Hence, the tandem reaches the highest performance only when the constituent single junction cells have closely matched characteristics in the stacked architecture.

The angle-dependent sensitivity of thin, organic devices arises from optical interference between the stacks comprising several layers with different optical constants. We showed in Section 6.6 that interference significantly affects the OLED emission spectrum. The same angle-dependence affects the total diurnal energy generated by a solar cell, whose efficiency may vary with the incidence angle. The variation of the efficiency vs. incident angle of AM1.5G simulated illumination of a DBP:C<sub>70</sub> single junction cell, a DTDCPB:C<sub>70</sub> front subcell/DBP:C<sub>70</sub> back subcell tandem, and four-junction cells comprising a double stack of the tandem structure is shown in Fig. 7.178. Details of the various devices are provided in Section 7.5.3. Also plotted is  $\cos\theta$  which is proportional to the expected cell angular response as a function of angle from the normal (at  $\theta = 0$ ) in the absence of microcavity effects. The single and tandem junction cells closely follow the cosine law. Only the four-junction cell, comprising a stack of over 20 layers and a thickness of 250 nm, shows a noticeable angle-dependence at  $\theta > 45^\circ$ . While the efficiency at higher angles is marginally lower, the total energy available for harvesting at such oblique angles also decreases. Hence, the penalty incurred due to angle dependent interference within a deeply stacked multijunction cell is small compared to the advantage of its significantly higher efficiency at normal incidence.

The angle dependence of the current in even deeply stacked OPVs is significantly less pronounced than the angle-dependent emission observed in stacked OLEDs. This is a result of the “damping” effect of absorption in OPVs that is absent in light emitters. As light propagates within the multijunction stack it is partially absorbed by each subcell, attenuating the magnitude of the optical interference.

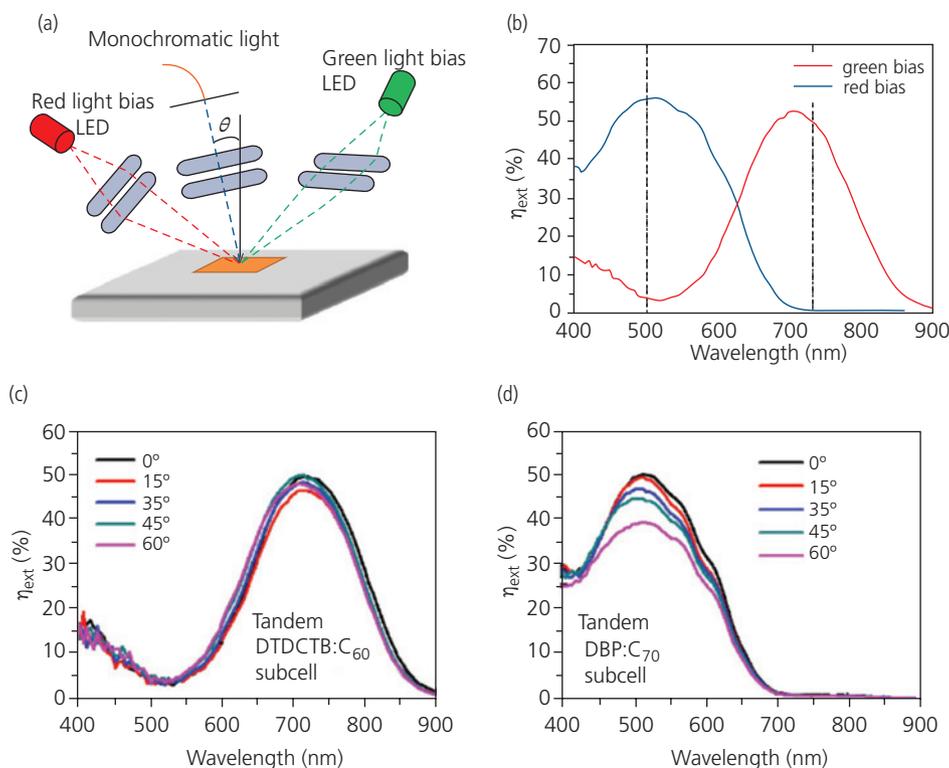

To understand where the angle dependence originates in the stacks, light biasing described in Section 7.3.3 was used to separately determine the quantum efficiencies vs. angle for both the DTDCPB:

**Figure 7.178** Measured short circuit current vs. angle of incidence,  $\theta$ , for single, tandem, and four-junction OPVs described in Section 7.5.3. Also shown is the  $\cos\theta$  dependence expected for a device with no microcavity effects (Che, 2018).

C<sub>70</sub> front and DBP:C<sub>70</sub> back subcells. The experimental setup is shown in Fig. 7.179a. The  $\eta_{ext}$  of the long wavelength DTDCPB:C<sub>70</sub> cell is obtained by providing light bias from an intense, 505 nm wavelength LED, whereas the short wavelength DBP:C<sub>70</sub> cell is biased using LED emission at 735 nm. The  $\eta_{ext}$  of the separate cells under normally incident monochromatic light delivered using an optical fiber is shown in Fig. 7.179b, along with the light biasing wavelengths (dashed lines). This is a nearly ideal system to obtain accurate efficiency measurements of the separate components due to their lack of significant spectral overlap of the subcells.

The angle of the monochromatic light source is varied from  $\theta = 0$  to  $60^\circ$ , with results for the two cells shown in Fig. 7.179c and d. Almost all angle dependence arises from the short wavelength absorbing back subcell (SC-1). This is consistent with

**Figure 7.179** (a) Experimental setup for measuring the angle-dependent external quantum efficiencies of separate subcells in a tandem OPV. (b) The  $\eta_{ext}$  of the separate subcells measured at normal incidence with light bias wavelengths shown by the dashed lines, and  $\eta_{ext}$  for the (c) front and (d) back subcells vs. angle,  $\theta$ . After Che (2018).

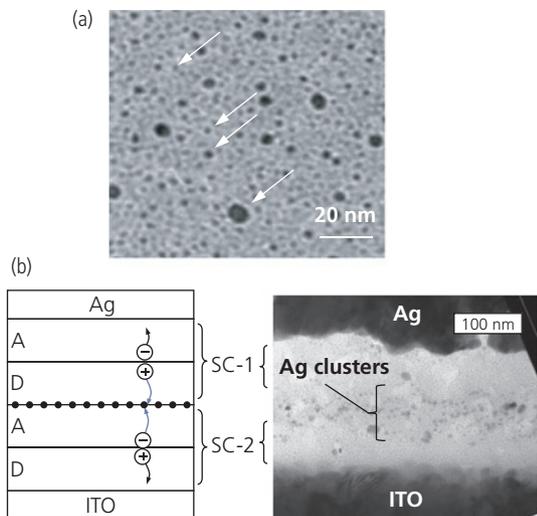

optical models, whereby short wavelength light in a microcavity has a longer optical path length (equal to  $nd/\lambda\cos\theta$ , where  $d$  is the layer thickness and  $n$  is its index of refraction) than light at longer wavelengths. For this device, there is a 15% decrease in  $\eta_{ext}$  of the DBP:C<sub>70</sub> cell as  $\theta$  is varied from 0° to 60°, which accounts for nearly all of the deviation of the cell response in Fig. 7.178 over this angular range.

### 7.5.2 Charge recombination zones

The CRZ is interposed between each subcell in a multi-junction OPV. It serves a purpose similar to a tunnel junction between subcells in inorganic multijunctions; that is, it provides a site for electrons in one subcell to recombine with holes in the adjacent subcell to “complete the circuit.” In its absence, the photogenerated electrons and holes cannot reach the opposing electrodes, creating a buildup of charge and, consequently an opposing internal potential that halts the current flow. The ideal CRZ should be electrically lossless, that is, it must provide a site with 100% recombination efficiency. It must also be optically lossless to avoid absorption outside of the OPV active region.

The first demonstration of a CRZ was a thin (3 nm) Au layer placed between two identical H<sub>2</sub>Pc-MePTC subcells (Fig. 7.89) (Hiramoto et al., 1990). Energy barriers between the Au thin film and the subcells leads to a less than unity recombination efficiency, and the relatively thick layer also introduces significant optical losses (Hadipour et al., 2006). This situation was improved by replacing Au with an ultrathin (1–5 Å) Ag layer that is both optically and electrically lossless (Yakimov and Forrest, 2002; Che et al., 2014).

The submonolayer Ag CRZ is orders of magnitude thinner than the optical skin depth (Eq. 7.176), making the layer nearly transparent. Its effectiveness as a site for charge recombination is understood in the context of the TEM images in Fig. 7.180. The thin Ag deposit does not consistently wet the surface; rather it forms a widely dispersed population of Ag clusters on the organic surface that range from < 1 nm to 7–8 nm diameter (Fig. 7.180a). The cross-sectional image of a CuPc/PTCBI tandem cell in Fig. 7.180b shows that the clusters do not form into a 2D layer, but rather diffuse into the organic film, creating a band of nanoparticles (NPs).

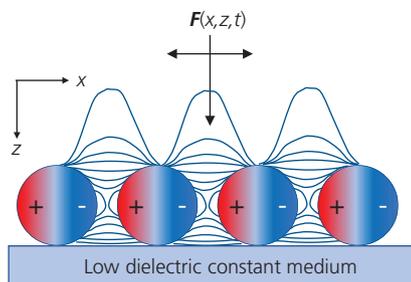

**Figure 7.180** (a) Transmission electron microscope images of a PTCBI surface on which Ag nanoparticles (mean Ag film thickness, 5 Å) are deposited. Arrows point to Ag clusters of different diameters (Peumans et al., 2003b). (b) *Left*: Schematic diagram of a tandem cell with a Ag NP CRZ (dots) between subcells 1 and 2 (SC-1, SC-2, respectively). *Right*: TEM image of a thinned cross-section of the tandem cell. Ag NPs are shown as dark clusters (Rand et al., 2004).

The NP layer provides for highly efficient charge recombination without optical losses. When an electron from an adjacent acceptor layer is at distance  $r$  from a neutral Ag NP metal sphere, it is attracted by its mirror image with a force of  $q^2/(4\pi\epsilon_r\epsilon_0r^2)$ . Once the electron binds to the sphere, the NP is negatively charged, and subsequently attracts a hole from the adjacent donor layer with the same force. The electron and hole recombine, and the process begins once more starting with the neutral NP. The binding energy of an electron to the NP is  $E_B = q^2/(8\pi\epsilon_r\epsilon_0r)$ . At room temperature, and at a distance,  $r = 4$  nm,  $E_B = 2.4k_B T$ . From the small field approximation of Onsager theory, the capture probability of the charge is given by (Onsager, 1938, Tachiya, 1988)

$$P_{cap} = \exp\left(-\frac{r_c}{r}\right) \left(1 + \frac{qr_c}{2k_B T} F\right), \quad (7.196)$$

where the capture radius is  $r_c = q^2/(4\pi\epsilon_r\epsilon_0k_B T)$ . For  $F = 0$ ,  $P_{cap} \rightarrow 0.99$  (see Section 4.7.2), making the NPs extremely efficient recombination centers even though they cover only a small fraction of the organic surface.

Closely packed metallic NPs also affect the incident illumination by supporting plasmons that reradiate into the adjacent layers. Silver has a pronounced plasmonic absorption feature centered at approximately  $\lambda = 440$  nm (Rand et al., 2004). The plasmonic field is

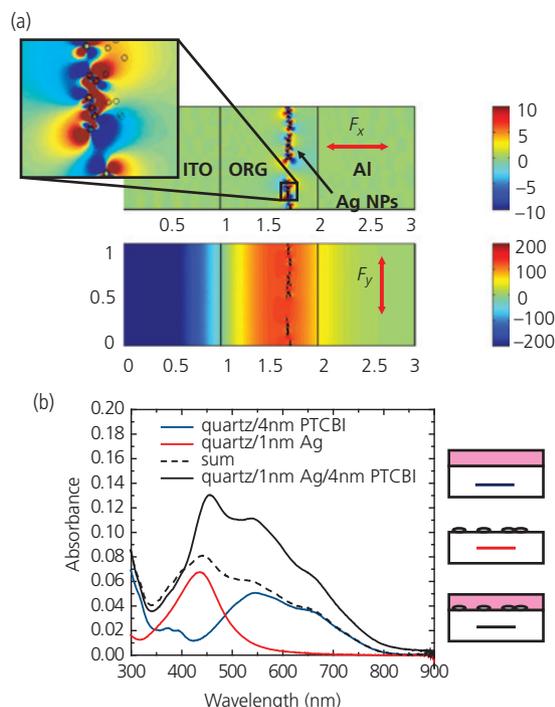

**Figure 7.181** Instantaneous field lines due to plasmons in metal spheres induced by an incident field,  $F(x,z,t)$ . The metal spheres lie on a half plane occupied by a low dielectric medium (e.g. glass), and the upper half-plane is filled by a higher dielectric organic film resulting in an asymmetric field profile. The instantaneous induced charge distribution is shown by “+” and “-.”

depicted in Fig. 7.181, where the normally incident electromagnetic field induces an instantaneous redistribution of charge on the surfaces of the spheres. The charge density wave reradiates in a pattern determined by the surrounding dielectric medium. In the illustration, the spheres are located on the surface of a low index medium (e.g. glass), and are buried in a higher index dielectric such as an organic semiconductor. The NPs act as an antenna array that “focuses” the field intensity within a nearby junction, thus increasing absorption. The field intensification is responsible for the increased efficiency of multijunction cells in Fig. 7.90b, where the dual junction cell has a power conversion efficiency  $> 2.5$  times that of the single junction cell. This 20% enhancement is due to the increased field arising from plasmons supported by the Ag NP layer.

A simulation of the electric field enhancement due to a Ag NP layer embedded in an organic film, and sandwiched between ITO and Al is shown in Fig. 7.182a (Peumans, 2004). The inset shows an increase of 100–1000 times the incident field. Indeed, the field intensity remains high in a zone whose width is 10–20 nm, which overlaps the D and A layers on either side. Figure 7.182b shows the measured absorbance for a Ag NP layer on quartz, a PTCBI layer on quartz, and a quartz/NP/PTCBI structure. The absorbance of the latter structure (black line) is nearly double the sum (dashed line) of the contributions of just the NPs and PTCBI, accounting for the increased efficiency of the tandem cell compared to the single junction cell in Fig. 7.90.

The most common CRZ used for solution processed multijunction cells comprises a layer of ZnO NPs (Gilot et al., 2007, Janssen et al., 2007, Li et al., 2013). The metal oxide NPs were initially

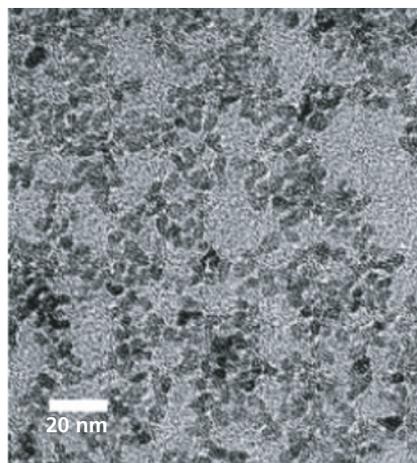

**Figure 7.182** (a) Calculated relative perpendicular (top) and parallel (bottom) electric field intensities in an ITO/organic/Al structure. The field strengths are relative, with red being the most intense. Scales on the plot axes are in 100 nm units. Inset: A detail of a section of the NP layer. Circles indicate positions of the layers. (b) Absorbance of the quartz/NP/PTCBI structure (black line) is greater than the sum (dashed line) of the quartz/PTCBI (red line) and quartz/PTCBI (blue line) layers. After Peumans (2004).

introduced as an acceptor in BHJ cells employing MDMO-PPV as the donor (Beek et al., 2005). However, an electron-transporting ZnO NP layer, in combination with a pH-neutral PEDOT:PSS hole transporting layer, forms an efficient and transparent CRZ that can be cast from solution.

The monodisperse particle populations are synthesized by a combination of hydrolysis and condensation of a Zn acetate dehydrate in a KOH: methanol solution. A TEM image of a solution cast ZnO NP film is shown in Fig. 7.183. Layer thicknesses of 10–30 nm provide optimal interconnection between subcells with minimal optical losses (Gilot et al., 2007). To produce a more continuous network and drive off excess solution, the NPs are often annealed at elevated temperatures (e.g. 150°C for 10 min.), although this may damage the underlying organic layers (Hau et al., 2010, Kouijzer et al., 2012).

The ZnO NPs result in a Schottky barrier with the adjacent layers, which creates an internal series resistance within the multijunction cell. A *self-*

**Figure 7.183** TEM image of a monodisperse film of 5 nm diameter ZnO NPs (Beek et al., 2005).

*assembled monolayer* (SAM) cast onto the NP layer surface is one means for changing the surface energy with the objective of decreasing the barrier to charge injection from the active region into the CRZ. A SAM is a space-filling, ultrathin (e.g. a single molecular layer) film of molecules. When attached to a surface, it can change the film morphology and/or energetics. A SAM comprising pyrrolidine-functionalized C<sub>60</sub> molecules was used to improve injection from the compound ZnO NP/PEDOT:PSS CRZ in multijunction polymer cells (Zhang et al., 2006). Following the deposition of the NP layer, the SAM is deposited from a solution of CB and THF, and then excess molecules unattached to the ZnO surface are removed by rinsing in a pure THF solution (Hau et al., 2008). When applied to single, double and triple junction OPVs based on P3HT:PC<sub>61</sub>BM BHJs, the SAM improves the *FF* (e.g. from 0.49 to 0.61 for single junction cells without and with the SAM, and 0.49 to 0.55 for tandem cells) due to a significant reduction in barrier resistance at the BHJ/CRZ interface (Hau et al., 2010).

### 7.5.3 Example multijunction OPV structures and performances

Multijunction OPVs have enjoyed continuous improvement since their introduction in the 1990s, to the point where efficiencies of over 15% have been achieved. The narrow absorption spectrum characteristic of excitonic materials makes it probable that multijunction cells, with their combination of

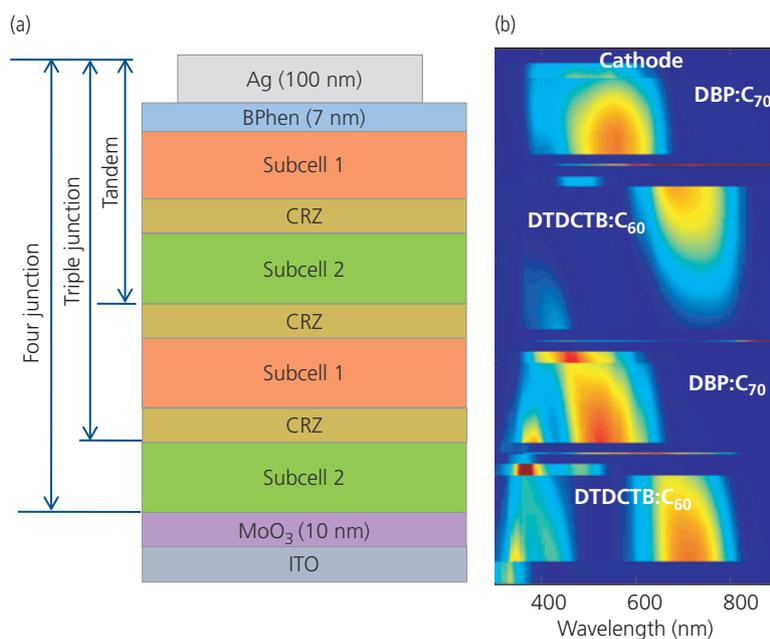

several absorbing materials that achieve a broader spectral coverage than single junction cells will ultimately become the structure that achieves the highest efficiencies. The lower current and higher voltages offered by series-connected cells also leads to reduced resistive losses when used in large area modules. In this section we provide examples of tandem and triple junction cells as a means to point out the benefits of, and challenges in realizing multijunction organic solar cells.

*Vapor deposited multijunction solar cells.* Vapor deposited materials easily form, multilayer complex devices since dry processing does not affect the morphology of previously deposited layers, regardless of their composition or conditions used in their deposition. Unfortunately, there are only a limited number of high efficiency donors and NFAs that can be thermally deposited without decomposition. Nevertheless, multijunction OPVs with at least some of the subcells deposited from the vapor phase have achieved among the highest OPV efficiencies to date (Che et al., 2018b, Li et al., 2018).

Vacuum-deposited tandem, triple, and quadruple junction cells are shown in Fig. 7.184a. A DTDCPB: C<sub>60</sub> (1:1)/C<sub>60</sub> (5 nm) PM-HJ cell (SC-2) used to absorb primarily in the infrared is paired with a DPB:C<sub>70</sub> (10:1)/C<sub>70</sub> (5 nm) PM-HJ cell (SC-1) that absorbs broadly across the visible. The CRZs interposed between the subcells comprise a BPhen:C<sub>60</sub> (1:1) (5 nm)

electron filtering buffer adjacent to the neat C<sub>60</sub> or C<sub>70</sub> layer of the corresponding cell, followed by a 0.1 nm thick Ag NP layer, and a 5 nm thick MoO<sub>3</sub> spacer. The optical field intensity profile for a four-junction cell is shown in Fig. 7.184b. The absorption maximum of the DPB:C<sub>70</sub> (10:1)/C<sub>70</sub> (5 nm) active region is centered at  $\lambda = 500$  nm, which creates a window for transmitting NIR photons to the DTDCPB:C<sub>60</sub> (1:1)/C<sub>60</sub> (5 nm) PM-HJ active regions with a peak absorption at 650–700 nm, and a somewhat weaker absorption at 400 nm that overlaps with a similarly weak absorption in the DBP-based subcell. Importantly, the BPhen:C<sub>60</sub> (1:1) (5 nm)/Ag (0.1 nm)/MoO<sub>3</sub> (5 nm) CRZs are nearly completely transparent across the visible and NIR, as shown by the solid blue coloration of those layers in the figure.

The CRZ is also nearly electrically lossless. In Table 7.26, we see that the sum of the  $V_{OC}$  values for the separately fabricated subcells is  $0.82 + 0.90$  V = 1.72 V. This is identical to the measured  $V_{OC}$  of the tandem. The quadruple OPV should have double the voltage of the tandem, that is, 3.44 V. The actual voltage is only slightly lower than this at 3.38 V. The residual voltage loss may be due to losses from lower illumination intensity of the individual subcells in a four-junction stack. Recall that  $qV_{OC} \propto k_B T \log(j_{SC}/j_0 + 1)$ . Since  $j_{SC}$  is lower for multijunction than for single junction cells, we expect that  $V_{OC}$  will also be less than that of individual subcells

**Figure 7.184** (a) Vacuum-deposited multijunction OPV structures. The active regions are Subcell 1: DTDCTB:C<sub>60</sub> (1:1) and DBP:C<sub>70</sub> (10:1). (b) Optical field distribution calculated for a quad-junction cell. Red indicates the highest absorption, and blue the lowest. After Che et al. (2014) and Che (2018).

exposed to full 1 sun intensity. The drop in  $V_{OC}$  is partially compensated by an increased  $FF$  at the reduced  $j_{SC}$  (cf. Fig. 7.72). That is,  $FF$  is limited to some extent by cell series resistance that becomes less significant as the intensity per subcell decreases with number of junctions in the stack.

The power conversion efficiencies summarized in Table 7.26 show that the tandem does not have double the efficiency of the individual subcells. The subcells in the stack have different (thinner) layer thicknesses to ensure current balance. Nevertheless, the tandem cell has  $\eta_P = 10\%$ , which is substantially higher than either of the optimized single junction cells of 5–6%. Increasing the number of stacked elements to three

**Table 7.26** Measured subcells and tandem, triple, and quadruple junction cell performances (Che et al., 2014, Che, 2018)

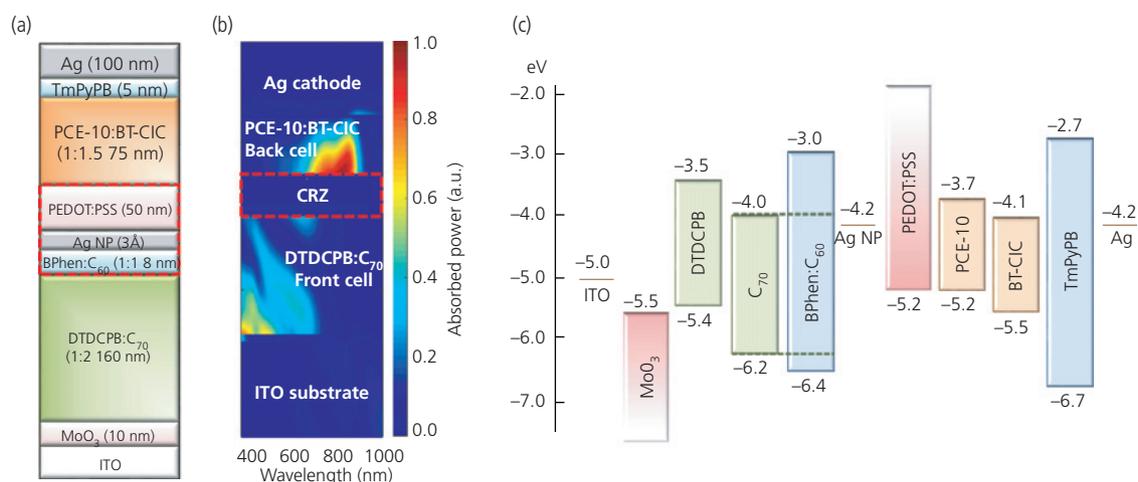

Cells <sup>a</sup>	$j_{SC}$ (mA/cm <sup>2</sup> )	$V_{OC}$ (V)	$FF$	$\eta_P$ (%)
SC-1	11.3	0.90	0.61	6.2
SC-2	10.4	0.82	0.59	5.1
Tandem	9.9	1.72	0.59	10.0
Triple	7.3	2.58	0.59	11.1
Quadruple	6.4	3.38	0.58	12.6

<sup>a</sup> SC-2 refers to a PM-HJ DTDCB:C<sub>60</sub> subcell nearest the anode in the tandem; SC-1 refers to the PM-HJ DBP:C<sub>70</sub> subcell near the cathode in the tandem; “tandem” employs a BPhen:C<sub>60</sub> interconnecting buffer layer; “triple” employs a second DBP:C<sub>70</sub> subcell adjacent to the substrate in addition to the tandem structure. Quadruple employs a final DTDCB:C<sub>60</sub> subcell nearest the cathode.

and four results in a continuously decreasing advantage, with  $\eta_P = 11.1\%$  and  $12.6\%$ , respectively. Note, however, that these efficiencies may be approximately 10% higher than their actual values as the measurements were made without a mask on very small (1 mm diameter) devices. Thus, edge currents result in an artificially higher  $j_{SC}$  when the samples are flooded with illumination (Che et al., 2014).

We have seen that the highest efficiency single junction OPVs employ solution-processed small molecule NFAs. Hence, to employ these materials in tandems requires that at least one subcell be deposited from solution. A tandem device employing a combination of vapor deposited, fullerene-based subcell (SC-2) and a second, NIR absorbing NFA-based subcell (SC-1) is shown in Fig. 7.185 (Che et al., 2018b). The challenge in fabricating this device is to avoid damage to the vapor deposited SC-2 during the solution deposition of SC-1 onto its surface with only a thin, and potentially porous CRZ separating the stacked elements.

The problem of eroding the underlying layers is solved by using an acidic (pH = 1–2) PEDOT:PSS layer cast onto the surface of the Ag NP/BPhen:C<sub>60</sub> CRZ. Both the Bphen:C<sub>60</sub>/Ag NP layer and PEDOT:PSS are hydrophilic, leading to uniform wetting by the PEDOT:PSS. Pinholes, or other physical defects through the CRZ may expose the underlying DTDCPB:C<sub>70</sub> (1:2) active region, but the PEDOT:PSS does not penetrate into the pre-deposited active layer. The hydrophobic PCE-10:BT-CIC (1:1.5) BHJ

**Figure 7.185** (a) Architecture and (b) calculated absorbed power distribution in the solution/vapor deposited fullerene/NFA-based tandem OPV. (c) Equilibrium energy level diagram of the cell in (a). The energy levels of C<sub>60</sub> in the electron-filtering BPhen:C<sub>60</sub> layer are indicated by dashed lines. The buffer layer used for the back cell (SC-1) is the wide energy gap, vapor-deposited TmPyPB (Che et al., 2018b).

non-fullerene active region is cast from a CF/CB solution (10:1 by vol.) which prevents it from fully wetting, and hence dissolving the aqueous PEDOT:PSS layer underneath, thereby preventing damage to the underlying layers. The device is completed by the vacuum deposition of a 5 nm thick TmPyPB exciton blocking buffer layer. Using the combination of hydrophobic and hydrophilic materials results in >95% fabrication yield of devices ranging in areas from 2 mm<sup>2</sup> to 1 cm<sup>2</sup>. In addition, the performance characteristics of the devices are stable over storage periods of several months, indicating that the layers do not host residual solvents that may continue to degrade the layers in the completed device (Che et al., 2018a).

The optical intensity distribution within the tandem cell shows nearly complete absorption in the visible by the vacuum-deposited DTDCPB:C<sub>70</sub> mixed junction, with the NIR illumination out to 900 nm absorbed in the PCE-10:BT-CIC BHJ non-fullerene active region. The 2 mm<sup>2</sup> antireflection coated (ARC) devices showed an efficiency of up to 15% under 1 sun, AM1.5G simulated illumination, decreasing to 11.5% for 1 cm<sup>2</sup>, non-ARC devices. The drop in efficiency for the larger devices is primarily a result of the series resistance of the ITO anode contact to SC-2 (see Section 7.3.3).

The efficiency of devices without the ARC is approximately 14.3%. From Eq. 7.26, we find that Fresnel reflections at the glass surface result in a 4% loss for a glass refractive index of 1.5. A low index, bilayer ARC comprising 120 nm MgF<sub>2</sub> (with index  $n = 1.38$ ) and a low index SiO<sub>2</sub> ( $n = 1.12$ ) reduce the reflections to < 1%. We have shown in Section 6.6.3 that thermally depositing SiO<sub>2</sub> at a large oblique angle relative to the source results in a porous layer with an index that is the weighted mean of the volume of air and SiO<sub>2</sub> within the layer. Oblique incidence of the vapor results in random nucleation of silica across the substrate. The islands thus formed then shadow further deposition of material, creating voids that make an open, low index structure (see Fig. 7.186a). By depositing the ARC on the distal surface of a substrate, the optical coupling to the OPV increases by 4% across much of the visible spectrum, as shown in Fig. 7.186b. In Fig. 7.186c we find that the increased optical intensity results in a concomitant increase in  $j_{SC}$ , thus increasing the maximum  $\eta_p$  from 14.3% to 15%.

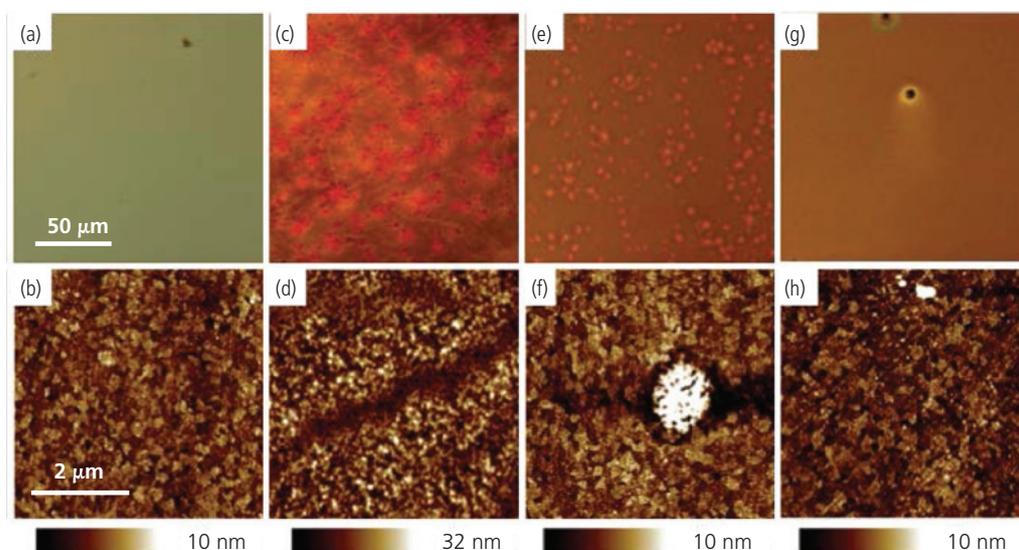

This same solution/vapor deposited device structure was demonstrated, except where the solution-processed binary layer was replaced by a broader NIR absorbing DA<sub>1</sub>A<sub>2</sub> ternary subcell. The subcell comprised a blend of PCE-10:BT-CIC:TT-FIC (1:1.25:0.5), with absorption extending to 1000 nm. By including an ARC, The device efficiency using light biasing to obtain the quantum efficiencies of

**Figure 7.186** (a) Two SEM views of the surface of the SiO<sub>2</sub> ARC layer thermally deposited at glancing angle of 85° from normal. (b) Ratio of transmitted light through a glass substrate with a bilayer ARC to that of an uncoated surface. both the front and back subcells, yielding a nearly constant  $\eta_{ext} = 80\%$  from 380 nm – 900 nm. Including an ARC on the bottom glass substrate surface resulted in  $\eta_p = 15.4\%$ , with  $V_{OC} = 1.56V$ ,  $FF = 0.71$ , and  $j_{SC} = 13.8 \text{ mA/cm}^2$  under 1 sun, simulated AM1.5G illumination (Li et al., 2018).

*Solution-processed multijunction cells.* There are two principal methods for achieving high quality solution-processed multilayer structures: using orthogonal solvents to deposit successive layers, and inserting an insoluble and relatively thick CRZ between the subcells. In either case, the options for achieving optimized optical absorption and electrical performance are limited by the inherent constraints on the choice of materials, solvents and desired morphologies.

**Figure 7.187** Optical (top row) and atomic force (bottom row) micrographs for samples processed using: (a, b) SVA, no THF exposure; (c, d) as-cast, 5 nm MoO<sub>3</sub>, THF exposure; (e, f) SVA, 5 nm MoO<sub>3</sub> layer, THF exposure; (g, h) SVA, 20 nm MoO<sub>3</sub>, THF exposure. The vertical scales for the bottom row of micrographs are indicated beneath each image (Lassiter et al., 2013b).

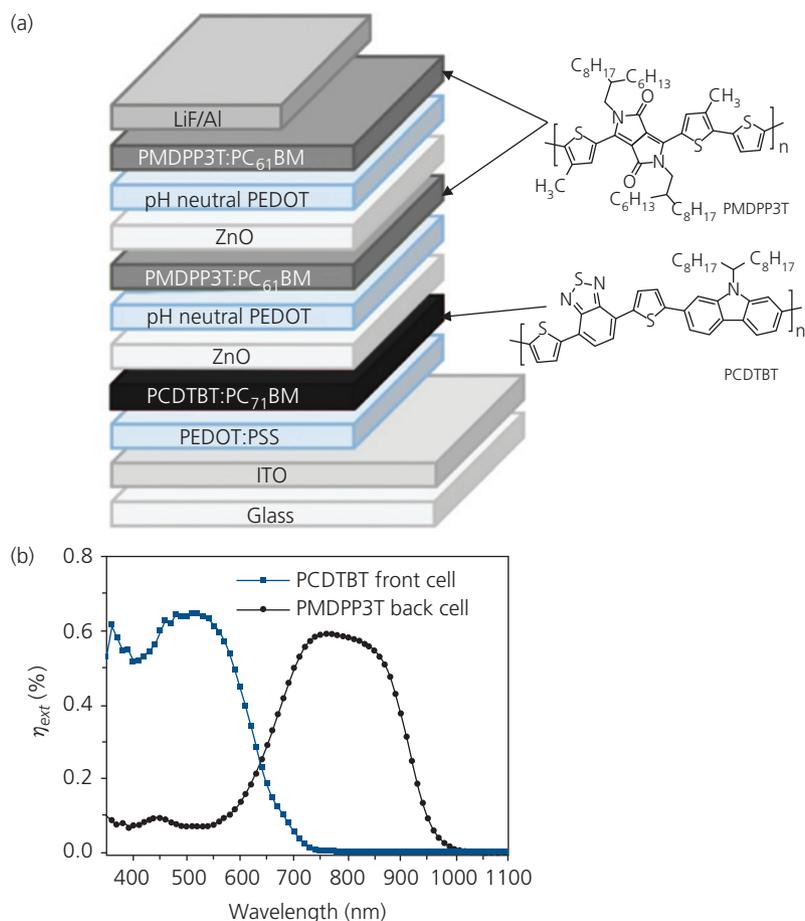

As discussed in Section 5.4.2, only three orthogonal (i.e. non-interacting) solvent classes are employed in organic electronic device fabrication: aqueous, organic, and the less frequently used fluorinated solvents. Hence, using orthogonal solvent systems to produce deeply stacked multijunction OPVs offers only limited opportunities to achieve the desired structures. One example of an orthogonal solution-processed, *f*SQ-based tandem cell used a combination of CF and THF solutions in the following structure: glass/ITO/25 nm MoO<sub>3</sub>/15 nm blended *f*SQ (CF)/10 nm C<sub>70</sub>/5 nm PTCBI/0.1 nm Ag/7 nm MoO<sub>3</sub>/15 nm blended *f*SQ (THF)/28 nm C<sub>60</sub>/5 nm PTCBI/100 nm Ag (Lassiter et al., 2013b). The layers were solvent vapor annealed after deposition of each PTCBI layer. The *f*SQ layers comprised a DPASQ:DPSQ (4:6 by vol.) blend. The neat C<sub>70</sub> and other layers in the stack (e.g. MoO<sub>3</sub>, PTCBI and Ag) were vacuum deposited after the active, blended layers were spun-on from their respective solutions. The SVA was accomplished by exposure of the layers to a DCM vapor to achieve a dense, nanocrystalline morphology of the *f*SQ blend. The annealed morphology reduces the layer porosity, improving its resistance to penetration by the solvents applied during subsequent processing. The MoO<sub>3</sub> and C<sub>70</sub> layers on the surface of the front subcell (SC-2) provide additional barriers that impede penetration of the THF used in deposition of SC-1 into underlying layers.

Damage incurred by spinning THF on the top of the base structure of: glass/ITO/25 nm MoO<sub>3</sub>/15 nm

blended *f*SQ (spun on using CF)/10 nm C<sub>70</sub>/5 nm PTCBI/0.1 nm Ag/*x* MoO<sub>3</sub>, where *x* = 5 or 20 nm is shown in the micrographs in Fig. 7.187. Figures 7.187a and b correspond to a SVA sample with a MoO<sub>3</sub> thickness of *x* = 5 nm. The layer was not exposed to THF, resulting in a smooth surface morphology, with a rms roughness of 1.5 nm. Figures 7.187c and d show as-cast films with *x* = 5 nm, where THF was spun on the top of the same structure. The films significantly roughen to 4.9 nm due to re-dissolution of the underlying *f*SQ layers. In Figs. 7.187e and f, the layers were solvent vapor annealed after deposition of PTCBI, followed by exposure to THF. The film contains ~1 μm-diameter by 10 nm-high protrusions covering 10% of its surface due to swelling from THF penetration into the underlying layers. As the MoO<sub>3</sub> thickness is increased to *x* = 20 nm, the density of protrusions decreases, and are nearly eliminated (Fig. 7.187g and h). Tandem cells processed using these structures and procedures had  $V_{OC} = 1.78$  V,  $FF = 0.67$ , and  $\eta_P = 6.2\%$  (Lassiter et al., 2013b).

In this example, the devices areas were only 1 mm<sup>2</sup>. It is unclear, therefore, what yield can be achieved by scaling the OPVs to larger areas. Their vulnerability to pinholes, along with the limited selection of available orthogonal solvent chemistries, has focused work on solution-processed tandem designs that employ relatively thick ZnO NP/PEDOT:PSS CRZs that have a low density of pinholes and other physical defects.

Fullerene-based tandem and triple junction cells based entirely on solution processed layers (with the

**Figure 7.188** (a) Schematic illustration of a solution deposited triple junction cell. The short-wavelength absorbing PCDTBT-based SC-3 and the longer-wavelength absorbing PMDPP3T cells, SC-1 and SC-2 are shown along with the active polymer molecular structures. (b) External quantum efficiencies of the subcells employed in a tandem cell that contains only a single PMDPP3T-based element (Li et al., 2013).

exception of the cathode and anode contacts) have been demonstrated with at least a 50% increase in efficiency over optimized single junction cells that are used with the stacked devices. The structure of the triple junction cell is shown in Fig. 7.188a, along with the materials comprising both the long and short wavelength subcells. The short wavelength absorbing SC-3 positioned adjacent to the anode is a BHJ comprising a PCDTBT:PC<sub>71</sub>BM (1:4) blend. This is combined with a PMDPP3T:PC<sub>61</sub>BM (1:3) BHJ that absorbs at wavelengths > 900 nm. The triple junction analog of the tandem employs two PMDPP3T:PC<sub>61</sub>BM elements, SC-1 and SC-2.

The external efficiency spectra of the two subcells in the tandem are independently obtained by appropriate light and electrical biasing (Section 7.3.3), with the results shown in Fig. 7.188b. The peak efficiencies of the two cells is ~60%, which is nearly identical to the efficiencies obtained in the discrete cells as a

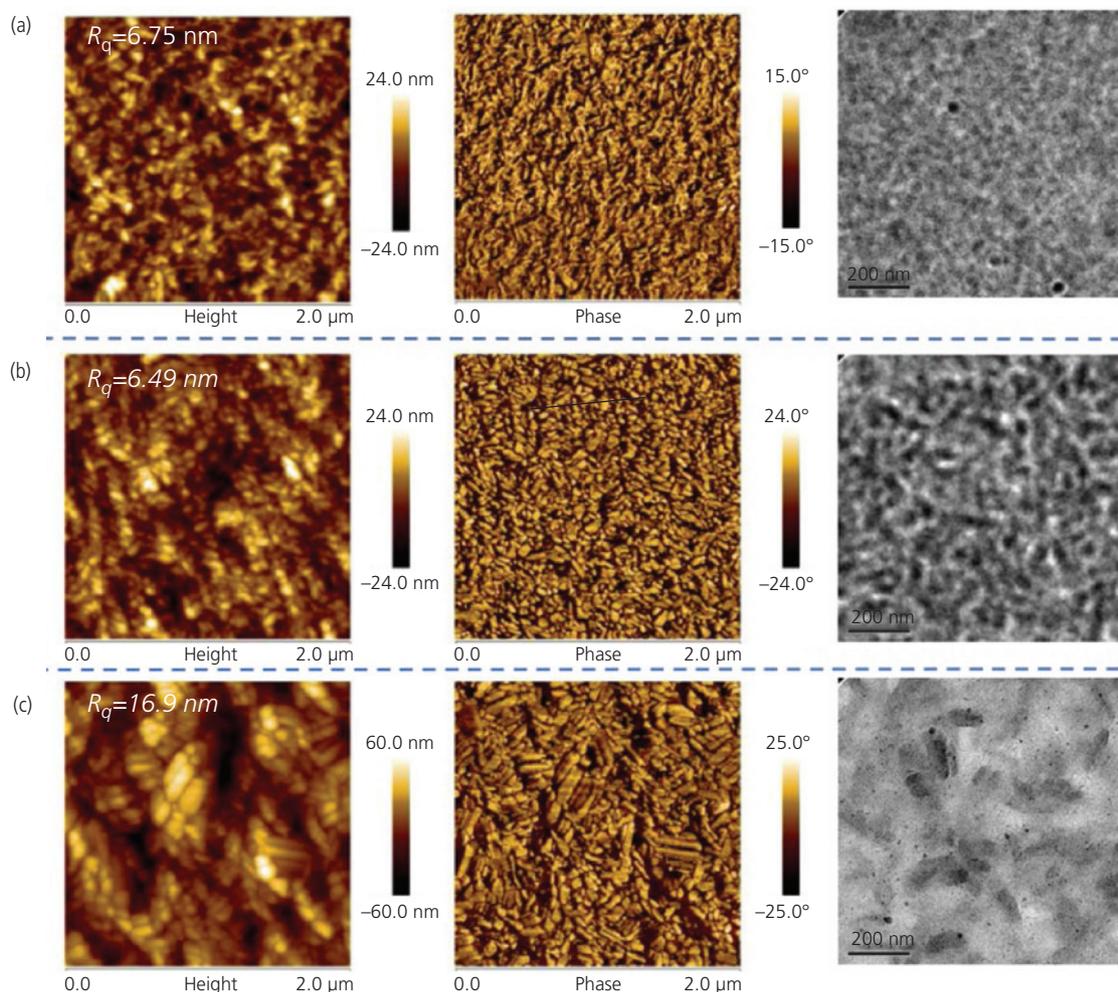

**Table 7.27** Performance characteristics of single, tandem, and triple junction, solution-processed fullerene-based cells (Li et al., 2013)

Measurements made at 1 sun intensity, AM1.5G simulated illumination without solar spectral mismatch correction.

consequence of the complementary spectra of the subcells employed.

A summary of the performance of the single, tandem and triple junction cells is provided in Table 7.27. The tandem cell efficiency is significantly higher than that of the individual cells, with  $V_{oc,T} \approx V_{oc,1} + V_{oc,2}$ , that indicates that the CRZ has very low

**Figure 7.189** Micrographs of a PBDTTT-E-T:IEICO blend film (a) as-deposited, (b) after 1 min and (c) after 4 min SVA in a chlorobenzene solution. From left to right: AFM topography, AFM phase, and TEM images (Cui et al., 2017).

Fine-tuned photoactive and interconnection layers for achieving over 13% efficiency in a fullerene-free tandem organic solar cell. *J. American Chem. Soc.*, 139, 7302-7309. Copyright 2017 by the American Chemical Society.

electrical loss. The tandem cell efficiency is limited by the unbalanced current generation of the short and long wavelength elements. That is, the current from the long wavelength SC-2 is larger than from SC-3. The balance is improved by splitting the long wavelength cell into two subcells, SC-1 and SC-2 in a 1+2 triple junction design. While this decreases the current generated by an individual PMDPP3T:PC<sub>61</sub>BM BHJ, the efficiency is increased by the increases in  $V_{OC}$  and  $FF$ , and the incrementally higher current generated by SC-3. As a result, the triple junction cell has the highest power conversion efficiency of 9.64%.

The reduced energy loss and improved NIR response of NFA-based OPVs leads to significantly improved efficiency when these acceptors are

incorporated into multijunction cells (Cui et al., 2017, Qin et al., 2017, Cheng et al., 2018). However, while NFAs are useful for NIR absorption, there are few examples of these molecules that have sufficiently large energy gaps for absorption in the visible. An exception is ITCC-M used in a 1:1 mixture with the donor PBDB-T, a large energy gap derivative of ITIC. This species has an absorption peak at 600 nm ( $E_G = 1.68$  eV), which is blue-shifted by approximately 50 nm from that of IT-IC. The narrow energy gap cell consists of a blend of the donor polymer, PBDTTT-E-T (Huo et al., 2011), with the acceptor, IEICO, the latter molecule with  $E_G = 1.36$  eV. This combination of active materials results in a fullerene-free tandem OPV with  $\eta_p = 13.0\%$  (Cui et al., 2017).

There are two interesting features of this NFA-based tandem cell. The first is the replacement of the PEDOT:PSS hole conducting component of the ZnO NP CRZ with a 6 nm thick film of the strongly electron-accepting polyelectrolyte, PCP-Na (**Scheme 1**) (Cui et al., 2016). The benefit of this material is that it is more transparent in the NIR than PEDOT:PSS, although it has a relatively strong absorption between 400–500 nm. The tandem  $V_{OC,T} = 1.79$  V, which is 2% less than  $V_{OC,1} + V_{OC,2} = 1.82$  V, suggesting that it supports high efficiency charge recombination comparable to PEDOT:PSS.

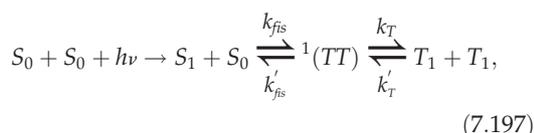

**Scheme 1**

The second interesting aspect is the development of the morphology of the PBDTTT-E-T:IEICO blend due to annealing in a CB solution. The micrographs in Fig. 7.189a shows that the as-deposited films have a surface rms roughness of 6.75 nm, which is unchanged after SVA for 1 min (Fig. 7.189b). However, the TEM images show the development of a fibrous structure indicative of small, nanocrystalline domains due to the aggregation of IEICO molecules. As the exposure to the CB solution is extended to 4 min (Fig. 7.189c), the surface exhibits a distinct and larger-scale, fibrous domain structure. The highest performance device is obtained for cells annealed for only 1 min, which results in the optimal phase separation between the donor polymer and the small molecule NFA.

## 7.6 Singlet fission

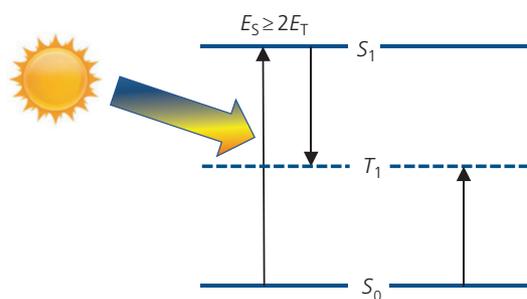

Multijunction cells are only one way to reduce thermalization losses and incomplete solar spectral coverage in single active layer solar cells. Another method to reduce losses incorporates *singlet fission* (SF) into the solar energy harvesting process (Dexter, 1979). SF is a *multi-exciton generation* (MEG) process that occurs when the singlet energy,  $E_S$ , is at least twice that of the triplet, that is,  $E_S \geq 2E_T$ . Then, it is possible for a photogenerated singlet exciton to split into two triplets via the reaction (Johnson and Merrifield, 1970, Smith and Michl, 2010):

where  $S_0$  is the molecular ground state,  $S_1$  is the first excited singlet, and  $T_1$  is the first excited triplet state. The third step in the reaction results in the formation of a *correlated triplet state*,  ${}^1(TT)$ , with singlet multiplicity (i.e. total spin quantum number  $S = 0$ ), followed by separation into two uncorrelated triplets,  $T_1$ , that diffuse in the medium. The reaction in Eq. 7.197 is reversible, with  $k_{fis}$  equal to the rate of triplet pair formation (with the opposite reaction rate of  $k'_{fis}$ ). The correlated pair can resolve into two, uncorrelated triplets at rate  $k_T$  (with reverse rate  $k'_T$ ).

If the triplets are harvested at a type II HJ, the SF process can, in principle, double the internal quantum yield, that is, the number of excitons generated per incident photon. The benefit of this process is that triplets have longer diffusion lengths than singlets, and the diffusion length is often longer than the optical absorption length (Dexter, 1979). Hence, coating a layer of organic SF material (i.e. a singlet fission sensitizer) onto the surface of an inorganic semiconductor can potentially provide a flux of triplet states that dissociate into charges at the organic/inorganic interface. Likewise, this process can be active at fully organic HJs.

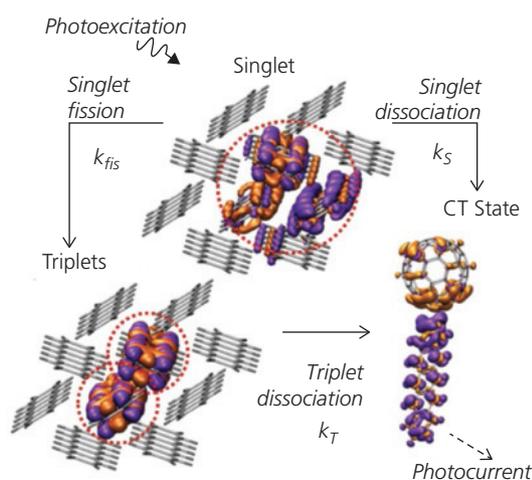

Figure 7.190 shows an illustration of the energetics leading to the reaction in Eq. 7.197. Fission involves the formation of two triplets on adjacent molecules in a radiationless transition analogous to internal conversion. Efficient fission requires that the two molecules that host the triplets be strongly coupled, allowing for fission prior to radiative relaxation of the singlet. Fission is very fast ( $\sim$ ps), and hence competes efficiently with fluorescence that occurs on a nanosecond timescale. The various combinations of spins of the excited states can produce three possible, nearly degenerate correlated triplet pair states: the singlet  ${}^1(TT)$  ( $S = 0$ ), triplet  ${}^3(TT)$  ( $S = 1$ ), and quintet  ${}^5(TT)$  ( $S = 2$ ). The multiplicity of each of the states implies that there are up to nine possible outcomes for triplet fission from  $S_1$ : one from the singlet, three from

**Figure 7.190** Singlet fission into two triplets. The singlet and triplet energies are  $E_S$  and  $E_T$ , respectively.

the triplet, and five from the quintet state. Only one of the states ( $^1(TT)$ ) has singlet character, and hence its formation is spin-conserving. Nevertheless, all nine states can partially mix at zero magnetic field. Their near degeneracy lifts the prohibition against violation of total spin and symmetry conservation (Smith and Michl, 2010). This allows all three combinations to originate from  $^1(TT)$ , particularly in systems where the coupled molecules are the same, that is, in homo-fission systems most commonly active in OPVs. In contrast to intersystem crossing that couples singlets and triplets via spin-orbit interactions, SF is governed by spin dipole-dipole interactions that sensitively depend on the molecular shape and the spatial relationship between neighboring molecules that enhance the dipole coupling matrix elements.

The sequence of steps leading to photocurrent generation is illustrated in Fig. 7.191 for pentacene. Initially, a photon is absorbed, generating a singlet state that is delocalized over two or more pentacene molecules. The singlet subsequently forms a correlated triplet pair on neighboring pentacene molecules at rate,  $k_{fis}$ , or if there is an acceptor molecule such as  $C_{60}$  nearby, it will form a CT state that dissociates into electrons and holes. Presumably, the correlated pair is formed via a briefly transient excimer intermediate state with a lifetime of a few hundred femtoseconds to picoseconds. The triplet pair then separates into two uncorrelated triplets at rate  $k_T$  that diffuse to the acceptor molecule and dissociate into free charges.

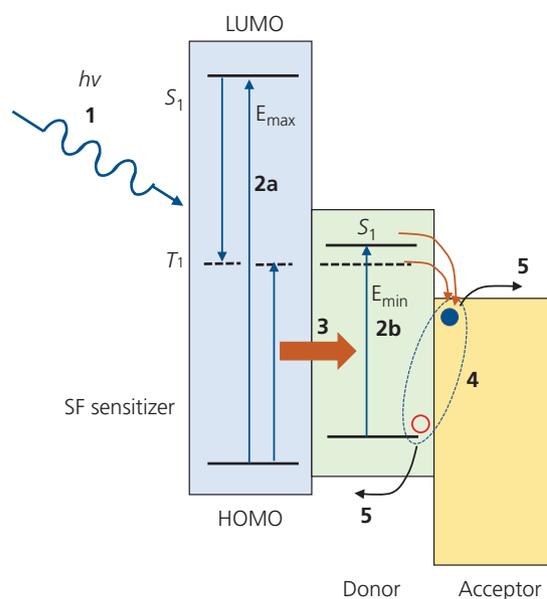

**Figure 7.191** Steps from photoexcitation of a pair of pentacene molecules, to singlet fission, ending with dissociation into an electron–hole polaron pair at the interface with an acceptor molecule (in this example,  $C_{60}$ ). The orange and purple regions indicate electronic orbitals, and the dashed circles indicate the location of singlet and triplet excited states. Rates ( $k_{fis}$ ,  $k_S$ ,  $k_T$ ) for each of the reactions are indicated (Congreve et al., 2013).

The rates of forward and reverse fission depend on the multiplicity of states available for both reactions (9 and 2, respectively). In thermal equilibrium, the rates are related via a Boltzmann distribution, viz. (Merrifield et al., 1969, Groff et al., 1970)

$$\frac{k'_{fis}}{k_{fis}} = \frac{9}{2} \exp[-(2E_T - E_S)/k_B T]. \quad (7.198)$$

Hence,  $k_{fis}$  increases with the number of available states, which in turn should result in a decrease in direct fluorescence intensity. Equation 7.198 shows that the SF efficiency is thermally activated, as has indeed been found for the external quantum efficiency of tetracene/CuPc/ $C_{60}$  detectors (Jadhav et al., 2011). In tetracene, SF is marginally endothermic, with  $E_S = 2.36$  eV and  $E_T = 1.2$  eV.

Simply generating triplets via fission cannot increase the power output of a solar cell since, while the current can be doubled, the voltage is reduced by at least 50%. However, the power output of a solar cell can be increased if a SF sensitizing layer contacts a low energy gap D-A HJ that also harvests photons into the NIR. The triplets generated from absorption of high energy photons by the sensitizer transfer to the HJ where they subsequently dissociate into free polarons in the usual manner. This process is illustrated by energy level diagram in Fig. 7.192 for a conceptual SF-sensitized OPV (Jadhav et al., 2011,

**Figure 7.192** Energy level diagram of a conceptual singlet fission-sensitized OPV showing the steps (1–5) leading to charge generation. The dashed oval line shows the PP state which is a precursor to the free electron (solid circle) and hole (open circle). The block arrow (3) indicates exciton transfer to the HJ.

Wu et al., 2014). The steps for charge generation are: (1) photon absorption in the sensitizer and the HJ layers. Singlets are generated in the sensitizer (2a) and in the HJ (showing only absorption by the donor for clarity, 2b) due to absorption of short and long wavelength light, respectively. No triplets are excited in either material since these are optically dark states. That is, due to spin selection rules they cannot be directly generated via absorption. The narrow excitonic absorption bands of organics limit the minimum and maximum photon energies that are absorbed. The minimum energy absorbed,  $E_{min}$ , is determined by the optical energy gaps of the materials comprising the D-A junction, which also determines the open circuit voltage of the device. The maximum photon energy ( $E_{max}$ ) is extended to the highest absorption energy of the sensitizer. Over the spectral bandwidth of the sensitizer, two triplets are generated for each absorbed photon. (3) Triplet exciton fission products diffuse and transfer to triplet states in the D-A HJ materials via the Dexter process (see Section 3.8.2). This introduces a requirement that the  $T_1$  state of the SF sensitizer be nearly equal to, or greater than  $T_1$  of the D or A material that it contacts. Endothermic transfer is also possible if  $E_T$  of the sensitizer is within a few  $k_B T$  of the  $E_T$  of the HJ materials. The generated triplet and singlet excitons arrive at the HJ where they form a PP, or CT state (4), and subsequently dissociate into free charges (5). Note that the HOMO energies of the sensitizer and the donor should nearly align to prevent trapping of photogenerated holes.

Following the detailed balance treatment in Section 7.3.2, the thermodynamic limits to an ideal SF device can be calculated (Hanna and Nozik, 2006). The total current generated is equal to the difference of the optically generated current ( $j_{ph}$ ) and the recombination current ( $j_0$ ). In the absence of losses (cf. Eqs. 7.137, 7.147 and 7.148),

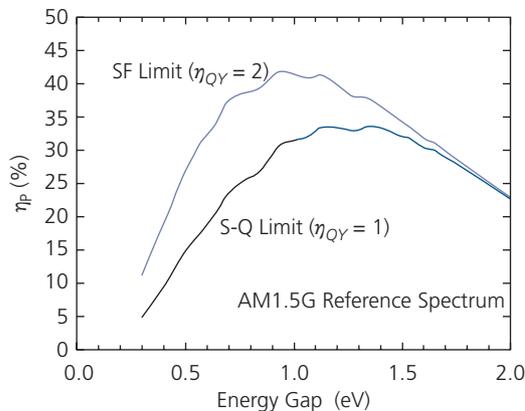

$$j_{ph} = q \int_{E_G}^{E_{max}} \eta_{QY}(E) \phi_s(E) dE \quad (7.199)$$

and

$$j_0 = \frac{2\pi q}{c^2 h^3} \int_{E_G}^{\infty} \frac{\eta_{QY}(E) E^2}{\exp\left(\frac{(E - q\eta_{QY}(E)V)}{k_B T}\right) - 1} dE, \quad (7.200)$$

with

$$j_T = j_{ph} - j_0. \quad (7.201)$$

**Figure 7.193** Thermodynamic power conversion efficiency limit under AM1.5G illumination in the absence ( $\eta_{QY} = 1$ ) and presence ( $\eta_{QY} = 2$ ) of singlet fission. Here, we assume the material energy gap is the triplet energy. Adapted from Hanna and Nozik (2006).

Here,  $\eta_{QY}$  is the quantum yield for exciton-to-charge generation. For lossless SF, then  $\eta_{QY} = 1$  at  $E_T < E < 2E_T$ , and  $\eta_{QY} = 2$  at  $E > 2E_T$ . In this simple case we thus assume step-wise response to the incident photon energy.

The thermodynamic efficiency limit for SF OPVs using these assumptions is plotted in Fig. 7.193 assuming an AM1.5G reference spectrum. The SQ limit of 33.7% corresponds to  $\eta_{QY} = 1$ . Note that this is different than the limit in Section 7.3.2 (~31%) since that earlier calculation assumed an ideal black body source, which neglects the details of the AM1.5G spectrum. For a SF-sensitized device,  $\eta_{QY} = 2$  and the efficiency limit increases dramatically to 41.9% while the energy gap at the peak efficiency red-shifts to 0.93 eV from 1.34 eV. Note that these calculations assume  $E_{loss} = 0$ . However, for organics,  $E_{loss} = 0.3\text{--}0.7$  eV, and hence the maximum efficiency must be decreased accordingly (cf. Fig. 7.74).

Exploitation of the excited state multiplication process sensitively depends on several factors. As noted, the condition of  $E_S \geq 2E_T$  must be satisfied. To reach maximum efficiency,  $E_S$  should exceed 2 eV to achieve an optimal triplet energy of ~1 eV, according to Fig. 7.193. Furthermore, the interaction requires two strongly coupled molecules, which depends on molecular shapes and their relative conformations to ensure appropriate orbital overlap in the solid state that leads to efficient correlated triplet pair production. The coupling cannot be so strong, however, that it prevents triplets from diffusing to the D-A junction. That is, strongly coupled triplets may not separate, in which case  $k'_{fis} > k_{fis}$  in Eq. 7.194. Finally, if the formation of uncorrelated triplets,  $^1(TT) \rightarrow T_1 + T_1$ , is slow,

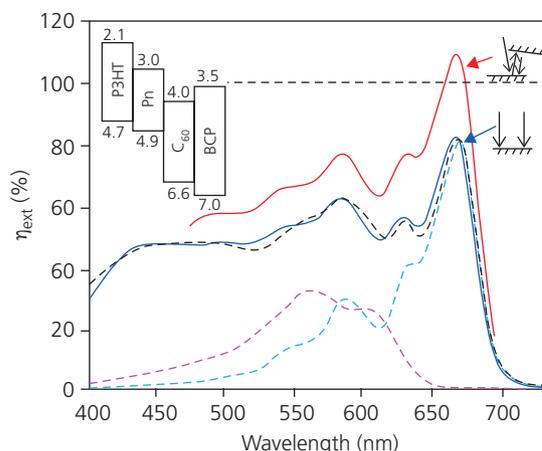

the reverse reaction back to  $S_1$  is again favored. The trapped triplet may annihilate with polarons generated by the dissociation of excitons at the HJ, or even with other triplets. Beyond these fundamental considerations, the energetic alignment of the SF sensitizer with the donor, large triplet diffusion lengths and efficient energy transfer create additional constraints to SF in OPVs.

The observation of SF can be traced back to spectroscopic measurements made on the polyacenes, anthracene and tetracene (Singh et al., 1965, Swenberg and Stacy, 1968, Geacintov et al., 1969, Johnson and Merrifield, 1970). The transitions are *endergonic*, meaning that they occur most efficiently from the first vibronic excited state, and hence the probability for SF increases with temperature (Singh et al., 1965). The presence of SF in the polyacenes was inferred from the low PL efficiency of tetracene, which was attributed to strong singlet quenching by the nearly resonant generation of two triplets (Swenberg and Stacy, 1968). Since then, numerous materials have been developed and the photophysical processes leading to SF have been studied from both practical and fundamental perspectives (Pope and Swenberg, 1982, Zimmerman et al., 2010b, Chan et al., 2012, Yost et al., 2014, Busby et al., 2015, Ito et al., 2018). Given the many factors that must be avoided to achieve high performance devices, there have been few if any reports where SF has led to improvement in the photogeneration efficiency. In this context, two methods have been used to exploit SF in detectors: employing a SF sensitizer (i) in an all-organic OPV as in Fig. 7.192 or (ii) in an organic-semiconductor QD, hybrid HJ.

### 7.6.1 Fully organic singlet fission OPVs

An all-organic, pentacene-based SF OPV has been demonstrated with an external quantum efficiency  $>100\%$ . The structure for the device active region is shown in the inset of Fig. 7.194. It consists of an 8 nm thick P3HT EBL on a PEDOT-PSS/ITO anode, followed by a 15 nm thick pentacene (Pn) SF/donor layer, a 35 nm thick  $C_{60}$  acceptor capped by a BCP blocking layer immediately beneath the Ag cathode. Both Pn and P3HT generate singlets. The P3HT singlets transfer to the Pn where fission occurs, resulting in potentially twice as many excitons that contribute to the photocurrent. A  $MgF_2$  ARC is applied to the substrate to minimize reflective losses at the glass/air interface.

Lacking P3HT, the peak external quantum efficiency is 24%. However, with all three layers,  $\eta_{ext} =$

**Figure 7.194** External quantum efficiency of an organic SF photovoltaic, with (red line) and without (blue line) optical trapping. The efficiencies calculated based on optical modeling of the thin films are shown for pentacene (blue dashes) and P3HT (purple dashes). The model applied to the full device structure with SF is shown by black dashes. Inset: upper left is the energy level diagram of the SF OPV. Upper right is the mirror arrangement for light trapping and for direct, one pass light incidence (Congreve et al., 2013).

82% at  $\lambda = 670$  nm. A very thin (15 nm) Pn layer is employed to minimize losses in exciton diffusion from the donor to the D-A heterointerface. As a result, only 49% of the incident light at 670 nm is absorbed. From this, along with modeling of the optical intensity distribution within the OPV microcavity, the internal quantum efficiency is calculated to be 160% for absorption in the Pn, and 150% for absorption in P3HT. These  $>100\%$  efficiencies are not possible without the presence of multiple exciton generation per incident photon.

The external quantum efficiency is increased using light trapping via illuminating the OPV through an aperture that has a reflecting surface (see Section 7.7). Thus, light that is not absorbed in the first pass through the active region is reflected off of the Ag cathode, returns to the aperture/mirror and has a second opportunity for absorption. Using the arrangement shown in the upper right inset in Fig. 7.194, the peak external quantum efficiency increases to 109%. The power conversion efficiency of the SF device under 1 sun, simulated AM1.5G illumination is 1.8% (Congreve et al., 2013), which is not significantly different from 1.5% obtained using conventional Pn/ $C_{60}$  OPVs (Yoo et al., 2004).

The high detector quantum efficiency provides inferential substantiation for SF. A more direct signature is the photocurrent and/or fluorescence response to an applied magnetic field. In a magnetic field ( $B$ ), Zeeman splitting of the states lifts their

degeneracy. Under a weak magnetic field, the number of triplet states sharing some singlet character increases from three to six, and then decreases to two at high magnetic field (Groff et al., 1970). Thus, at low fields, the photocurrent decreases due to enhanced singlet quenching with increasing  $B$  when SF is present.

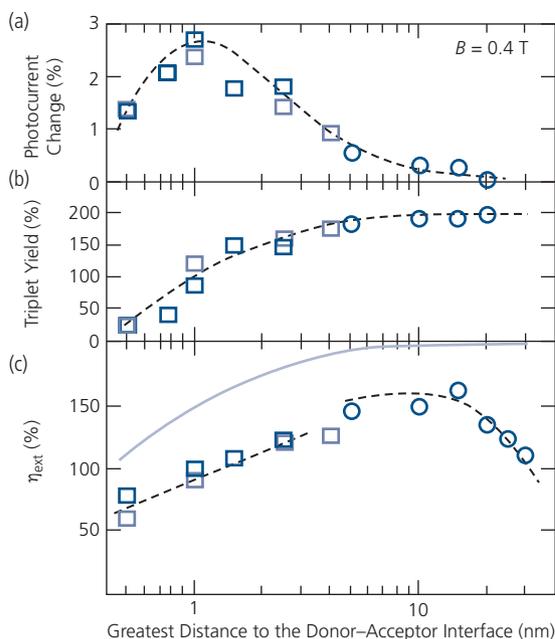

Writing the dependence of the fission rate on  $B$  as:  $k_{fis}(B) = \chi(B)k_{fis}^0$ , the fractional change in photocurrent with  $B$  is given by (Congreve et al., 2013)

$$\delta(B) = \frac{j(B) - j(0)}{j(0)} = \frac{k_S k_{fis}^0 (\chi(B) - 1)}{(2k_{fis}^0 + k_S) (\chi(B)k_{fis}^0 + k_S)}, \quad (7.202)$$

where, as above,  $k_S$  is the fluorescence decay rate. Here,  $\chi(B)$  contains the functional dependence of the fission rate on field. Now  $\delta$  is maximized at  $k_S = \sqrt{2\chi(B)}k_{fis}^0$ , which from Eq. 7.202 leads to an expression for the triplet yield of

$$\eta_{fis}(B) = \frac{2k_{fis}^0}{k_{fis}^0 + k_S} = \frac{(1 - \delta(B))\chi - 1 \pm \sqrt{[\delta(B)(\chi + 2) - \chi + 1]^2 - 8\delta^2(B)\chi}}{(\delta(B) + 1)(\chi - 1)}. \quad (7.203)$$

The pentacene device using either PTCBI or  $C_{60}$  as the acceptor, and with varying pentacene thicknesses were placed in a low magnetic field (0.4 T). The resulting changes in photocurrent, triplet yield, and  $\eta_{int}$  are shown in Fig. 7.195. The photocurrent change increases with Pn layer thickness, until approximately 1 nm (see Fig. 7.195a), after which it begins to decrease. Equation 7.202 is used to extract the triplet yield in Fig. 7.195b. At thicknesses of  $> 8$  nm, the yield approaches 200%, that is, every singlet generated in Pn results in the formation of a triplet pair. Finally, using the values of  $\delta$ , and  $\eta_{ext}$  and optical modeling, the internal quantum efficiency reaches a maximum of  $\eta_{int} = 160\%$  at a Pn thickness of 10 nm (Fig. 7.195c). The roll-off at larger thickness is due to the generation of triplets that recombine prior to charge separation at the HJ due to their limited diffusion length in Pn. The maximum  $\eta_{int} = 200\%$  is not achieved due to recombination and other losses of the triplets. The results are independent of the acceptor used ( $C_{60}$  or PTCBI), indicating that the effects are entirely due to photo-generation within the donor layer, consistent with the SF process. Similar magnetic field dependences are observed for tetracene-based devices (Wu et al., 2014).

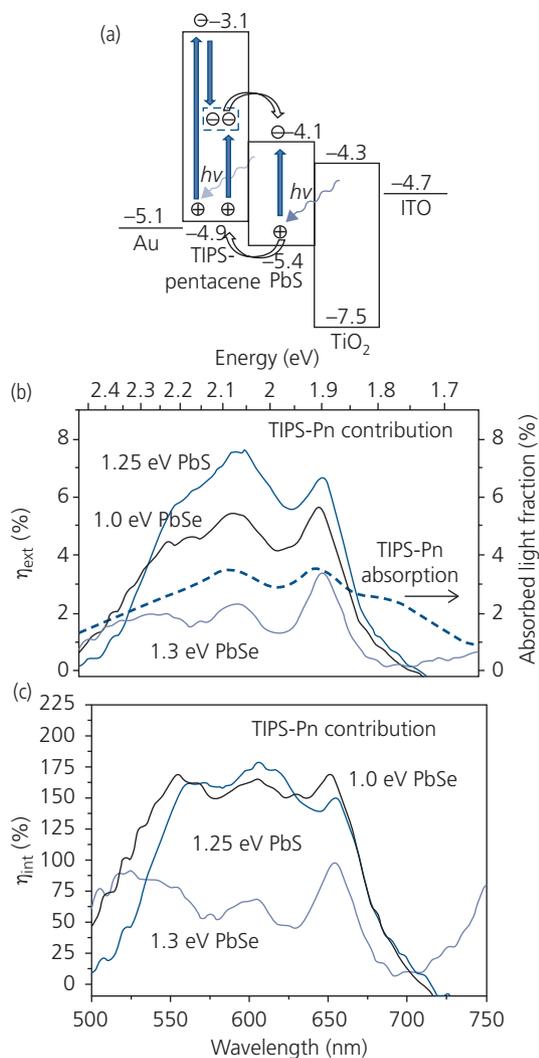

**Figure 7.195** (a): Photocurrent change ( $-\delta$ ), triplet yield ( $\eta_{fis}$ ), and  $\eta_{int}$  for P3HT/Pn/ $C_{60}$  (circles) or PTCBI (squares) devices in Fig. 7.194 vs. Pn layer thickness. Dashed lines are guides to the eye. Solid line is the maximum achievable  $\eta_{int}$  as determined from the measured  $\eta_{ext}$  and optical modeling of the thin device structure (Congreve et al., 2013).

## 7.6.2 Hybrid organic/QD singlet fission OPVs

An alternative design for harvesting triplets generated by SF is the hybrid organic-inorganic QD structure shown in Fig. 7.196 (Ehrler et al., 2012, Yang et al., 2015). This is similar to the organic-Si detector initially proposed by Dexter (1979). If transfer across the organic/inorganic HJ is efficient (see Section 4.7.3), this may ultimately be superior to SF at fully organic HJs (Tabachnyk et al., 2014, Thompson et al., 2014). The device in Fig. 7.196a comprises a 16 nm thick TIPS-Pn SF sensitizing layer solution-cast onto a pre-deposited layer of either PbSe or PbS QDs of various diameters. The active region is sandwiched between a  $TiO_2$ /ITO cathode and a Au anode. Photocurrent is due to direct singlet exciton generation via absorption in the QDs, or triplet generation via fission following absorption by the TIPS-Pn  $S_1$  state (dashed line, Fig. 7.196b). Up to 85% of the illumination intensity incident on the QD layer is absorbed, which limits the contribution due to SF to the remaining 15% absorbed in the TIPS-Pn.

The external quantum efficiency spectrum contributed by only the TIPS-Pn is extracted from the calculated light fraction (via transfer matrix methods) absorbed by this layer, with results in Fig. 7.196b for

**Figure 7.196** (a) Device structure for a SF organic–QD solar cell. (b) Contribution to the external quantum efficiency spectrum from TIPS-Pn of the device in (a) employing either PbSe or PbS quantum dots of different diameters (and hence absorption energies). The calculated fraction of absorbed light in the TIPS-Pn layer is also shown. (c) Internal quantum efficiencies for the devices in (b) (Yang et al., 2015).

several different diameter PbSe and PbS QDs. As shown in Section 7.2.2, the transition energy (given in the figures) is directly related to the dot diameter: the energy increases with decreasing dot size. Notably, the PbSe QD absorption at 1.3 eV is greater than the  $T_1$  energy of TIPS-Pn. In this instance, therefore, the peak  $\eta_{ext}$  is only 3%, or roughly half that of the 1.35 eV PbS and 1.0 eV PbSe QDs where the corresponding  $T_1(Pn) \rightarrow 1S_e(QD)$  transition is exothermic. Here  $1S_e$  is the lowest electronic excited state of the QD (cf. Fig. 7.50). Accounting for the limited absorption in the TIPS-Pn layer, the internal quantum efficiency spectrum is shown in Fig. 7.196c. It is inferred that a

maximum  $\eta_{int} = 170\%$  is obtained for the low energy gap QDs, and the PbSe cell with a 1.3 eV energy has  $\eta_{int} = 80\%$ , presumably due solely to direct  $S_1$  transfer from TIPS-Pn to the QD. The presence of SF was confirmed using B-field measurements as previously described for the Pn-C<sub>60</sub> devices. When illuminated with a simulated solar spectrum (conditions not specified), the TIPS-Pn/PbS cell had  $\eta_p = 4.8\%$ ,  $FF = 0.41$ , and  $V_{OC} = 0.59$  V (Yang et al., 2015). The voltage increases with QD bandgap, consistent with its increased HOMO–LUMO offset energy with the organic.

It remains unclear whether OPVs employing SF will ultimately have improved power conversion efficiencies compared to single or multijunction devices. While the process has been realized in both organic and colloidal QD systems, the most useful application may yet be that originally envisioned by Dexter, where the efficiency of conventional Si cells is enhanced by depositing an organic fission layer onto its surface. This sensitizing layer converts singlets generated by high energy (blue) photons into a pair of triplets, which augments the photocurrent generated by the inorganic cell (Dexter, 1979, Einzinger et al., 2019). Many challenges must still be overcome to find appropriate materials, morphologies and device structures before SF can be effectively exploited in solar energy harvesting applications.

## 7.7 Light trapping and concentration

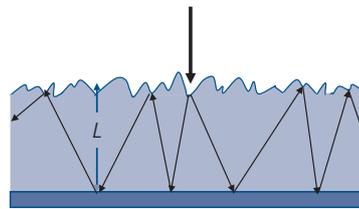

OPV cells are thin film devices comprising a substrate, multiple organic and metal layers that form optical microcavities. As such, OPVs trap light. As we have shown in Section 7.1.2, the light reflected by the metallic contact supports a standing wave that has more than one opportunity to be absorbed within the device active region. By the same process, the optical field can suffer losses on reflection and scattering from the several interfaces in the structure. However, the weak microcavity of the thin film OPV is usually insufficient to result in complete absorption of the incident solar radiation. In Sections 7.4.2 and 7.5.2, we introduced several methods that improve the absorption via optical trapping that include application of ARCs, out-coupling layers, ADRs, and plasmonic field focusing from nanoparticles in the CRZs of multijunction cells. Yet, even these light coupling schemes fall short of increasing the absorption efficiency to  $\sim 100\%$  achieved by conventional solar cell materials and structures. In this section, we describe additional light trapping schemes used to increase  $\eta_{ext}$ .

The basic strategy of all light trapping or in-coupling schemes is the same: to increase the optical path length

(and hence, the photon lifetime) within the OPV. This allows for increased light absorption in the thin active layers. The requirements that are placed on all practical schemes are nearly identical to those needed for white organic light emitting devices. These are:

- (i) *Low cost over large areas.* The primary application of organic electronic appliances is for large area and low cost devices. Solar energy harvesting is a prime example of such an application, since a solar cell is only effective if it captures a large amount of sunlight whose power density is only  $1 \text{ kW/m}^2$ . This demand for low cost electricity places stringent demands on the light trapping scheme, since it must not add significantly to the solar module cost.
- (ii) *Insensitive to wavelength and incidence angle.* The useable solar spectrum extends from the near UV ( $< 400 \text{ nm}$ ) to the NIR ( $> 1.1 \mu\text{m}$ ). In addition, the sun follows a *diurnal solar path* (the day arc), requiring that the time available for power generation is maximized, extending from solar angles as low as  $10\text{--}20^\circ$  above the horizon near dawn and sunset, to the azimuth at midday. Non-tracking solar modules offer the lowest cost. Furthermore, many solar trackers are unsuitable for use in building integrated or building applied PV. These conditions demand an optical trapping scheme whose efficiency is relatively independent of the angle of incidence of the solar flux.
- (iii) *Non-invasive of the OPV active region.* Great care is taken to maximize the efficiency of solar cells by a judicious choice of materials, processing methods to achieve the desired morphology, and multilayer device architecture. Optical trapping designs are generally “added on” to the device or to its substrate after device fabrication is completed. Hence, it is beneficial to avoid schemes that impact the design, or intrude upon the structure of the OPV. To the extent that this is possible, the method should be general, such that it can be applied to any number of device types, independent of the details of their structure or film properties. This non-invasive property creates significant added value to a particular light coupling approach.

The effects of light trapping are illustrated for light incident on a rough surface in Fig. 7.197. The light enters a medium with index of refraction,  $n$ , and is absorbed in the device active region before being specularly reflected off of the back surface reflector (e.g. a metal cathode). The unabsorbed light once more scatters from the top surface or escapes. This process occurs until all of the incident photons are

**Figure 7.197** Light incident on a rough surface of a sample of thickness,  $L$ , is scattered and reflected off of a back reflecting surface in a thin film solar cell.

either absorbed or escape back toward the direction of illumination. Assuming that the scattered light intensity distribution over time is identical to its distribution in phase space, the distribution is said to be ergodic, and hence we can treat the scattering using statistical ray optics (Yablonoitch, 1982). Then, the intensity of radiation from a black body within a medium at frequency,  $\omega$ , within a solid angle  $d\Omega$  is

$$I(\omega) = \frac{n^2 \omega^2}{4\pi^3 c^2} \frac{\hbar\omega}{\exp(\hbar\omega/k_B T) - 1} d\Omega d\omega. \quad (7.204)$$

This expression implies that the intensity within the medium ( $I_{med}$ ) is increased by  $n^2$  compared to the incident light intensity,  $I_{inc}$ , viz.

$$I_{med}(\omega) = n^2 I_{inc}(\omega). \quad (7.205)$$

For simplicity we assume that  $n$  is frequency-independent, and varies only slowly with position. The back surface reflector (BSR) in the solar cell then doubles this intensity to

$$I_{med}(\omega) = 2n^2 I_{inc}(\omega). \quad (7.206)$$

For a sample of thickness  $L$ , and absorption coefficient  $\alpha$ , the fraction of incident light that is absorbed is obtained by integrating over the optical paths within the volume, viz. (Yablonoitch, 1982)

$$f = \frac{2\alpha L A_{inc} I_{med}}{A_{inc} I_{inc}} = 4n^2 \alpha L, \quad (7.207)$$

where we assume that  $\alpha$  is wavelength independent, and that the dependence of both  $I_{med}$  and  $I_{inc}$  on  $\omega$  are the same. Here,  $A_{inc}$  is the area illuminated by the incident radiation. This is an important result since it implies that the absorption in the film is increased by a factor of  $4n^2$  due to light trapped within its volume. In organics,  $n \sim 1.5\text{--}2$ , resulting in an increase in absorption by 9–16 simply by using an efficient light trapping scheme. This increase provides flexibility in the choice of materials and structures where the charge extraction and cell series resistance can be reduced by using very thin cells that still absorb most of the

incident radiation. Importantly, the high volume intensity also leads to an increased open circuit voltage according to Eq. 7.122. This, in turn increases the cell power conversion efficiency (Eq. 7.119).

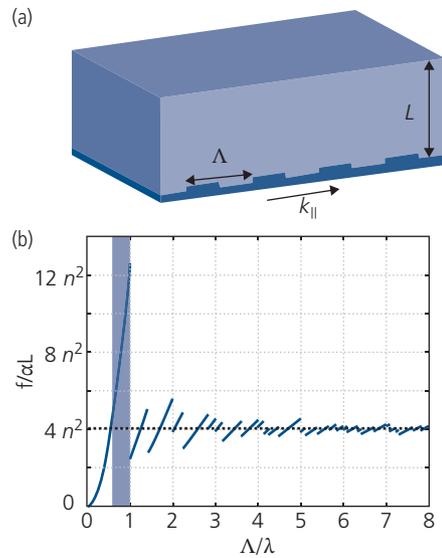

If the incident angle is restricted to the half-angle,  $\theta$ , the enhancement factor is similarly increased to  $4n^2/\sin^2\theta$  (Campbell and Green, 1986). This restriction can be implemented by using solar concentrators, lenses and other external means, as will be shown in the examples discussed below.

The absorbing medium in many thin film cells based on inorganic semiconductors fills the entire scattering volume as in Fig. 7.197. However, we have seen that the active region thicknesses in OPVs are typically  $L \ll \lambda$ . In this case, the modal power can be considerably enhanced even over that predicted by Eq. 7.207. For example, by replacing the BSR with a grating of period,  $\Lambda$ , the incident radiation can be redirected into the relatively high index absorption region surrounded by low index media (i.e. a glass substrate). The modes confined within the waveguiding active region are subsequently absorbed, generating photocurrent. An illustration of the geometry for a waveguide employing a grating on one surface is shown in Fig. 7.198a. The in-plane modes have propagation vector  $k_{\parallel} \leq \omega/c$ . Figure 7.198b is the absorption enhancement factor for a square grating coupler obtained using statistical coupled mode theory (Yu et al., 2010). The enhancement is as large as  $12n^2$  using a sub-wavelength periodicity of  $\Lambda/\lambda \leq 1$ . Numerous modes exist at larger grating periods, although these do not result in enhancement  $> 4n^2$  obtained in a non-wavelength dispersive structure. Thus, there is considerable potential benefit to be gained by employing sub-wavelength structures within the OPV, although these benefits may be outweighed by the increased complexity and cost required in their fabrication.

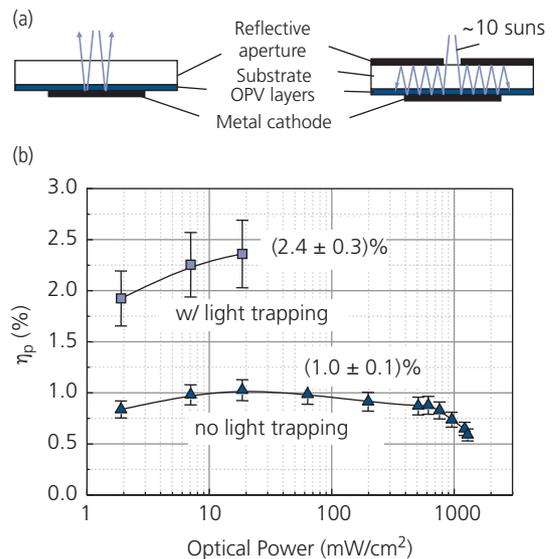

In the remainder of this section, we introduce several light trapping solutions demonstrated in OPVs. Since light trapping and concentration schemes employing surface plasmons from metal nanoparticles in tandem CRZs, ARCs, and ADR stacks have already been considered, we do not discuss them further here.

### 7.7.1 Light trapping using reflective apertures

The high quantum efficiencies for the SF device in Fig. 7.194 were obtained using a narrow reflective aperture, whose principle of operation of this method is illustrated in Fig. 7.199a. In a conventional device, the light is incident on the flat, distal surface of the OPV, and is reflected once from the cathode. The thin layers do not absorb all of the incident radiation, which is subsequently lost to radiation

**Figure 7.198** (a) Modal propagation with in-plane wavevector  $k_{\parallel}$  in a guided wave structure of thickness,  $L$ , and back surface grating of periodicity,  $\Lambda$ . (b) Absorption enhancement factor vs.  $\Lambda/\lambda$ . The shaded region shows an absorption enhancement greater than the thick structure with a roughened surface whose enhancement is  $4n^2$  (dashed line) (Yu et al., 2010).

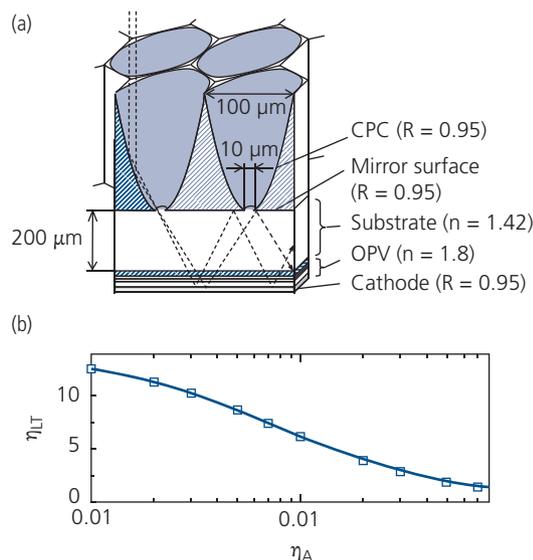

**Figure 7.199** (a) A conventional OPV structure (left), and one with light concentrated through an aperture that reflects light trapped within the substrate. The optimum light intensity concentration at the aperture is equal to the ratio of the reflective OPV cathode to the aperture area. (b) The efficiency of a CuPc/PTCBI OPV with no light trapping, and with 10 suns intensity focused through a reflective aperture. Adapted from Peumans et al. (2000a).

back toward the emitter (i.e. the sun). A mirror containing an aperture can accept concentrated radiation at a limited angle,  $\theta$ . The light that is reflected from the

cathode and not absorbed in its second pass through the active region is then once more reflected from the mirror, providing additional opportunities for re-absorption. If we ignore mirror losses, the potential increase in photocurrent can be as high as  $4n^2/\sin^2\theta$ . Effective light trapping occurs for an aperture diameter,  $d$ , less than the total mirror diameter,  $D$ . Then the incident light must be concentrated by a factor of  $(D/d)^2$  to result in a net increase in absorption.

The benefit of employing the light trap has been realized using an ITO/CuPc (15 nm)/PTCBI (6 nm)/BCP:PTCBI (30 nm)/Ag OPV with results shown in Fig. 7.199b (Peumans et al., 2000a). We have seen in Section 7.4.1 that this device structure is capable of achieving high efficiency even at very high intensities. Indeed, the maximum efficiency of the conventional structure is  $\eta_p = 1\%$  up to intensities of at least 6 suns. The use of a 10 sun concentrating aperture increases the power conversion efficiency to  $\eta_p = 2.4\%$  due to the increased opportunity for absorption enabled by reflections from the mirror surface.

Practical implementation of this scheme requires concentration of the incident radiation using mini-Winston collectors or compound parabolic concentrators (CPCs) that can be made from a metallized thermoformed plastic sheet, a polymer poured into a suitably shaped mold, etc. (Winston and Hinterberger, 1975). The example shown in Fig. 7.200a is a  $10\times$  concentrator with an aperture of  $10\ \mu\text{m}$ , and a concentrator opening of  $100\ \mu\text{m}$ . The reflectivity of the mirror

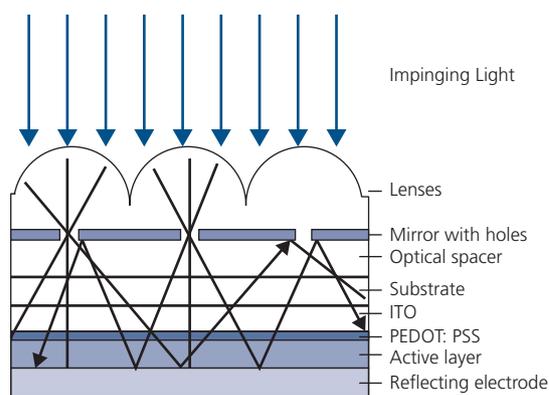

**Figure 7.200** (a) Design of a  $10\times$  mini-compound parabolic concentrator attached to a mirrored aperture surface on the substrate of an OPV. The reflectivity ( $R$ ) of each surface is indicated. (b) Calculated light trapping efficiency vs. absorption efficiency of the OPV layers (Peumans, 2004).

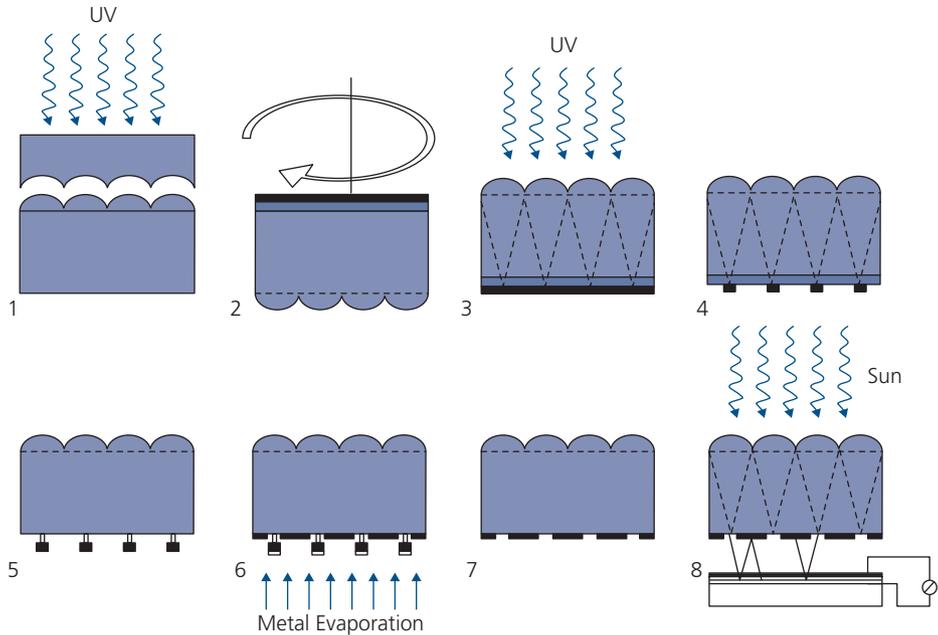

surface at the distal side of the glass substrate, the cathode, and on the interior of the CPCs is  $R = 0.95$ , typical of a Ag mirror. Ray tracing simulations show that the maximum intensity at the cell assuming a hexagonal arrangement of concentrators never locally exceeds 1.4 suns.

The light trapping efficiency,  $\eta_{LT}$ , is equal to the ratio of the light absorbed in the OPV using the  $10\times$  CPCs to that in the absence of the CPCs. This efficiency is plotted vs. the total absorption efficiency ( $\eta_A$ ) of the active region in Fig. 7.200b. The benefit of the light trap increases as  $\eta_A$  decreases, with the advantage disappearing as  $\eta_A \rightarrow 1$ . For nearly transparent layers with  $\eta_A = 0.01$ , the advantage increases to  $\eta_{LT} > 15$ . Note that concentration with mini-CPCs requires solar tracking throughout the day and year (Lee et al., 2015). This increases the cost and size of the solar cells, potentially eliminating advantages gained in their use. Furthermore, solar tracking is not always practical in applications such as BIPV.

Microlens arrays (MLAs) that are focused into an array of apertures can also serve as light traps, as shown in Fig. 7.201. The incident illumination is focused by the microlenses onto the small diameter apertures. By displacing the OPV below the aperture plane, the light passing through the aperture defocuses, and the non-absorbed radiation reflected back from the electrode returns to the mirror surface where only the fraction of light directly incident on the aperture escapes. The remainder then has a second chance to be absorbed. This architecture depends on alignment of the aperture array to the lens focal points and that the light is normally incident to the substrate plane. This demands precise solar tracking to maintain the focal points in the center of each aperture, regardless of incidence angle. Also, the

**Figure 7.201** Microlens array concentrators. The lens focal points are at the aperture array located at the surface of an optical spacer layer (e.g. a glass substrate) above the OPV active layers (Tvingstedt et al., 2008).

**Figure 7.202** Example process for fabricating a microlens array that is self-aligned with the aperture array (Tvingstedt et al., 2008).

focal plane of the hemispherical lenses describes an arc such that off-normal illumination will both move the focal point as well as elevate it above the aperture, causing defocusing and a loss of illumination intensity in the OPV active region.

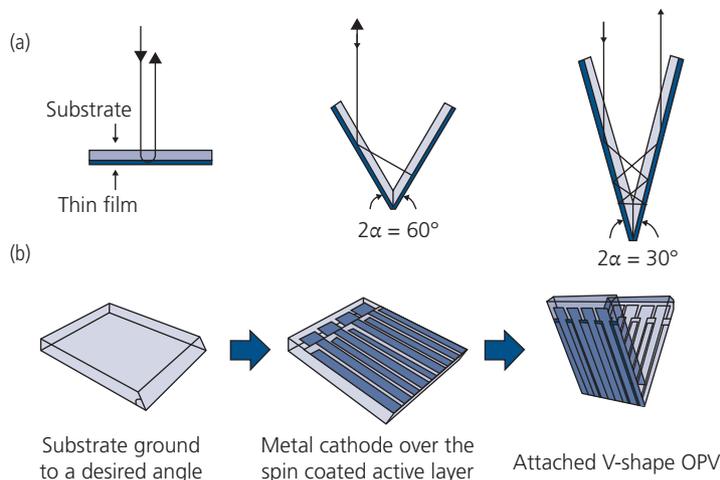

Self-alignment of the focal points to the apertures is achieved by using the MLA itself to pattern the aperture array (see the process in Fig. 7.202). In step 1, the polymer MLA (lens radius,  $r$ ) is formed by embossing the polymer layer with a glass mold comprising an array of hemispherical depressions, and then curing by exposure to UV light. Alternatively, as shown in Section 6.6.2, a thermally cured polymer can be poured into the mold and then peeled off and attached to the substrate (Möller and Forrest, 2001, Sun and Forrest, 2006). Next (step 2), a bilayer photoresist is applied to the opposite side of the substrate whose thickness is equal to the lens focal length of  $f_{lens} = r[n_{lens}/(n_{lens} + 1)]$ , and is exposed (step 3) through the lenses themselves using UV light. The index of the lens ( $n_{lens}$ ) is assumed to match that of the substrate, although suitable adjustments can be made if this is not the case. The use of the lens array to expose the photoresist ensures accurate self-alignment. The photoresist is then developed (steps 4 and 5) to form an undercut pattern due to the different development rates of the two resists comprising the bilayer. The reflective metal layer is deposited (step 6), and excess metal is lifted off by dissolving the photoresist (step 7), thus leaving behind the aligned aperture

array. The entire assembly can be attached to, or integrated with the OPV, as shown in step 8.

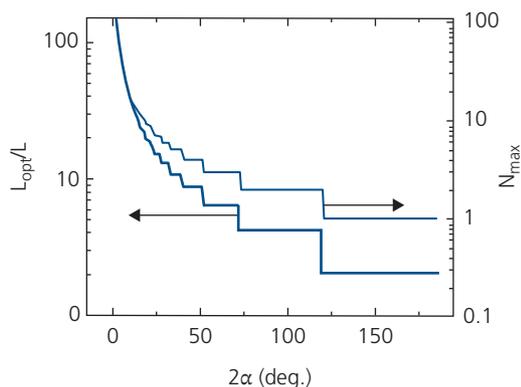

A lensed aperture OPV has been demonstrated employing 200  $\mu\text{m}$  diameter microlenses with 90% transmission in the forward direction (microlenses facing the illumination source), and 15% in the opposite direction. Combining this with a 30 nm thick fluorene copolymer donor (APFO Green-9):PC<sub>71</sub>BM (1:3) OPV increased the cell efficiency by 25%. Most of the improvement came from increased absorption in the wavelength range from 500–750 nm where the BHJ absorbed <50%, whereas the system was less effective at shorter wavelengths where absorption reaches 90% (Tvingstedt et al., 2008). This coupling improvement can possibly be increased using a larger lens radius-to-aperture ratio, although doing so requires an improved optical quality of the lenses and more precise tracking of the light source throughout the day.

### 7.7.2 V-traps

A V-trap is the combination of two opposing OPVs forming a V-shaped substrate symmetrically disposed about an opening angle,  $2\alpha$  (see Fig. 7.203a). For only partially absorbing active regions, the incident light undergoes several bounces before exiting the V, thus providing a longer optical path length that increases with decreasing  $\alpha$ . Fabrication of the trap is straightforward. In Fig. 7.203b, the substrate is prepared by beveling one edge to match it with an identical substrate. This sets the opening angle. The

**Figure 7.203** (a) Schematic illustration of V-trap OPVs with different opening angles,  $2\alpha$ . (b) Assembly of the V-trap (Kim et al., 2013). Reprinted with permission from Kim, 2013, The Optical Society.

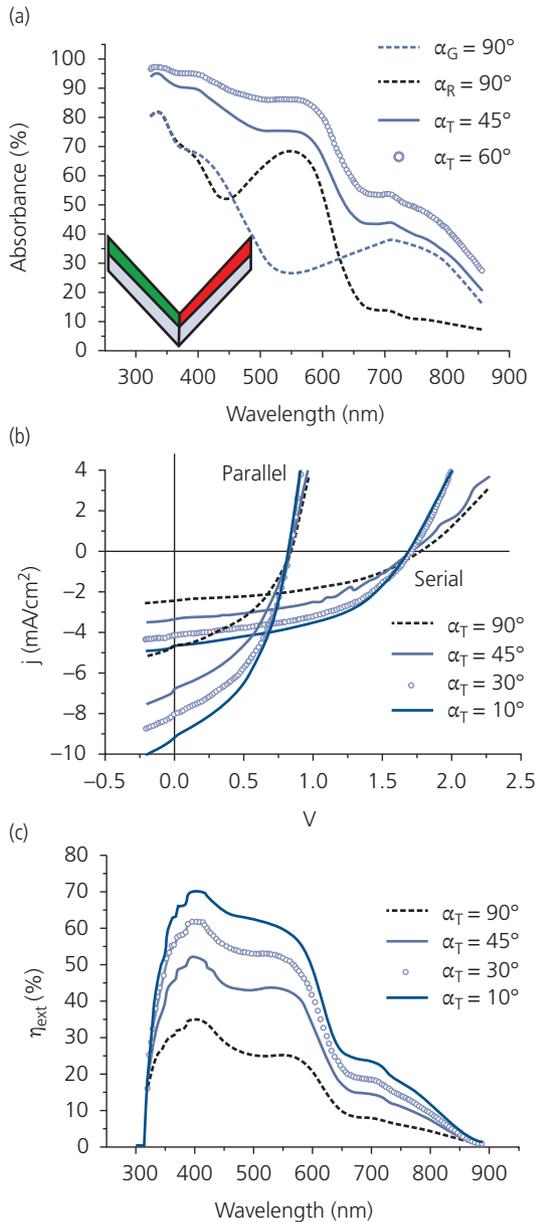

**Figure 7.204** Optical path length normalized to the OPV active layer thickness vs. “V” opening angle. Also shown is the maximum number of bounces ( $N_{max}$ ) experienced by a ray incident along the axis bisecting the V before it escapes (Rim et al., 2007).

reflective cathode is applied over the top of the device active region, and the substrates are bonded to form the V with the semi-transparent contacts facing the inner side of the trap.

The number of bounces,  $N_{max}$ , increases as the opening angle is decreased, with the highest density of illumination found near the vertex. A plot of the optical path length,  $L_{opt}$ , normalized to the active layer thickness,  $L$ , along with  $N_{max}$  vs.  $2\alpha$  is shown in Fig. 7.204. The functions are step-wise in  $2\alpha$ , with  $N_{max} \rightarrow 1$  as  $2\alpha \rightarrow 180^\circ$ , corresponding to a planar substrate. In contrast, when the sides become parallel, we have  $N_{max} \rightarrow \infty$ , leading to an infinite optical path length. Of course, the optical path length and number of bounces only reaches these values if the absorption

on each bounce is negligible, suggesting that there is an optimum angle that leads to the largest combination of opening (and hence maximum solar acceptance), and photocurrent. Furthermore, the length of the cell increases with  $\alpha$ . This introduces another trade-off between module depth, OPV size, and optical path length. An important distinction between this trapping scheme and that using apertures is that the V-trap is not a concentrator. Hence, in principle it does not require solar tracking as long as the aperture is sufficiently open (i.e.  $2\alpha \sim \pi/2$ ) to capture most of the sunlight generated during the day. The planar-V architecture should be oriented in an east-west direction to capture sunlight during most of the day, as long as the opening angle is not too shallow as to create shadowing in the early morning and late afternoon hours.

V-traps have demonstrated increased efficiency when identical cells are used on both legs, with the largest enhancements corresponding to cells with the lowest absorption, or in spectral regions where the cells are most transparent (Rim et al., 2007, Tvingstedt et al., 2007). Alternatively, V-traps provide opportunities to combine different cells on the opposing planes, forming either parallel- or series-connected tandem OPVs. This is shown in Fig. 7.205, inset, for a device comprising a green absorbing APFO-G9:PC<sub>61</sub>BM BHJ cell on one arm (Inganäs et al., 2004) and a red absorbing APFO3:PC<sub>61</sub>BM BHJ on the other (Tvingstedt et al., 2007). The absorbance spectra of the two discrete, planar cells do not significantly overlap (Fig. 7.205a), allowing the two sections to be either connected in series or parallel while maintaining current and voltage balance, respectively. The spectra of the tandem cells folded at

**Figure 7.205** (a) Absorbance, (b)  $j$ - $V$  characteristics, and (c) external quantum efficiency spectra of planar green and red absorbing OPVs ( $\alpha_G, \alpha_R = 90^\circ$ , respectively), and tandem cells at different V-trap opening angles ( $\alpha_T$ ). Inset in (a): V-trap structure with  $\alpha_T = 45^\circ$ , with the green absorbing cell on the left and the red cell on the right (Tvingstedt et al., 2007).

either  $45^\circ$  or  $60^\circ$  are broadened, and are a superposition of spectral features of both subcells. Note that the smaller opening angle results in increased absorption due to the longer effective optical path length.

The series and parallel-connected tandem cell  $j$ - $V$  characteristics under 1 sun illumination are shown in Fig. 7.205b. The series-connected cell has an increase in  $\eta_p$  from 2.0% to 3.7% on decreasing the opening

angle from  $90^\circ$  to  $10^\circ$ . The parallel junction performs somewhat better since current balance is not required, increasing from 3.3% to 4.4%. Finally, the external quantum efficiency in Fig. 7.205c for the parallel-connected cell exhibits the broad response characteristics of both the long and short wavelength arms of the V. Indeed, the efficiency is more than doubled for the cell with a  $10^\circ$  opening angle compared to a conventional planar tandem cell.

An additional degree of freedom offered by V-traps with different cell types on each arm is that the orientation toward the sun can be optimized to generate the greatest total diurnal energy harvesting. Since the red content of sunlight at Earth's surface is larger in the morning and early evening, it is advantageous to orient the long wavelength-absorbing cell on the upper half of the V toward the south (when in the northern hemisphere). Simulations of total daily energy harvesting have found that the most efficient combination of OPVs employing V-traps is using a parallel connection to avoid problems with current balance during the course of a day. Except for large tilt angles where the cosine losses are significant, the diurnal energy harvesting for a V-trap with a module opening angle of  $\alpha = 70^\circ$  can be as much as 1.5 times greater than for an equivalent flat cell (Andersson et al., 2011).

### 7.7.3 Nanoscale dielectric scatterers

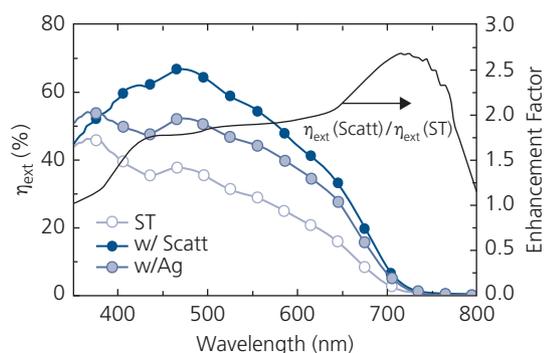

Surface roughening leads to light scattering, which in turn increases the optical path length within the OPV active region. In Section 6.6.2 we found that 240 nm diameter  $\text{TiO}_2$  spheres embedded in a transparent organic film beneath the OLED increases the outcoupling by scattering light from the active region into the substrate escape cone. Likewise, such a tactic can be used to scatter light within an OPV, also resulting in enhanced efficiency (Adams et al., 1993, Tang et al., 2013). The high dielectric constant of the  $\text{TiO}_2$  within a low index matrix can effectively randomize the ray angles entering the active region.

Improved performance of both single and tandem junction polymer OPVs has been demonstrated by embedding 25–35 nm diameter  $\text{TiO}_2$  NPs in a PDMS film, and then pressing the solution between two glass slides to form a 300  $\mu\text{m}$  thick, flexible, diffuse reflector that is attached to the OPV (Tang et al., 2013). The visible reflectivity of the films is varied from near 100% for a  $\text{TiO}_2$ :PDMS weight ratio of 2:1 (the high reflective, HR, film), to  $\sim 85\%$  for a ratio of 0.1:1 (the low reflective, LR, film). The ratio can be adjusted to full transparency as the  $\text{TiO}_2$  concentration is

decreased. Absorption in the  $\text{TiO}_2$  reduces the reflectance to near zero at  $\lambda < 400$  nm. The films can be attached after the OPV fabrication is complete, their response is relatively wavelength independent, and they are lightweight and flexible. As such, scattering layers satisfy many of the requirements of practical light traps.

The external efficiency of a semitransparent (ST) OPV comprising a TQ1:PC<sub>71</sub>BM (2:5) active region sandwiched between an ITO/PFFPA-1 bottom cathode on glass (Tang et al., 2012) and a PEDOT:PSS anode is shown in Fig. 7.206. The efficiency has a maximum of 45% at 380 nm, and a second peak of 38% at 475 nm. Using a Ag mirror placed parallel to the glass substrate, the efficiency at 475 nm increases to 52%, whereas with the HR scattering film, it reaches 70%. The increase obtained by using a mirror *vs.* the dielectric film is due to the Lambertian scattering profile of the latter, leading to the optical field intensification in the in-plane direction as inferred from Fig. 7.197. The enhancement factor, which is the ratio of the external efficiency of the ST device with the scattering layer to that lacking the layer is also shown in Fig. 7.206. There is no enhancement at short wavelengths due to absorption by the  $\text{TiO}_2$ , while at longer wavelengths where the devices are most transparent, the enhancement factor is  $>2.5$ . Absorption within the layers or contacts decreases the enhancement by attenuating the intensity of the light during multiple passes through the OPV.

Scattering layers with adjustable transparency and reflectance can improve current balance in series-connected multijunction cells. An example tandem structure is shown in Fig. 7.207, which is a

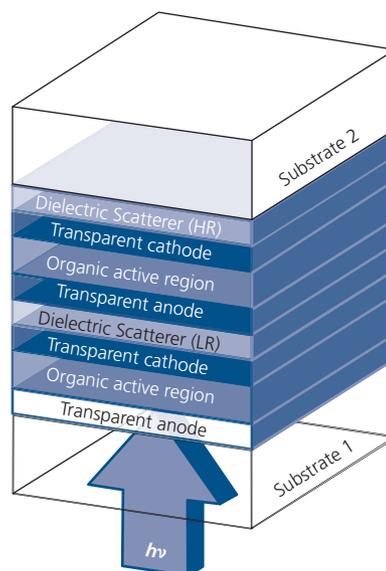

**Figure 7.206** External quantum efficiency spectrum of a semitransparent (ST) TQ1:PC<sub>71</sub>BM OPV compared with a similar device positioned parallel to a Ag mirror, or with a high reflectivity (HR)  $\text{TiO}_2$ /PDMS scattering layer attached to the glass substrate. Also shown is the enhancement ratio in  $\eta_{\text{ext}}$  of the device with the scattering layer to the ST device (Tang et al., 2013).

combination of two, semitransparent single junction OPVs grown on different substrates. The OPV on substrate 2 employs a high reflectance scattering layer that sets up a standing wave within the stack. A second, lower reflectance scattering layer is positioned between the cells. This limits the light penetrating to the upper cell while increasing the reflection into the lower cell. Using the appropriate spectral response and transparency of the LR layer, the current generated in the two cells can be precisely balanced, leading to a higher overall efficiency. In a parallel-connected tandem, only one HR layer is required since current balance is not essential.

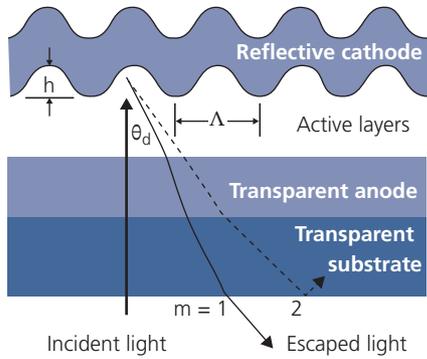

A cell using the LR and HR  $\text{TiO}_2$ /PDMS scattering layers was assembled to implement this strategy. It combined a short wavelength absorbing TQ1:PC<sub>71</sub>BM top subcell and a second P3TI:PC<sub>71</sub>BM (2:3) longer wavelength absorbing subcell adjacent to the HR scattering layer. The device with the LR layer interposed between subcells exhibited  $\eta_p = 6.9\%$ , but without this balancing layer, the efficiency fell to 6.0% (Tang et al., 2013).

#### 7.7.4 Scattering via gratings and textured surfaces

Gratings are effective in coupling incident radiation into waveguide modes (cf. Fig. 7.198), and hence can significantly increase absorption. The gratings can be

**Figure 7.207** A tandem cell assembled from two semitransparent OPVs separated by a low reflectance (LR) dielectric scattering layer to balance currents in the series connected subcells, and a high reflectance (HR) scattering layer to increase the optical path length within the device.

**Figure 7.208** Illustration of grating coupling of incident light into the active layers of an OPV. Grating orders  $m = 1$  and 2, and the diffraction angle relative to the substrate normal,  $\theta_d$ , are shown.

placed either beneath or on the surface of the detector, but in either case, they must be in close proximity to efficiently couple light into the absorptive active region. Also, 2D gratings are more efficient than 1D gratings since they provide coupling independent of the relative orientation of the sun to the solar module. An illustration of an OPV with a grating on its reflective (metal) cathode surface is shown in Fig. 7.208. The grating period is  $\Lambda$ , with depth,  $h$ . The diffraction condition for the grating is

$$m\lambda = n_{act}\Lambda(\sin \theta_i + \sin \theta_d), \quad (7.208)$$

where  $m = 0, \pm 1, \pm 2, \dots$  is the diffraction order,  $\theta_i$  is the angle of incidence, and  $\theta_d$  is the diffraction angle. Two values of  $m$  are shown in the figure ( $m = 0$  is omitted since it corresponds to specular reflection at  $\theta_i = -\theta_d$ ). For solar radiation in the spectral range of  $300 \text{ nm} < \lambda < 500 \text{ nm}$ , Eq. 7.208 is satisfied for  $m = 0, \pm 1, \pm 2$  at a grating period of  $\Lambda = 500 \text{ nm}$  and  $n = 2$ , whereas when  $500 \text{ nm} < \lambda < 700 \text{ nm}$ , then  $m = 0, \pm 1$ . Note that beyond redirecting light into the waveguide modes, the diffraction angle for some radiation can also exceed the angle for total internal reflection (TIR) at the substrate–air interface (i.e. at  $\sin \theta_d \geq 1/n_{sub}$ , where  $n_{sub}$  is the substrate index). This reflects the mode back through the active layers, allowing a second opportunity for absorption.

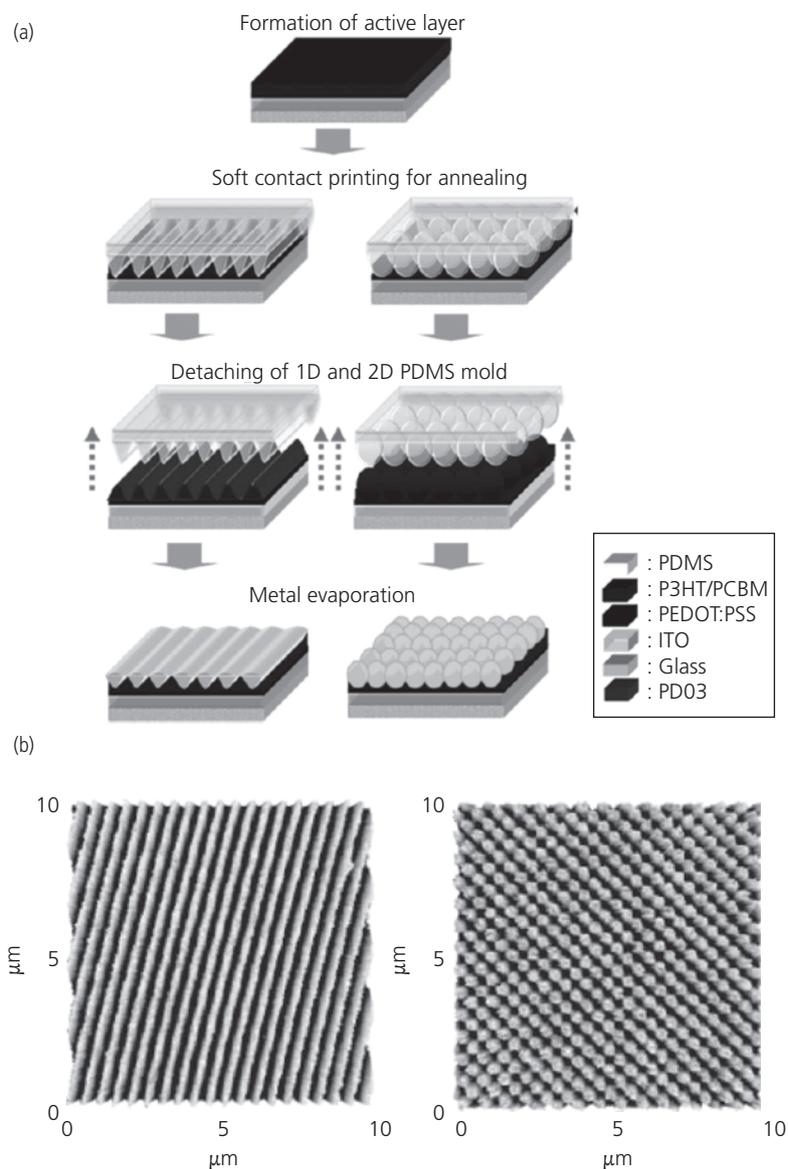

An example soft imprint stamping process (see Section 5.6.4) used for forming gratings on the surface of a P3HT:PC<sub>61</sub>BM OPV active region is illustrated in Fig. 7.209. The first step is to fabricate the 1D and 2D grating stamps by patterning a photosensitive polymer using optical exposure via a holographic interference pattern with a period,  $\Lambda$ , equal to that required for the grating. Alternatively, an inorganic master template can be coated with a suitable photoresist and similarly exposed.

The master is then processed to create indentations that replicate the grating pattern. For a 2D grating, the master is exposed twice, the second exposure made after rotating by  $90^\circ$  followed by development. The master can be directly used as the printing tool, or it can serve as a template by coating it with an elastomer that is cured, and then removed from the master to form the stamp. The advantage of using a replica stamp is that its composition can be made compatible with the processing of the OPV grating. PDMS is a suitable option since it can be easily peeled off from the active device layers without damage owing to its high elasticity (Stolz Roman et al., 2000, Niggemann et al., 2004, Na et al., 2008).

Next, the active layer is spun onto the substrate. Prior to curing, the stamp is pressed onto its surface (Fig. 7.209a), followed by detachment, and then coating the surface with the metal cathode. The surface and the active region are thus left with an impression of the grating pattern as defined by the master. AFM images of 1D and 2D grating patterns on the surface of ITO/P3HT:PC<sub>61</sub>BM/Ca/Al OPVs using an azopolymer master and PDMS stamp are shown in Fig. 7.209b. Patterns of similar dimensions are replicated on the master and the stamp, indicating the high fidelity of the multiple transfer and stamping processes (Na et al., 2008).

The fourth quadrant  $j$ - $V$  characteristics of devices with 1D and 2D gratings are compared with an analogous, conventional (reference) OPV in Fig. 7.210. The inset shows the corresponding external quantum efficiencies for these same diodes. The  $j_{sc}$  is increased for the grating devices compared to the reference OPV due to the increase in  $\eta_{ext}$ , with a larger enhancement achieved with the 2D grating. The power conversion efficiencies are  $\eta_p = 3.6\%$ ,  $4.1\%$  and  $4.3\%$  for the reference, 1D and 2D devices, respectively. One of the drawbacks that decreases the advantage of this design is having the metal cathode in such close proximity to the waveguiding active region. We have shown in Section 6.6.4 that optical modes efficiently couple strongly to lossy plasmon modes in metal layers in the near field. This loss channel significantly reduces the light intensity in the OPV active region, and hence reduces the photocurrent.

Gratings rely on wavelength-scale features to couple incident plane waves into guided modes. While in principle these structures can lead to an increase of  $12n^2$  in intensity within the waveguide, more easily fabricated micron-scale textures can also be beneficial, although they lead to a somewhat reduced optical coupling. An advantage of larger scale

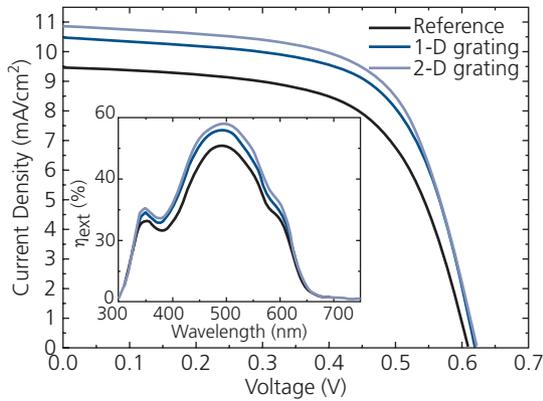

**Figure 7.209** (a) Soft lithography stamping process for forming 1D and 2D gratings in a solution-cast OPV active region. (b) AFM images of (*left*) a P3HT:PC<sub>61</sub>BM OPV surface with a 1D grating with  $\Lambda = 500\text{nm}$ ,  $h = 20\text{nm}$ , and (*right*) a 2D grating with the same dimensions (Na et al., 2008).

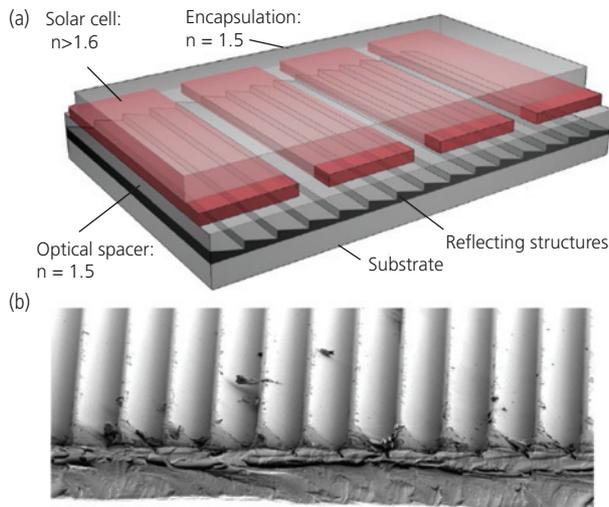

features are their reduced sensitivity to wavelength and incidence angle. Numerous texturing schemes have been explored, including *echelle reflectors* (Tvingstedt et al., 2012), multifaceted prismatic retro-reflectors (Esiner et al., 2013), MLAs (Myers et al., 2012), and substrates with sharp creases and folds (Kim et al., 2012).

An example of a reflector with a large feature size is the echelle prism reflector in Fig. 7.211. An echelle grating is one with coarsely defined grooves that are useful in scattering near-normal incidence light into

the in-plane direction. The reflector shown comprises a series of right, triangular ridges standing  $40\ \mu\text{m}$  from base to apex, with a pitch of  $55\ \mu\text{m}$ . It is formed by micro-embossing an acrylic resin substrate, and is then coated with a Ag reflective layer. The prism array is attached to the back surface of a semitransparent OPV. It functions by scattering unabsorbed light into angles greater than TIR. By doing so, it traps the light within the substrate plane until it is finally absorbed. The asymmetric shape of the prisms is chosen to prevent scattering back into the incident

**Figure 7.210** Fourth quadrant  $j$ - $V$  characteristics of a reference P3HT:PC<sub>61</sub>BM OPV on a conventional substrate, and similar devices with 1D and 2D surface gratings. Inset: External quantum efficiency spectra of the devices (Na et al., 2008).

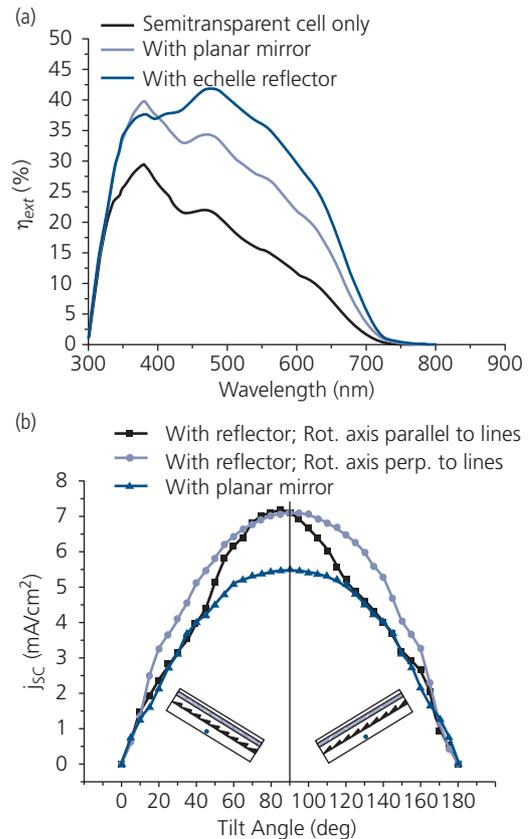

**Figure 7.211** (a) An array of four OPVs with a reflecting echelle light trap attached to the substrate. Semitransparent top electrodes are shown in red. (b) A SEM image of the echelle reflector. The prism pitch is 55 μm, and the height is 40 μm (Tvingstedt et al., 2012).

direction, as would happen for equilateral ridges. The shape is not unique; there are any number of macroscopic, asymmetric retroreflectors that can serve the same purpose. However, a triangular shape is simple to produce and uniformly coat with a reflecting layer using vacuum deposition.

The external quantum efficiency of a semitransparent TQ1:PC<sub>71</sub>BM OPV compared with that using the prism reflector, or a flat Ag mirror is provided in Fig. 7.212a. The increased efficiency using the prism reflector compared to that using a flat mirror is significant, particularly at long wavelengths where the active region is most transparent. This has been a

common theme of all light trapping methods considered; the enhancement is greatest when the light requires a long optical path through thin active regions to be fully absorbed. For this combination of light traps and OPV active region materials, the ratio of  $\eta_{ext}$  of the echelle reflector to the planar mirror reaches 1.5 at  $\lambda = 700$  nm, falling to 1.0 at  $\lambda < 400$  nm where the active region absorption is quite strong. Under illumination from an AM1.5 simulated solar spectrum, the increase in  $j_{SC}$  is 24% over the device with the planar mirror.

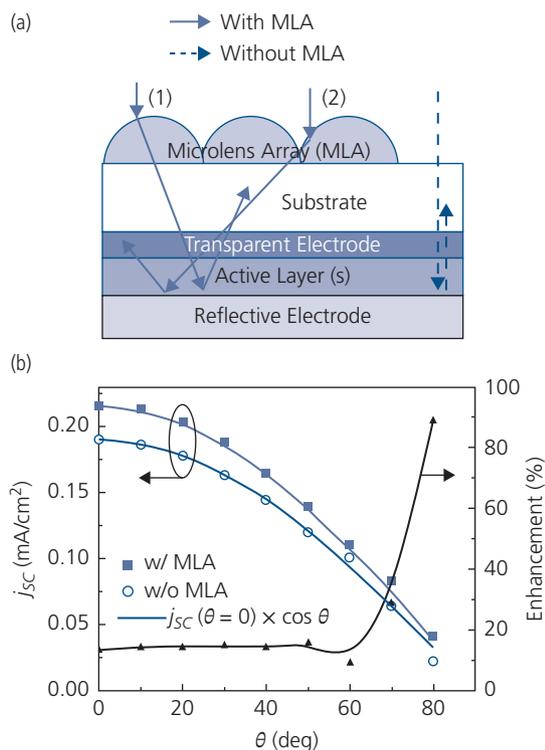

The efficacy of many of the strategies described thus far is sensitive to incidence angle, and hence they require solar tracking throughout the day to fully exploit their advantages. Large-scale texturing, on the other hand, avoids this problem. For example, in Fig. 7.212b we show the short circuit current of the device with a flat mirror vs. one with the prism grating as a function of angle to a normally incident light

**Figure 7.212** (a) External quantum efficiency spectrum of a semitransparent TQ1:PC<sub>71</sub>BM OPV without a reflector, with a Ag mirror, and with an echelle reflector attached to its distal surface. (b) Short circuit current of the OPV with a flat Ag mirror and with an echelle reflector rotated parallel and perpendicular to the structure ridge lines relative to a fixed, normally incident light source (Tvingstedt et al., 2012).

source, thereby replicating the response to the diurnal solar path. The amount of energy harvested in a day (which is proportional to the areas under the curves) depends on the relative orientation of the blaze lines and the axis of rotation, but in either axial orientation, it is larger than that harvested using a planar mirror. The largest energy benefit is accrued when the prism ridges are aligned perpendicular to the rotation axis, which is equivalent to aligning the prism lines along the east–west direction.

MLAs attached to the substrate are another means for using microscale texture to redirect light into angles greater than that required for TIR. The effects on the incident illumination using a MLA are illustrated in Fig. 7.213a. The lens array refracts the incoming light into directions that increase the optical path length within the active region. To exploit their benefits, the active layer position and thickness must be adjusted relative to that of a device where MLAs are absent. Thus, ray tracing combined with transfer matrix modeling is necessary to find the optimum device design (Myers et al., 2012).

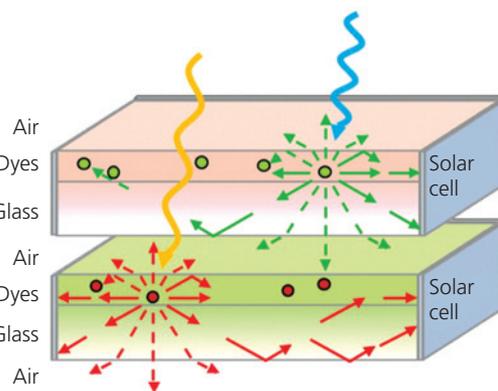

**Figure 7.213** (a) Illustration of a device with a MLA, showing redirection of light from the curved lens surface. Dashed arrows show light paths on a conventional, flat substrate. (b) Angular dependence of  $j_{sc}$  for a SubPc/ $C_{60}$  bilayer OPV with and without a MLA. The ratio of the currents is the enhancement factor, shown at right (Myers et al., 2012).

Figure 7.213b shows that the MLA generates an increased photocurrent at all incidence angles, eliminating the need for solar tracking. In this demonstration, a 100  $\mu\text{m}$  diameter, close-packed array of polymer microlenses with index of refraction  $n = 1.56$  were fabricated using a PDMS mold. The mold itself was fabricated by spreading the PDMS solution over a raft of closely packed polystyrene microspheres. Once cured, the microspheres are lifted off using scotch tape. The polymer employed for the array was then poured into the mold, and UV-cured. The efficiency enhancement for a variety of solar cell materials and structures is  $\sim 15\text{--}20\%$  compared to similar devices lacking the lens arrays. This enhancement is shown for the diurnal energy harvesting of a SubPc (12 nm)/ $C_{60}$  (80 nm)/BCP OPV in Fig. 7.213b. The enhancement compared to devices without the array is approximately 15%, significantly increasing at high angles where, unfortunately, the total energy generation is quite small.

### 7.7.5 Luminescent solar concentrators

An interesting application of the properties of organics to increase the performance of *inorganic* solar cells is via the use of *organic luminescent solar collectors* (OLSCs) that reduce the solar cell area, and hence module cost. The principle of operation of the OLSC is explained using Fig. 7.214. An efficient luminescent organic dye is dispersed in a transparent plate, for example, glass or plastic. The dye molecules absorb

**Figure 7.214** Configuration of two, stacked organic luminescent solar concentrators. Light is incident on the concentrators and is absorbed by fluorescent organic molecules in either a thin film (shown) or dispersed in the bulk of the collector plate. The molecules re-emit, with a large fraction of the emitted light trapped in the plate by TIR. The emitted photons are waveguided toward the periphery where they are absorbed and detected by inorganic solar cells. Stacking two such concentrators, one absorbing at short and the other at long wavelengths can be used to cover the solar spectrum (Currie et al., 2008).

light incident on the large, flat surface of the plate, and then re-emit light at their longer fluorescent wavelengths into  $4\pi$  solid angle. Light emitted within the escape cone leave the plate from the top and bottom surfaces, whereas other photons are trapped by TIR and propagate along its length. Solar cells positioned along the periphery of the plate absorb the waveguided photons. By stacking two plates as shown, short wavelength radiation can be absorbed in one plate, and long wavelength radiation in the other, thus filling in the gaps in the absorption spectra of the luminescent dyes at the expense of doubling the solar cell area required at the edges of the waveguide slabs. The *geometric gain*,  $G$ , is the ratio of the concentrator area to that of the PV cells. Since there are propagation losses inherent in this approach, we define the *flux gain*,  $F$ , which is  $G$  corrected for loss.

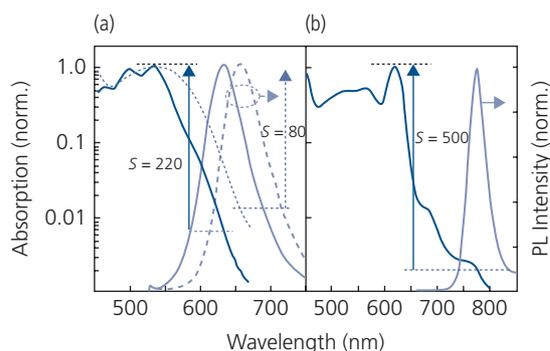

There are several benefits and shortcomings of using OLSCs. The primary benefit is that this arrangement does not require solar tracking. The only optical coupling loss is due to  $\cos \theta_i$ , where  $\theta_i$  is the incident solar angle from normal. If the concentrator cost is less than that of the solar cell, which is most likely the case, then the solar cell cost is reduced by  $F$ . Shortcomings of OLSCs include incomplete absorption over the relevant solar spectral band, a limited PL quantum yield (PLQY) of the dyes, and reabsorption of the emitted photons by other dye molecules in the waveguide (Hermann, 1982). The first problem is mitigated by making the concentrator suitably thick, and by using a high concentration of the luminescent molecules. The second is circumvented by using high efficiency lumophores, although as we have seen in Chapters 3 and 6, a high density of dopants generally leads to reductions in PQLY due to concentration quenching. The last challenge is met by selecting molecules with large Stokes shifts, that is, where the emission spectrum is significantly red-shifted from the absorption tail. Even when these conditions are met, the geometric gain in single dye systems is only between 3 and 4 (Batchelder et al., 1981). The stability of organic dyes, particularly in the presence of UV solar irradiation, is also a concern, although significant advances in developing highly stable lumophores for OLEDs have considerably reduced this problem.

Reabsorption losses can be minimized in host-guest luminescent systems, where the host molecule absorbs the incident radiation, and then transfers the excited state to the lumophore with nearly unity efficiency by FRET. The host absorption spectrum can be adjusted to cover greater portions of the solar

spectrum, it can result in highly efficient PLQY of the lumophore, and can also shift the absorption of the lumophore to regions of the spectrum that only weakly absorb the re-emitted photons. For example, using metal-organic phosphors as the luminescent molecule, the PLQY in doped systems can approach 100%, but the phosphors are very weakly absorbing due to the disallowed  $T_1 \leftarrow S_0$  transition, even in the presence of strong spin-orbit coupling (Section 3.7.3).

Doped OLSCs have been demonstrated using both fluorescent and phosphorescent molecular guest-host systems (Currie et al., 2008). Example absorption and emission spectra for the fluorescent laser dye, DCJTb, and the phosphor, Pt(TPBP), are shown in Fig. 7.215a and b, respectively. The dashed lines are the spectra due to a 5.7  $\mu\text{m}$  thick film of  $\text{Alq}_3$ :DCTJB (2%) on a glass substrate. The ratio of the peak luminescence intensity to the absorbance of the film at that same wavelength is the *self-absorption ratio*,  $S$ . Thus,  $S$  is an effective measure of how lossy the dye system is due to self-absorption of its emitted spectrum. For this blend,  $S = 80$ . Self-absorption is considerably reduced by including a sensitizer molecule (rubrene) that increases the Förster transfer efficiency from the wide energy gap  $\text{Alq}_3$  to the red emitting DCJTb. The presence of rubrene in a blend of  $\text{Alq}_3$ :rubrene (30%):DCJTb (1%) reduces the dopant concentration, and hence its absorbance, resulting in  $S = 220$  (dashed lines). The greatest luminescence to absorption advantage is obtained using the very weakly absorbing phosphor, Pt(TPBP). In Fig. 7.215b, we show  $S = 500$  for a 5.8  $\mu\text{m}$  thick  $\text{Alq}_3$ :DCJTb (2%):Pt(TPBP) (4%) film.

The performance of the OLSCs has been measured using single as well as double waveguide

**Figure 7.215** Absorption and emission spectra of an  $\text{Alq}_3$ :DCTJB (dashed line) and an  $\text{Alq}_3$ :rubrene:DCJTb (solid line) film, and (b) an  $\text{Alq}_3$ :DCJTb:Pt(TPBP) film.  $S$  is the self-absorption ratio equal to the normalized peak luminescence intensity to the absorption at that wavelength (Currie et al., 2008).

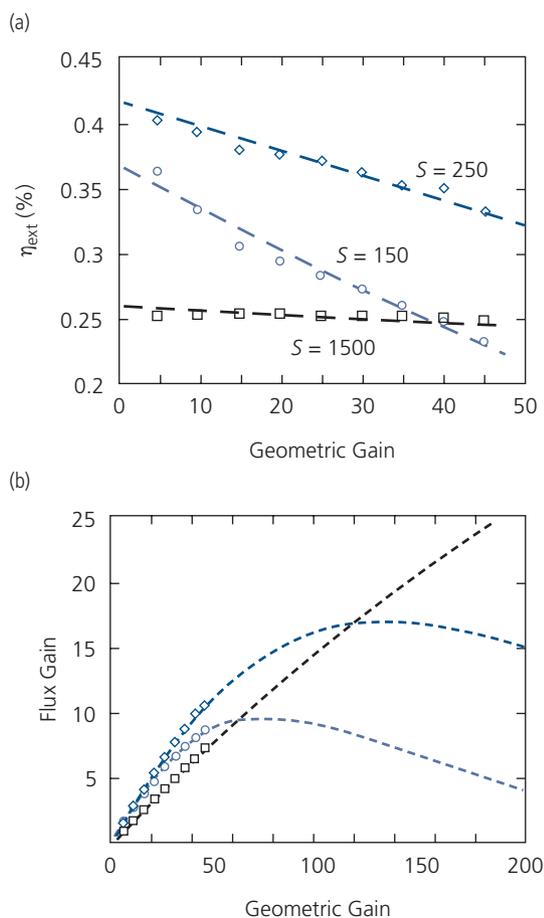

configurations. The efficiency obtained using the films in Fig. 7.215a and b ranges between 30% for the Alq<sub>3</sub>:DCJTb (2%):Pt(TPBP) (4%) film, to 50% for both DCJTb blends. Approximately 20% of the losses result from re-emission into the concentrator escape cone, and the remainder from reabsorption. Combining the phosphorescent and rubrene-based fluorescent OLSCs in tandem with the red emitting phosphor on the bottom, the concentrator efficiency increased to 60% with emission extending to  $\lambda = 675$  nm.

Crystalline Si solar cells have been mounted onto one edge of a  $100 \times 100 \times 1$  mm glass substrate with the external quantum efficiency and flux gains plotted vs. geometric gain in Fig. 7.216a and b, respectively. The geometric gain is varied by scanning a focused incident light beam normal to the edge supporting the

solar cell. The lines show fits based on optical modeling of the losses and the film optical properties. The efficiency falls off rapidly with  $G$  for films where reabsorption is strongest (i.e. for the DCTJB and rubrene:DCTJB films), providing the least benefit from concentration. Almost no losses are experienced by the Pt(TPBP) film due to its very low self-absorption. The flux gain, Fig. 7.219b rises rapidly until self-absorption dominates. As previously, the phosphor-doped film shows the possibility for high  $F$  along with large geometric gains, potentially leading to very low cost solar modules. However,  $F \sim 10$  was the maximum measured in the best cases, which is nevertheless a considerable improvement over demonstrations employing single, relatively highly absorbing fluorescent dye compounds (Slooff et al., 2008). While considerable work has been focused over the last several years on exploiting the fluorescent concentrator concept, the efficiencies still remain too low to make them cost competitive with conventional Si cells that are now commercialized for  $< \text{US } \$0.50/\text{Wp}$ .

We found in Section 6.6.5 that the emission from lumophores is most intense perpendicular to the excited state dipole moment. Hence, the 20% loss incurred due to emission within the escape cone of the slab can be reduced if molecules are intentionally aligned with their dipole moments oriented normal to the plate surface. This orientation, however, also results in increased absorption since the ground and excited state dipole moments are often approximately aligned. Placing a diffuser in front of an oriented film can randomize the light input wavevector. By using the rod-shaped, green-emitting Coumarin 6 molecules dispersed in a liquid crystal scaffold on a glass substrate, some degree of vertical alignment is achieved, increasing the light trapping efficiency to 81% from 66% for an OLSC where the dye molecules are randomly dispersed in a transparent polymer matrix (Mulder et al., 2010).

A potentially interesting variant on the OLSCs are those that absorb only in the UV or NIR spectral regions. This results in visible transparency, which may find applications as glass on windows, building facades, etc. While the idea is attractive (Yang and Lunt, 2017), there is a lack of NIR-absorbing and emitting lumophores with reasonably high efficiencies. We showed in Section 3.6 that the efficiency of organic materials falls off rapidly with energy gap (the energy gap law), making it unlikely that NIR OLSCs can achieve performance metrics necessary for practical applications. For example, OLSCs employing cyanine dyes have only achieved  $\eta_P = 0.4\%$  using edge-mounted Si cells (Zhao et al., 2014, Banal et al.,

**Figure 7.216** (a) External quantum efficiency and (b) flux gain vs. geometric gain for the Pt(TPBP) (black line), rubrene:DCTJB (dark blue), and DJTb (light blue) OLSCs. Data in (a) are measurements using a Si solar cell on one edge of the  $100 \times 100 \times 1$  mm plate with the luminescent film on its surface. Lines are fits based on optical modeling (Currie et al., 2008).

2015). While UV-absorbing organic materials may provide higher efficiencies, their stability to short wavelength solar radiation introduces additional concerns.

## 7.8 Reliability of organic photovoltaics

All solar cell technologies must possess three cardinal attributes: (i) low manufacturing cost at high yield, (ii) high efficiency, and (iii) long-term operational reliability. In fact, all of these attributes can be reduced to the primary consideration of low cost, since they all act in concert to deliver a higher output power using panels with the smallest area footprint at an acceptably low level of maintenance. In this section, we are concerned with understanding the factors that deliver long-term operational stability. In Section 6.7 we introduced the basic methodologies used to determine the reliability of semiconductor devices. Lifetime test methods used to qualify OPVs must account for the particularly challenging set of conditions to which solar cells are exposed that are not experienced by OLEDs or transistors. For example, OPVs are used out-of-doors, bathed in intense broadband solar irradiation that extends from the UV to the IR. The ambient temperatures can range from  $-40^{\circ}\text{C}$  to  $100^{\circ}\text{C}$ , and the humidity from  $\sim 20\%$  to  $100\%$ . To meet the standards of established technologies, the lifetime of OPVs must be at least 20 years as determined by the point at which their power conversion efficiency decreases by 20% from its initial value (also known as  $T_{80}$ , see Section 6.7). Other extreme environmental factors such as exposure to dust, hail, and wind loading, can apply significant stress to the OPV module. At this point, there are few OPVs that have been deployed in outdoor environments, since the technology is still in its infancy. If successful, however, OPVs may find widespread, and perhaps ubiquitous use for power generation on buildings, mobile appliances, and other applications where they have the potential to provide significant value over incumbent technologies. For this to occur, long-term OPV reliability must be established.

The primary objective of reliability testing is to identify significant failure mechanisms, and their origins. None of these mechanisms can be defined unless high purity and stable materials sets are developed, and packaging schemes are implemented that prevent extrinsic, short-term failure. Once the primary degradation routes are understood and resolved, qualification of devices and modules can be undertaken by exposure to the elements that possibly introduce new, extrinsic routes to failure. As with OLEDs, we attribute *intrinsic failure* mechanisms to aging of the

molecular constituents in the layer stack, contact degradation, changes in morphology, and device architecture. *Extrinsic failure* mechanisms arise from package failure, ingress of contaminants (e.g.  $\text{O}_2$  and  $\text{H}_2\text{O}$ ) into the package, impurities within the materials left during processing, delamination of contacts from the package, and so on.

Solar cell operational standards require a  $T_{80}$  of 10–30 years, a metric that is dependent on the application. Here,  $T_x$  is the time for the power conversion efficiency to drop to  $x\%$  from its initial value. It is impractical to qualify a new technology over even a small fraction of these times. Hence, accelerated aging protocols need to be established to accurately extrapolate the performance loss in the short term into the long term. We found in Section 6.7 that degradation in OLEDs can be predictably accelerated at elevated temperatures and drive currents. Accelerated aging of OPVs, with their use in out-of-doors venues, involve parameters that can be applied in the laboratory, but that also include aging tests that simulate the environment that is endured during actual field use. These environments can have widely varying demands, depending where the panels are deployed (e.g. in the arctic or equatorial regions, on the sea shore, or in the desert). This places demands on developing relevant and standardized testing protocols that are appropriate across technology platforms and their field of use.

Given this backdrop, efforts have been dedicated to defining standardized test conditions that are suitable for both laboratory, and for consumer-ready, qualification of OPVs. Recommended test protocols have been defined through a consensus study by the OPV community via the International Summit on OPV Stability (ISOS). The test protocols fall into three categories; basic (Level 1), intermediate (Level 2), and advanced (Level 3). The lowest level is meant for research laboratories with only modest access to necessary test equipment. It provides guidelines for those labs such that results can be widely understood and reproduced by independent investigators. Level 2 increases the comprehensiveness and standardization of the testing protocols that can lead to a unambiguous comparisons by different laboratories. Level 3 is close to, but not identical with standardized tests for market-ready products. Each level also has a different standard for shelf-life testing in the dark (D-1–D-3), outdoors (O-1–O-3), laboratory weather testing (L-1–L-3), thermal cycling (T-1–T-3), and solar-thermal humidity cycling (LT-1–LT-3). The conditions used in each of these testing regimes are summarized in Table 7.28. Further details can be found in the consensus report itself (Reese et al., 2011).

**Table 7.28** Test protocols for OPVs at different stages of development. (Reese et al., 2011)

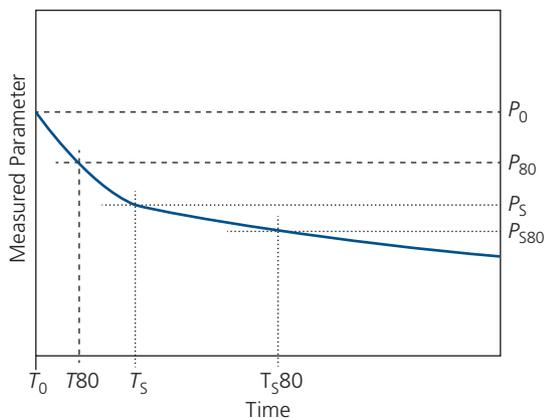

Three levels						
<b>Basic (Level 1)</b>	"Hand held" measurements using the simplest equipment and few conditions Fixed conditions and protocols suited for most labs Standardized tests applied in certified labs. Extended range of parameters to monitor, etc.					
<b>Intermediate (Level 2)</b>						
<b>Advanced (Level 3)</b>

<sup>a</sup> The ambient conditions are defined as 23 °C/50%RH in general, and 27 °C/65%RH accepted in tropical countries according to ISO 291(2008): Plastics —Standard atmospheres for conditioning and testing.

<sup>b</sup> Open circuit refers to a simply disconnected device or device connected to a sourcemeter set to 0 current.

Almost, but not all OPV tests have thus far used Level 1 protocols. With the increased performance of OPVs, both in terms of their electrical characteristics and reliability, there have been more frequent reports of Level 1 to Level 2, Level 2, and even field tests. This is an indication that OPV technology is maturing, and moving toward practical implementation.

Similar to OLEDs, the aging of OPVs often follows a two-stage trajectory illustrated in Fig. 7.217. The plot shows the dependence of a measured parameter,  $P$  (e.g.  $V_{OC}$ ,  $j_{SC}$ ,  $FF$ ,  $\eta_p$ , etc.) on operating time. The first stage of rapid but limited decrease is known as the *burn-in* period. During this decline, from the initial value of the test parameter (i.e.  $P_0$  at  $T_0$ , or alternatively,  $P_{100}$  at  $T_{100}$ ) the device undergoes adjustments to a condition that was not fully established during fabrication. That is, burn-in may result from early stage morphological annealing induced by current generation, uptake of residual impurities in the film or package that cause finite degradation until the impurities are exhausted, contact annealing and so on. It is possible, although not necessarily the case that the measured parameter will decrease to even less than 80% of  $P_0$ , corresponding to  $P_{80}$  at  $T_{80}$ . At some time,  $T_S$ , the characteristics take on a second, stabilized slope corresponding to long-term aging. As long as  $P_S$  is not significantly less than  $P_0$ , this long-term aging defines the useful term of operation of the device. Determining  $T_{S80}$ , that is, the usable lifetime of the solar cell during its stable phase of operation, is the objective of most reliability experiments. However,

**Figure 7.217** Characteristic parameter aging trajectory for an OPV. The initial value of a test parameter is  $P_0$  obtained at time  $T_0$ . There are two time constants for aging: Early rapid decay (called burn-in) that occurs until the onset of the second, more stable degradation at time,  $T_S$ , (with parameter value  $P_S$ ).  $T_{80}$  and  $T_{S80}$  are the times that the measured parameter is decreased to 80% of its initial value to  $P_{80}$  and  $P_{S80}$ , respectively.

since  $T_{S80}$  in practical cells is too long to measure in most laboratory settings. Hence, the aging process must be accelerated. This is accomplished by either elevating the cell temperature and/or the light intensity (which can also increase cell temperature and current) during the aging cycle. Here, temperature and intensity are two potential acceleration factors. For useful analysis, however, temperature and intensity must be analyzed independently, which can be done by aggressive cooling of the illuminated solar cell, or measuring the temperature dependence of degradation of the test parameter, and then subsequently measuring its intensity dependence at a fixed temperature. The independently observed thermal degradation is then used to separate out the contributions due only to high illumination intensity.

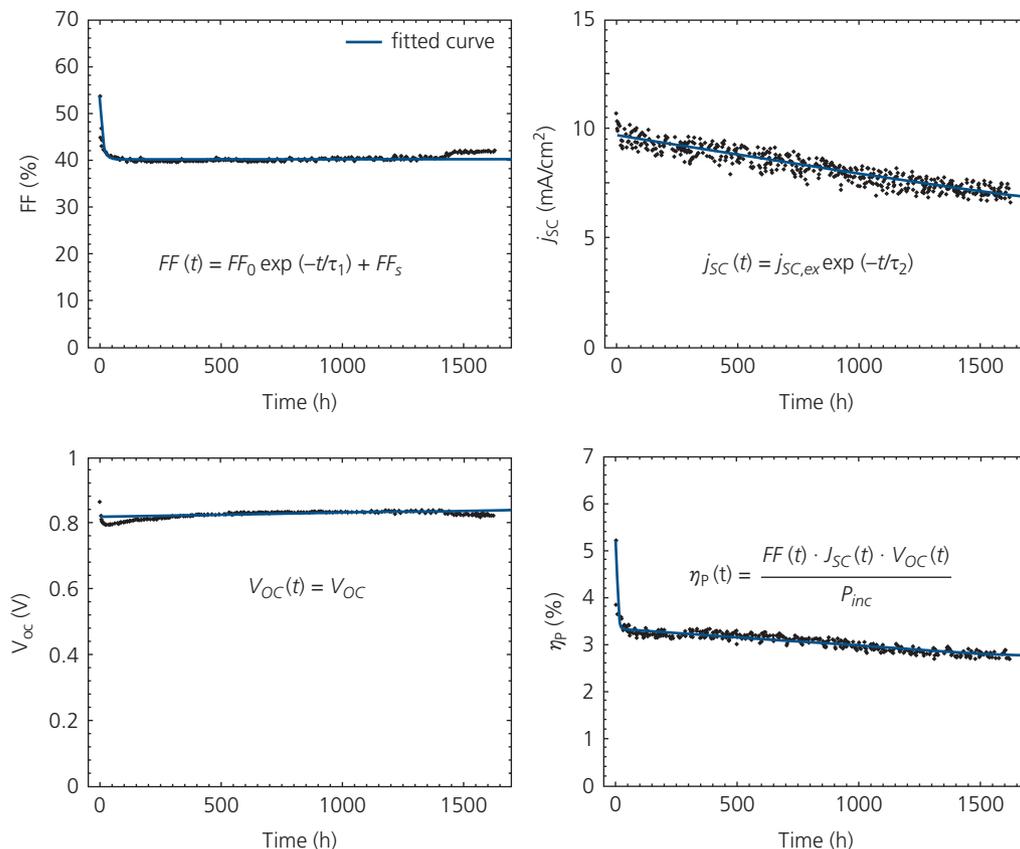

Accelerated aging must not be so harsh (i.e. by exposure to an excessively high temperature or light intensity) that aging processes not encountered under normal operation are introduced. This results in extrinsic degradation that may not provide an accurate prediction of cell lifetime during standard operating conditions.

The two-phase aging can be modeled using a *sum of exponentials* of the form (Section 6.7):

$$P(t) = P_0 \exp(-t/\tau_1) + P_{ex} \exp(-t/\tau_2), \quad (7.209)$$

where  $\tau_1$  is the characteristic burn-in time constant, and  $\tau_2$  is the long-term degradation time constant. Now,  $\tau_1 \ll \tau_2$  as is often the case, which allows for accurate determination of the coefficient,  $P_{ex}$ . A representative set of aging data is shown in Fig. 7.218. At the upper left, we find that  $FF(t)$  undergoes rapid change during burn-in, and thereafter is constant. From the  $FF$  data, therefore, we obtain the time constant,  $\tau_1$ . Note that the identification of  $T_S$  can be somewhat arbitrary, except in cases such as this one where  $\tau_1 \ll \tau_2$ . The short circuit current, however, does not show changes during burn-in, hence giving a value of  $\tau_2$  as well as an extrapolated value of  $j_{SC,ex}$  at  $t \rightarrow 0$ . The open circuit voltage is apparently unchanged from its initial value of  $V_{OC}$ . The product of all of these curves results in the time evolution of the power conversion efficiency shown at the lower right. For this device, the functional form of the efficiency is

$$\begin{aligned} \eta_p(t) &= \eta_{p0} \exp \left[ -t \left( \frac{1}{\tau_1} + \frac{1}{\tau_2} \right) \right] + \eta_{p,ex} \exp \left[ -\frac{t}{\tau_2} \right] \\ &\approx \eta_{p0} \exp \left[ -\frac{t}{\tau_1} \right] + \eta_{p,ex} \exp \left[ -\frac{t}{\tau_2} \right] \end{aligned} \quad (7.210)$$

**Figure 7.218** Aging of several OPV operating parameters and empirical fits (lines) to the data (points). The functional form of the fits to  $FF$ ,  $j_{SC}$ , and  $V_{OC}$  are indicated. Adapted from Roesch et al. (2015).

since  $\tau_1 \ll \tau_2$ . The constants  $\eta_{P0}$  and  $\eta_{P,ex}$  are easily obtained from the functions from which they are derived, or directly from the plot in Fig. 7.218.

Note that while an exponential decrease in performance is suggestive of a process related to chemical degradation, the long-term data in Fig. 7.218 can arguably be just as well fit by a linear empirical relationship, viz.

$$P(t) = P_0 \exp(-t/\tau_1) + P_{ex}(1 - t/\tau_2). \quad (7.211)$$

An additional functional form, often used in fitting the lifetime response of OLEDs, and that also has been applied to small molecule OPVs is the *stretched exponential*:

$$P(t) = P_0 \exp\left[-(t/\tau_1)^\beta\right], \quad (7.212)$$

where  $\beta \leq 1$  is a fitting parameter. This functional form does not distinguish between initial burn-in and long-term degradation, and hence is more appropriate for fitting those degradation processes that proceed monotonically from  $T100$  to  $T0$ .

Once the various lifetime parameters in Eqs. 7.209, 7.211, or 7.212 are determined, it is then possible to extrapolate the efficiency to  $T_{S80}$ . As in previous discussions on OLED reliability, there is an element of faith that is needed to assume that there are only two principal aging mechanisms captured by the time constants,  $\tau_1$  and  $\tau_2$ , and that a third set of parameters are not needed to extend the extrapolation to even longer times when additional failure mechanisms possibly emerge. In addition, catastrophic failure due to package leakage or breakage, or migration of a metal contact into the OPV active region, etc., may also lead to an early death of the devices that is not accounted for by the time constants,  $\tau_1$  and  $\tau_2$ . We will return to these extrinsic but nevertheless important failure mechanisms in subsequent sections.

Ultimately, the value of a cell is determined by the total energy that it delivers during its usable life. This is known as the *lifetime energy yield*, or  $E_{80}$ , and is calculated using (Roesch et al., 2015)

$$E_{80} = \int_{t=0}^{T_{S80}} \eta_p(t) P_{inc} dt, \quad (7.213)$$

where  $P_{inc}$  is generally taken to equal 1 sun intensity (i.e. 1 kW/m<sup>2</sup>). The  $E_{80}$  calculated for the device in Fig. 7.218 is presented in Fig. 7.219, yielding a  $T_{S80} = 1930$  h and  $E_{80} \approx 58$  kWh/m<sup>2</sup>.

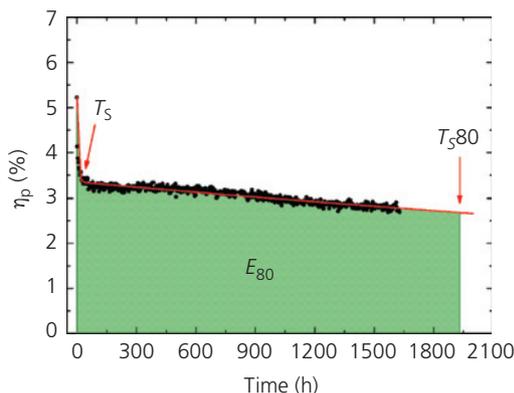

There is no need to accelerate the aging of the cell in Figs. 7.218 and 7.219 since the degradation is sufficiently fast that the experiment is completed within less than 1500 h, or 2 months. However, it would not be possible to obtain the  $T_{S80}$  for more durable cells, in which case the aging process needs to be accelerated by increasing temperature and/or intensity. If we assume that the post-burn-in decay of the parameter,  $P$ , is due to a single kinetically-driven process, for example, molecular fragmentation or reactions with other species in the active region, it should follow an Arrhenius behavior with activation energy,  $E_a$ . Then, the degradation rate of parameter  $P$  is:

$$k_{deg} = 1/\tau = k_0 \exp(-E_a/k_B T), \quad (7.214)$$

where  $k_0$  is a constant. If we assume that the decrease in performance is a function of the incident power, then,

$$k_{deg} = k_0 (I_{test}/I_{ref})^\gamma, \quad (7.215)$$

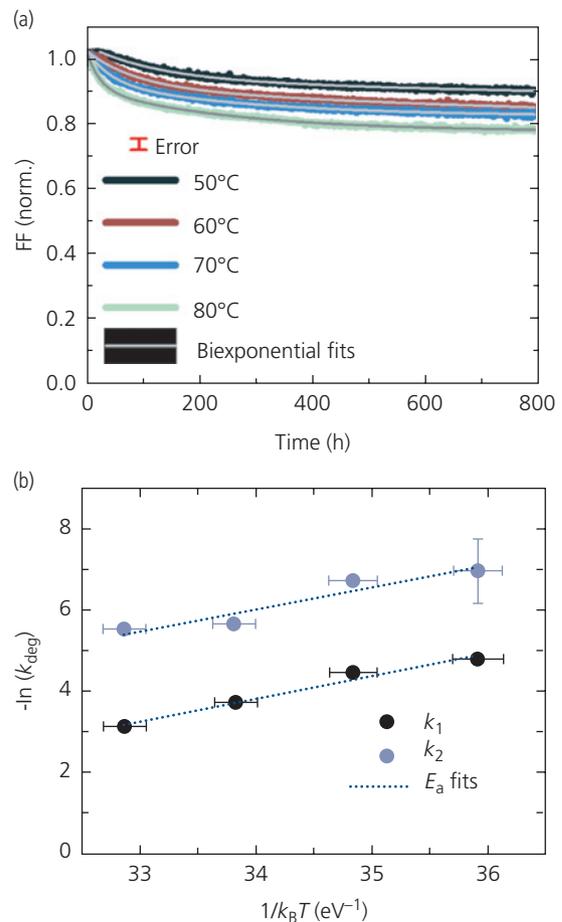

where  $\gamma$  is an empirical constant,  $I_{test}$  is the power used during the aging tests, and  $I_{ref}$  is that used during normal operation (typically 1 sun). Then we can define the *aging acceleration factor* between two different powers and temperatures ( $I_1$ ,  $I_2$  and  $T_1$ ,  $T_2$ , respectively) using

**Figure 7.219** The total energy harvested during the cell lifetime is the product of the area of the shaded region and  $P_{inc} = 1$  kW/cm<sup>2</sup>. Data are for the cell in Fig. 7.218 (Roesch et al., 2015).

$$A = \left(\frac{I_1}{I_2}\right)^\gamma \exp\left[-\frac{E_a}{k_B} \left(\frac{1}{T_1} - \frac{1}{T_2}\right)\right]. \quad (7.216)$$

The procedure for finding  $\gamma$  and  $E_a$  is similar to methods discussed for OLEDs. For example, if the decay constant is dominated by long-term degradation, then  $k_{deg} = 1/\tau_2$  is measured at several different temperatures (Schuller et al., 2004). An Arrhenius plot of  $k_{deg}$  vs.  $1/T$  yields  $E_a$ , from which the temperature dependence of  $A$  is found. This, in turn, yields  $\tau$  in the relevant operating regime and temperature. This procedure has been applied to a DBP:C<sub>70</sub> (1:8) OPV employing a Bphen:C<sub>60</sub>/BPhen exciton blocking buffer layer, with results for  $FF(t)$  at several temperatures given in Fig. 7.220a. The data are fit by the biexponential in Eq. 7.209 from which the rate constants,  $k_1$  and

**Figure 7.220** (a) Time dependence vs. temperature of the normalized  $FF$  of a DBP:C<sub>70</sub> (1:8) OPV employing a BPhen:C<sub>60</sub>/BPhen buffer layer. Lines are biexponential fits to the data (points). (b) Arrhenius plot of the fast ( $k_1$ ) and slow ( $k_2$ ) degradation rates obtained from the fits in (a). Lines are activation energy fits according to Eq. 7.214 yielding  $E_a = 0.53$ – $0.56$  eV (Burlingame et al., 2016).

$k_2$  are extracted at each temperature. These are plotted in Fig. 7.220b as a function of  $1/k_B T$  to obtain nearly equal activation energies ( $E_a \sim 0.55$  eV) for both burn-in and long term operation. While it is unusual for the activation energy to be the same over both time scales, the apparent coincidence arises since both are affected by BPhen crystallization; the short term loss in  $FF$  is due to increased shunt currents across the junction induced at high temperature, and the longer term loss arises from increased recombination due to slow intrusion of BPhen into the active region (Burlingame et al., 2016).

Similarly, the acceleration factor,  $\gamma$ , is found by measuring the rate of degradation of the OPV parameters at several different intensities. To separately measure mechanisms affected only by intensity, the temperature dependence must first be eliminated by cooling the devices, or by ensuring that the temperature dependence of the lifetime is minimal.

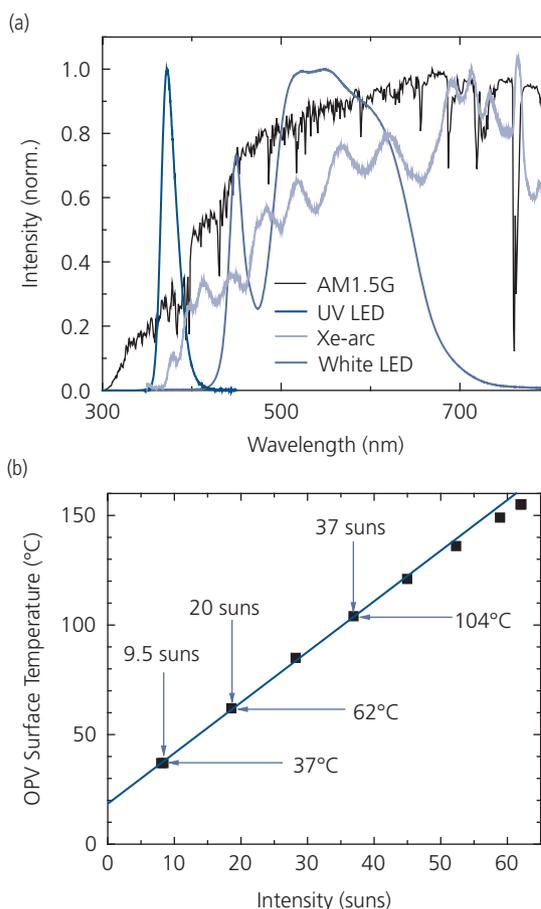

The degradation of DBP:C<sub>70</sub> (1:8) cells comprising a TPBi:C<sub>60</sub> (1:1, 10 nm)/TPBi (3 nm) buffer layer has been measured as a function of intensity. Thermal stability is ensured by replacing the low glass transition temperature BPhen ( $T_g = 61^\circ\text{C}$ ) blocking layer with TPBi, that has a substantially higher  $T_g = 120^\circ\text{C}$ .

It is challenging to achieve high intensity exposure using a standard solar simulator employing a Xe lamp. Intensity-dependent aging experiments, therefore, often use extremely high brightness (up to 70 suns) LED light sources. The LED intensity does not fade over the time scale of the experiment, although it has a significantly different spectrum from that of the sun. The spectra from cool-white and UV emitting LEDs are shown in Fig. 7.221a superimposed on the AM1.5G reference and the spectrum from a Xe-arc lamp conventionally used to simulate solar radiation. The most damaging spectral region for organics is the UV, which is not represented by the broadly emitting LEDs. Hence, the DBP:C<sub>70</sub> devices are also exposed to irradiation from a separate UV-emitting LED with a peak wavelength of 365 nm. The absorption of the OPV active region is minimal beyond 700 nm, thus the lack of NIR spectral content does not impact the measured lifetimes. Since active cooling is employed, the temperature of the devices remains well below  $T_g$  of the exciton blocking material (see Fig. 7.221b). Indeed, the devices exhibited no temperature-dependent aging up to  $T = 130^\circ\text{C}$  (Burlingame et al., 2016).

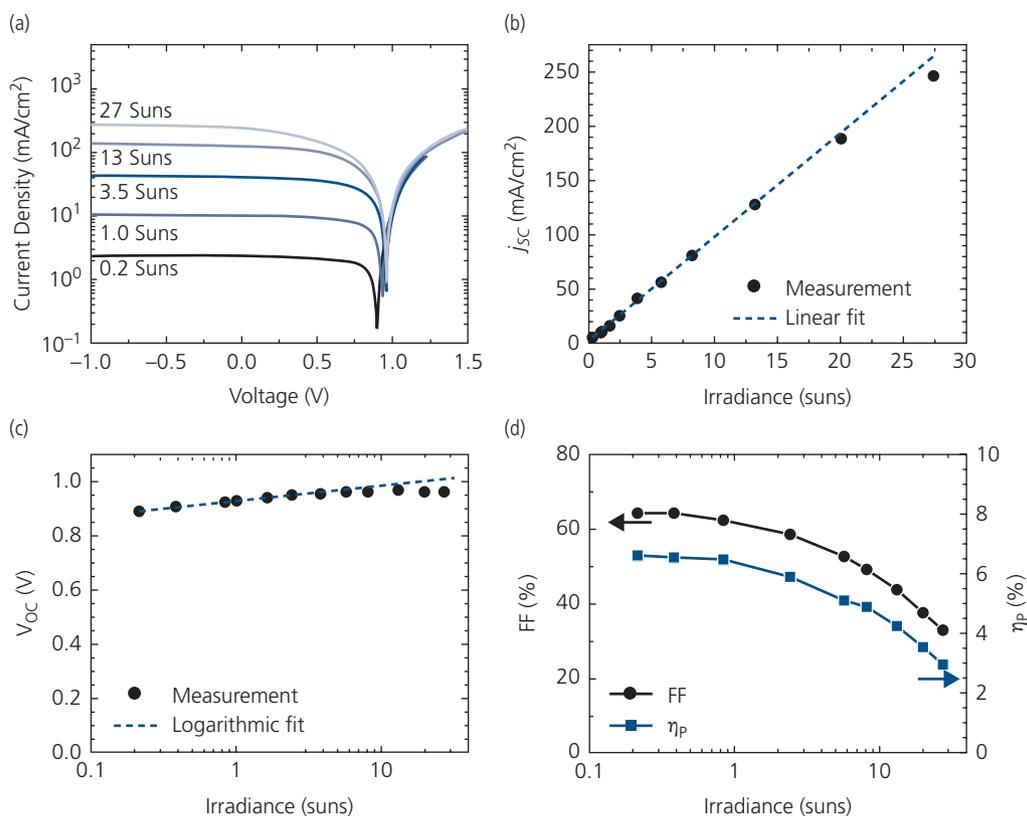

It is remarkable in itself that the OPVs can tolerate illumination at such the extreme intensities. The device characteristics up to concentrated *outdoor* solar irradiances of 27 suns are provided in Fig. 7.222. Since DBP:C<sub>70</sub> OPVs typically have

efficiencies  $\sim 8\%$ , the current at 37 suns is  $>0.3$  A/cm<sup>2</sup>. The  $j$ - $V$  characteristics (Fig. 7.222a) show that at the highest intensity, the forward and reverse currents are approximately equal, achieving a maximum of  $\sim 0.12$  A/cm<sup>2</sup>. The symmetry of the curves indicates that the current is limited by the internal cell series resistance.

The slope of the short circuit current in Fig. 7.222b is relatively constant until the highest intensity, indicating that the quantum efficiency is constant over this range of intensities. However, in Fig. 7.222c, a roll-off in  $V_{OC}$  from its expected logarithmic dependence on irradiance is observed, due to increased recombination from the accumulation of a very large density of charge in the mixed active region. Finally,  $FF$  is significantly decreased at high intensity (Fig. 7.222d), again due to cell series resistance. This results in a decrease in  $\eta_p$  from 6.5% at 1 sun, to 3% at 27 suns.

**Figure 7.221** White and UV LED spectra used in OPV aging. For comparison, the Xe-arc lamp and AM1.5G reference spectra are also shown. (b) Illumination intensity from a white LED vs. temperature on the OPV surface. The three aging conditions used for OPVs in Fig. 7.223 are indicated (Burlingame et al., 2019).

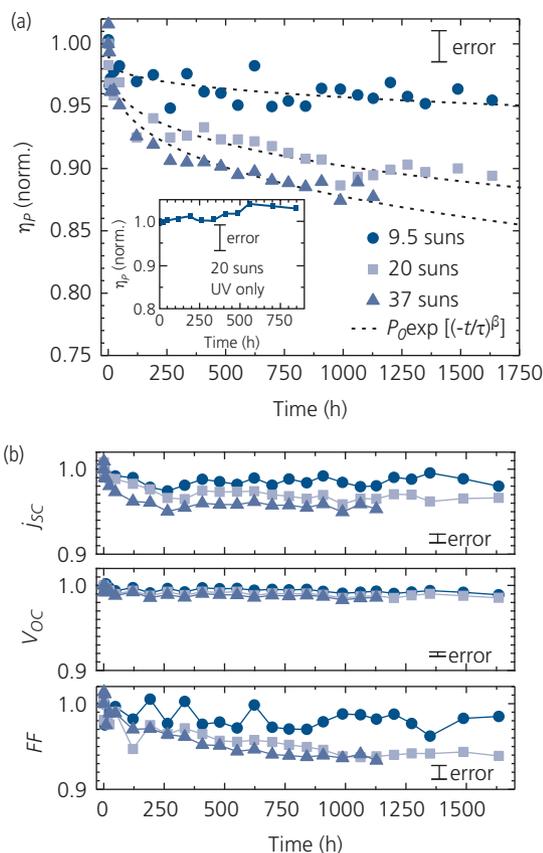

**Figure 7.222** Performance of CBP:C<sub>70</sub> OPVs vs. incident concentrated solar power intensity. (a) Current-voltage characteristics, (b) short circuit current, (c) open circuit voltage, and (d) *FF* and power conversion efficiency (Burlingame et al., 2017).

Figure 7.223 shows the performance characteristics of a population of TPBi-based OPVs aged at several different illumination intensities. This population shows no appreciable early stage (i.e. burn-in) degradation (<3–5%) in any of its characteristics, and hence only long-term aging data are shown. There is some deviation in  $j_{SC}$  and *FF* (Fig. 7.223b) at 36.9 suns (36.9 kW/cm<sup>2</sup>) from the data taken at lower intensities due to degradation of the ITO and MoO<sub>3</sub> anode buffer. That is, the reduction in efficiency of the highest intensity data is primarily due to loss of transparency of these metal oxides. This is accompanied by an equally small loss in charge extraction efficiency, as determined by measuring the change in slope of the reverse-biased  $j_{ph}$ -*V* characteristics both before and after aging (Burlingame et al., 2019). The change in power conversion efficiency is accurately fit by the stretched exponential function in Eq. 7.212 using  $\beta = 0.28$  and  $\tau = 1.1 \times 10^{10}$  h. Surprisingly, no degradation is experienced up to 20 suns equivalent UV illumination (inset, Fig. 7.223a), attesting to the remarkable stability of the materials employed.

Figure 7.224a shows  $k_{deg}$  vs.  $I_{test}$ . Fitting the data with Eq. 7.216 yields  $\gamma = 2.5$ . The equivalent lifetime under 1 sun ( $I_{ref}$ ) exposure can be extrapolated using  $\gamma$  for the OPVs aged at each intensity. As shown in Fig. 7.224b, the  $\eta_P$  at all intensities follows a similar trend that results in a lifetime of  $T_{80} = 4.9 \times 10^7$  h. This extremely long lifetime is similar to operating lifetimes that have been reported for phosphorescent organic light emitting devices operated at 10 mA/cm<sup>2</sup> (Burrows et al., 2000), which is comparable with 12.5 mA/cm<sup>2</sup> generated at 1 sun intensity by the OPVs.

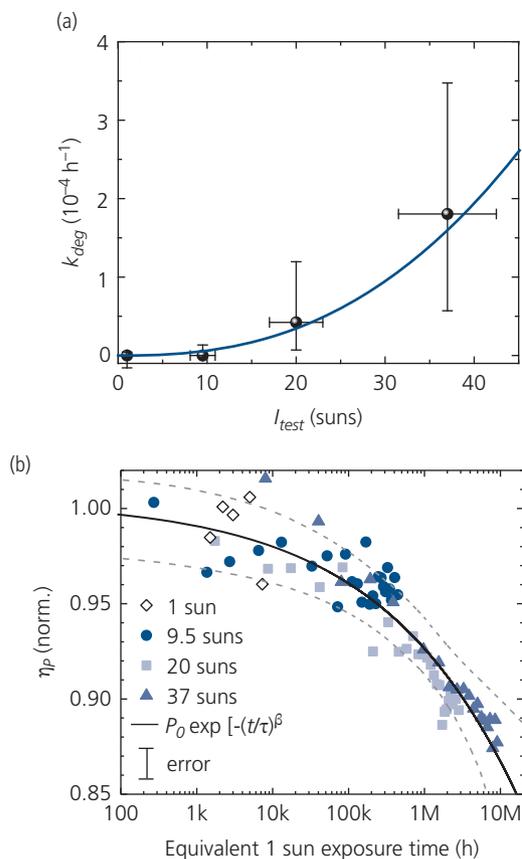

To convert the OPV lifetimes into outdoor lifetime projections, we assume an average of 5 kWh/m<sup>2</sup> of sunlight per day (e.g. 5 h of equivalent AM1.5G radiation), although value depends on location (e.g. 4.2 kWh/m<sup>2</sup>/day in Detroit, MI to 6.5 kWh/m<sup>2</sup>/day in Phoenix, AZ) (Habte et al., 2017). Therefore, the extrapolated  $T_{80}$  corresponds to  $> 2.7 \times 10^4$  yr, outdoor equivalent. While such lifetimes are not practically achievable given the presence of extrinsic failure mechanisms such as contact weathering, package failure, and the possibility of late-onset degradation, the extrapolation nevertheless suggests that the *intrinsic*

**Figure 7.223** Measured DBP:C<sub>70</sub> (1:8) OPV characteristics at various white LED intensities, from 1 to 37 suns. Full OPV performance data are found in (a) and (b). Dashed lines in (a) are fits to the stretched exponential function in the legend. Inset in (a): Power conversion efficiency vs. aging time under 20 suns equivalent illumination in the UV (Burlingame et al., 2019).

stability of OPVs in an O<sub>2</sub>- and H<sub>2</sub>O-free environment can substantially exceed the requirements of even the most demanding applications.

The remarkable stability observed in the OPVs is due to a combination of the photochemical stability of the constituent materials, the morphological and thermal stability of the blended organic layers, the rapid exciton dissociation provided by the blended HJ architecture, and the high purity of the thermally-evaporated organics. The only chemical weak point in either C<sub>70</sub> or DBP appears to be the single carbon-carbon bond in DBP that connects its perylene core to its peripheral phenyl groups. However, blending DBP into C<sub>70</sub> compensates for this weakness as no DBP fragments are observed in the mass spectra of aged DBP:C<sub>70</sub> films (Burlingame et al., 2019). As we found in Section 6.7.4, long-lived excitons can dissociate chemical bonds, a process exacerbated by multi-exciton annihilation interactions

**Figure 7.224** Degradation rate,  $k_{degr}$  vs. aging intensity,  $I_{test}$  for OPVs under 1 sun AM1.5G simulated, and 9.5, 20, and 37 suns equivalent illumination from white LEDs. The best fit (solid line) to Eq. 7.216 using the data in Fig. 7.223 is shown with an acceleration factor of  $\gamma = 2.5$ . (b)  $\eta_p$  vs. equivalent 1 sun exposure time, defined as time [h]  $\times$  intensity [suns<sup>2.5</sup>], for OPVs under all illumination conditions employed. The data are fit to a stretched exponential to estimate the  $T_{80}$  lifetime with the best fit shown as solid line while upper and lower 95% confidence bounds as dashed lines, respectively (Burlingame et al., 2019).

that result in highly energetic exciton species that are destructive to organic materials. The blended HJs based on co-evaporation of the donor and acceptor materials rapidly quench excitons via charge transfer, thereby preventing the excitons from dissipating energy and cleaving chemical bonds. Thermal stability of all the materials, and the blend morphology play important roles in the reliability of this particular materials system.

Having described the methodologies commonly employed to quantify aging of OPVs, the remainder of this section presents a few of the mechanisms leading to performance degradation due to materials, contacts, architectures and encapsulation. Only the latter source is extrinsic, although it is no less important than intrinsic degradation routes since the reliability of the fielded

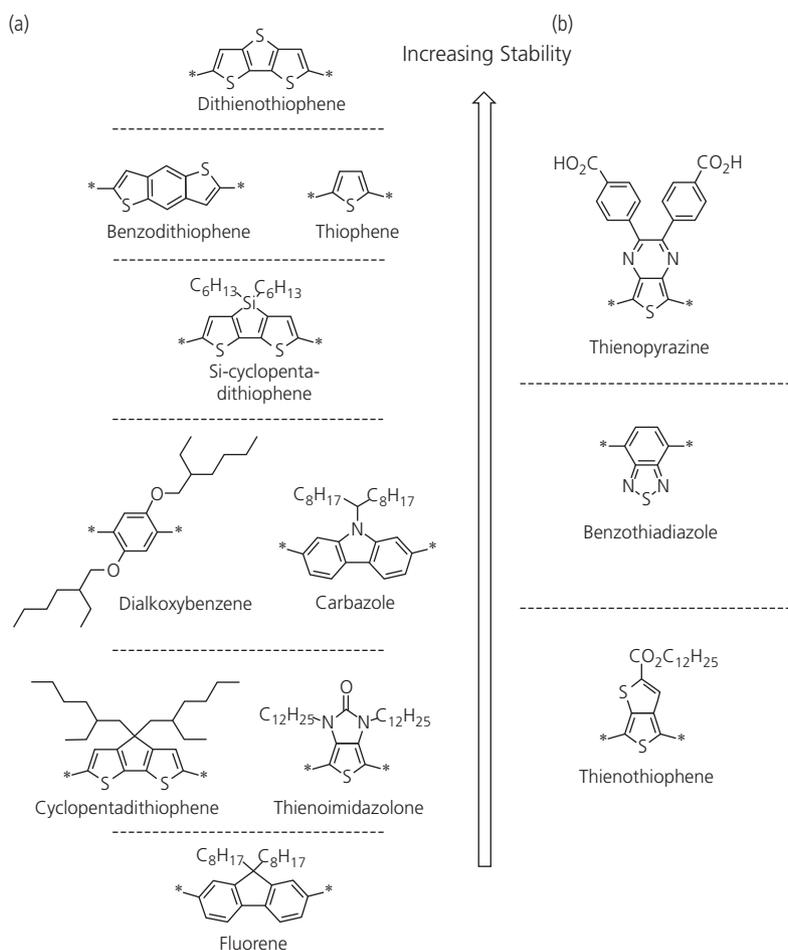

OPV module ultimately depends on all of these factors, regardless of origin. Several reviews on this topic present many detailed discussions beyond the few cases presented here (Grossiord et al., 2012, Jørgensen et al., 2012, Voroshazi, 2014, Cheng and Zhan, 2016).

### 7.8.1 Materials and morphological degradation

While there are several sources for the decrease of OPV performance over time, none is more fundamental than the degradation of the organic molecules comprising the layer structure itself. Many organic molecules are vulnerable to photooxidative reactions that cause bleaching of their absorption bands after exposure to light and air over a period of time (ranging from minutes to days). Bleaching of several copolymers employing donor–acceptor conjugated backbones in air under 1 sun, AM1.5G illumination (30% relative humidity, *RH*) has been systematically investigated to determine which moieties are most

susceptible to damage. Several commonly used donor and acceptor groups employed in block copolymer donors are listed in Fig. 7.225 (Manceau et al., 2011). The stabilities of these building blocks (arbitrarily defined as the time for the optical density of the film to decrease by ~50% from its as-deposited value) range from a few hours for fluorene to thousands of hours for thiophene.

Several factors that affect stability can be summarized as follows: (i) Polycyclic aromatic units within the backbone exhibit high stability. This is consistent with findings discussed in previous chapters where molecules comprising C=C double bonds are not susceptible to photophysical damage. (ii) Conjugated thiophene-containing structures such as P3HT tend to have far longer lifetimes than, for example, fluorenes with their weak quaternary C bonds. Indeed, the fluorenes appear to be the least stable of the family of molecular units shown. (iii) Molecules with exocyclic double bonds (e.g. vinyl groups in MEH-PPV) are

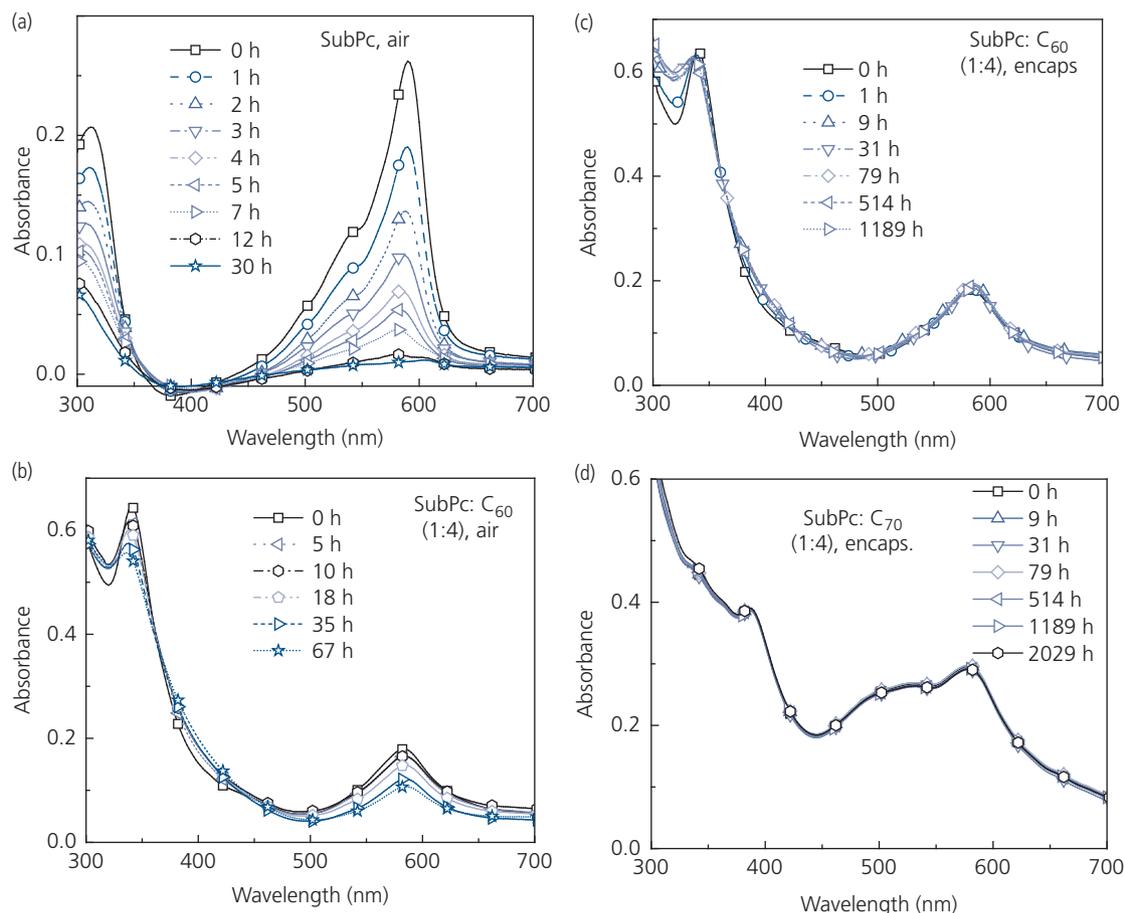

**Figure 7.225** Relative photooxidative stabilities of a selection of (a) donor and (b) acceptor moieties employed in block copolymers used as donors (Manceau et al., 2011).

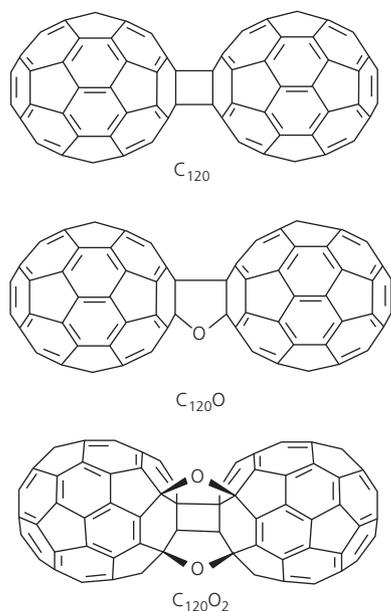

susceptible to oxidative cleavage. The vinylene bonds are vulnerable to side chain radicals cleaved during aging. (iii) The composition of the side chains can determine their ability to form radicals during photooxidation. (iv) Bond energies lower than  $C=C$ , such as  $C-N$  and  $C-O$ , are readily cleaved in the presence of photoexcitation and oxygen. This is similar to what is commonly observed in OLEDs, where molecules with such bonds are more rapidly degraded than those without.

There are two principal methods to reduce or even eliminate photooxidative bleaching. The first, obvious route is to eliminate oxygen by encapsulating the OPV in a package that prevents ingress of atmospheric contaminants. The second is to use a mixed or bulk HJ that decreases the lifetime of the excited state from nanoseconds typical of singlets, to picoseconds—a time determined by charge transfer from the donor

to acceptor in the blends. Elimination of excited state interactions has already been discussed in the context of long-lived DBP: $C_{70}$  OPVs. In contrast, neat films of SubPc exposed to 1 sun, AM1.5G illumination in air lose approximately 40% of their absorbance in only 2 h (see Fig. 7.226a). The three exposed phenyl rings of the molecule that are vulnerable to reductive reactions with radical oxygen or water in the atmosphere may be one source of this effect. This is supported by Fourier Transform IR (FTIR) spectra of SubPc films exposed to light and air, where a  $C=O$  spectral peak emerges over time (Burlingame et al., 2015). However, when blended with  $C_{60}$  in a 1:4 mixture (Fig. 7.226b), the change in absorbance is significantly reduced, even in air. Charge transfer to  $C_{60}$  results in a decrease in the SubPc singlet exciton lifetime, decreasing the probability that the excited state undergoes photooxidative bleaching. When the films are

**Figure 7.226** Absorbance spectra of SubPc and SubPc:fullerene blend films vs. time of exposure to (a, b) air and (c, d) encapsulated in a  $N_2$ -filled, epoxy-sealed glass package. The donor:acceptor ratio and species are indicated in each figure. Note the difference in time scales in the legends (Wang et al., 2014). Reprinted from *Solar Energy Mater. And Solar Cells*, 125, Wang, N., Tong, X., Burlingame, Q., Yu, J. & Forrest, S. R. 2014. Photodegradation of small-molecule organic photovoltaics, 170, Copyright 2015, with permission from Elsevier.

**Figure 7.227** Possible  $C_{60}$  oligomers formed during exposure to air and/or illumination (Lebedkin et al., 1998).

encapsulated in an ultrapure  $N_2$  atmosphere, oxygen is eliminated and the absorbance is stable over time, with the exception of a small decrease in  $C_{60}$  absorbance at  $\lambda = 350$  nm, as seen in Fig. 7.226c.

The change in  $C_{60}$  absorption has been attributed to photodimerization of adjacent  $C_{60}$  molecules. The spherical shape of the molecule puts its bonds under strain. Since two adjacent molecules are separated in the film by  $\sim 4.2$  Å, the molecular bonds can break to form a bridge, resulting in a 2+2 cycloaddition between C=C double bonds. This results in a  $C_{120}$  dimer, or even higher order oligomers. Further, FTIR spectra of the films exposed to air suggest the formation of  $C_{60}O_x$ - $C_{60}$  oligomers (Wang et al., 2014). The oligomeric reductions of  $C_{60}$  have been identified by Raman spectroscopy, and are shown in Fig. 7.230 (Lebedkin et al., 1998). The ability of  $C_{70}$  to photopolymerize is significantly less, since it has only 10 C=C bonds, compared with 30 in  $C_{60}$ . Hence, there are fewer equivalent orientations that  $C_{70}$  can take that result in photooxidation. Also, given its lower symmetry, not all  $C_{70}$  packing arrangements lead to dimerization. The stability of SubPc: $C_{70}$  (1:4) films is inferred from the lack of changes in absorbance over 2000 h, in Fig. 7.226d.

Photo-oligomerization results in a decreased exciton lifetime due to recombination at chemical impurities within the film. This, in turn reduces the exciton diffusion length, ultimately resulting in a decrease in  $\eta_{ext}$  in bilayer structures. Recall from

Section 7.1.4 that the process of exciton diffusion to the HJ is described in steady state by

$$D \frac{\partial^2 N(x)}{\partial x^2} - k_{ex} N(x) + G(x) = 0, \quad (7.217)$$

where  $D$  is the exciton diffusivity,  $N(x)$  is their density as a function of position,  $x$ , from the HJ,  $k_{ex}$  is the total exciton recombination rate, and  $G(x)$  is the generation rate (cf. Eq. 7.87). During device operation, a fraction of non-radiative exciton recombination events results in the formation of  $C_{60}$  oligomers. The fraction of monomers remaining at time,  $t$ , is then

$$\Gamma(x, t) = \frac{[M(x, t)]}{[M_0]} = (1 - \Gamma_\infty) \exp[-k_F N(x, t)t] + \Gamma_\infty, \quad (7.218)$$

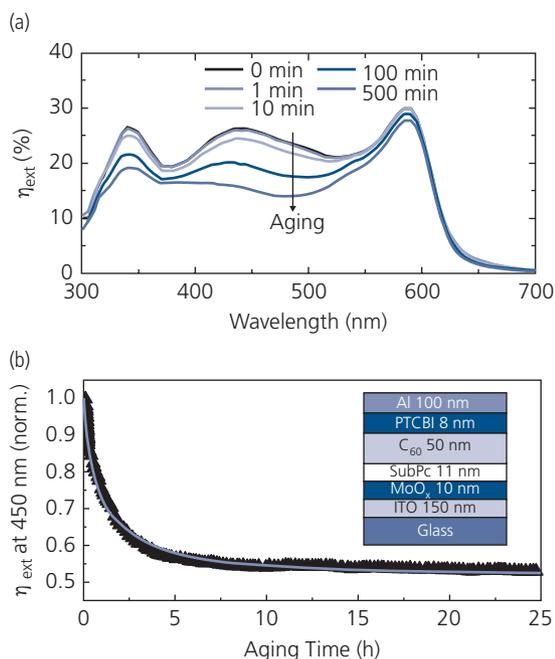

where  $[M(x, t)]$  is the monomer concentration at time  $t$ ,  $[M_0]$  is the initial monomer density,  $k_F$  is the oligomer formation rate, and  $\Gamma$  is the percentage of monomers that are unable to oligomerize due to their particular energetic and chemical environments. Including the effects of  $C_{60}$  oligomerization, Eq. 7.217 becomes

$$D \frac{\partial^2 N(x, t)}{\partial x^2} - [(k_{ex,1} + k_F)\Gamma(x, t) + k_{ex,n}(1 - \Gamma(x, t))] \times N(x, t) + G(x, t) = 0, \quad (7.219)$$

where  $k_{ex,1}$  is the exciton recombination rate on  $C_{60}$  monomers and  $k_{ex,n}$  is the rate on the oligomers.

The dependence of external quantum efficiency on aging time for the SubPc/ $C_{60}$  HJ OPV is shown in Fig. 7.228a, along with a schematic of the device structure in the inset, Fig. 7.228b. The spectral changes are only evident in the portions of the spectra related to  $C_{60}$ ; the SubPc peak at 600 nm remains nearly unchanged. The most pronounced decrease is centered at 450 nm, corresponding to the  $C_{60}$  CT state (see Section 7.4.1). The disappearance of this feature is consistent with oligomerization: if two adjacent  $C_{60}$  molecules share a CT state, this state will vanish once the molecules form a dimer.

The measured  $\eta_{ext}$  at 450 nm vs. aging time is shown in Fig. 7.228b. Burn-in results in a decrease in efficiency by nearly 50% after 5 h, which is followed by a much slower, exponential roll-off. The fit to the data using the quantitative analysis of Eq. 7.219 is shown by the line, using a  $C_{60}$  singlet recombination rate of  $10^6$  s $^{-1}$  (Kuhnke et al., 1997),  $k_{ex,n} = 6 \times 10^6$  s $^{-1}$ , and an oligomerization rate of 80 s $^{-1}$ . Further, it is assumed that the asymptotic concentration of monomers is  $\Gamma_\infty \rightarrow 0$ , that is, there is complete oligomerization of

**Figure 7.228** (a) External quantum efficiency spectra of a bilayer SubPc:C<sub>60</sub> OPV as a function of aging time. (b) Normalized efficiency (points) along with a fit to the data (line) assuming reduced exciton diffusion length due to C<sub>60</sub> photo-polymerization. Inset: Schematic of the OPV structure (Burlingame et al., 2015).

the C<sub>60</sub> over time (Burlingame et al., 2015). Note that the functional form of the analysis is strikingly similar to the sum of exponentials, with the burn-in rate controlled by that for oligomerization.

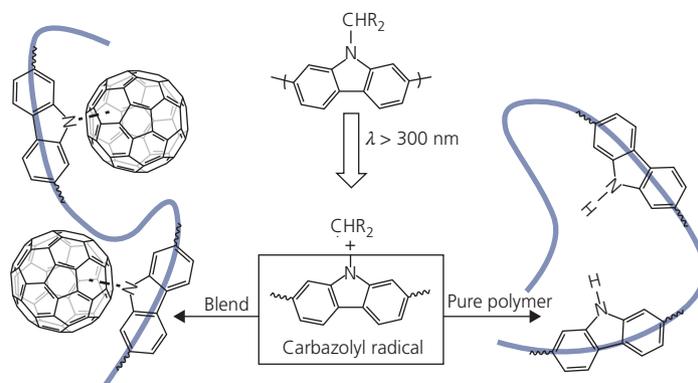

Laser desorption induced time of flight mass spectroscopy was used to determine the relative concentration of molecular species and reaction products in the aged films. From this study, it was determined that  $\Gamma_{\infty} = 10.4\%$  was reached during aging. Complete oligomerization, in practice is not possible since individual molecules become isolated from each other during the formation of intervening oligomers. In any case, the formation of a high concentration of oligomers with considerably shorter exciton lifetimes than in monomers results in a concomitant decrease in diffusion length. In a bilayer structure, this decreases the external efficiency accordingly. Once the monomer population is effectively exhausted, the OPV efficiency decline translates into a slow aging process having a different origin.

Beyond photo-polymerization, the chemical changes during burn-in may have contributions from complexation with the donor, or morphological changes within the blends. For example, reactions between the donor polymer, PCDTBT, and PC<sub>71</sub>BM

have been implicated in 40% loss of efficiency during burn-in. Comparisons of encapsulated (oxygen-free) devices using this BHJ blend employing a conventional PEDOT:PSS anode with Al/Ca cathode structure, or an inverted ZnO NP cathode with a MoO<sub>x</sub>/Ag anode, showed the same efficiency loss before leveling off into a more gentle aging rate with an extrapolated  $T_{80} = 7$  years (Mateker et al., 2015). With no apparent dependence on contact arrangement, morphology or exposure to oxygen, it is assumed that the aging is due to changes in the bulk as a result of increased resistance from recombination in the active region. An additional observation is that regiorandom and amorphous PCDTBT films degrade more rapidly than regioregular and more crystalline films, presumably due to the higher density of the latter morphologies that impedes intercalation by residual impurities left after film preparation.

Self-terminating chemical reactions must be responsible for burn-in since they occur over only a limited duration. The C<sub>60</sub> photo-oligomerization in SubPc/C<sub>60</sub> OPVs is one such self-terminating process. A combination of FTIR and electron spin resonance has shown that the early stage degradation of PCDTBT:PC<sub>71</sub>BM BHJs is due to a combination of complexation with the fullerene, and polymerization (Tournebize et al., 2014). The weak C–N bond between the carbazole group and its octane side chain in PCDTBT cleaves under illumination following the reaction pathway in Fig. 7.229. It is notable that even after 1500 h exposure to light in vacuum, the film absorbance does not change significantly, eliminating the possibility for photooxidation. The resulting carbazole radicals can undergo trapping by the fullerene. Scavenging of the N–CH(C<sub>8</sub>H<sub>17</sub>)<sub>2</sub> radicals by cross-linking with PC<sub>71</sub>BM effectively terminates the reaction. The result is a stable film chemistry and morphology whose properties are unchanged by further exposure to light over exceptionally long periods, as found by the long-term stability of OPVs employing this materials combination. No such termination occurs in the pure polymer films, where formation of long chain polycarbazole moieties continues to completion.

The foregoing has shown that fullerenes are implicated in several burn-in mechanisms, namely dimerization and complexation. Furthermore, its small diameter and symmetrical shape can lead to time-dependent morphological changes in blends with donors that also change the properties of the active region. Considerable care is used to achieve the optimum morphology in BHJs that promotes efficient exciton dissociation as well as low resistance to

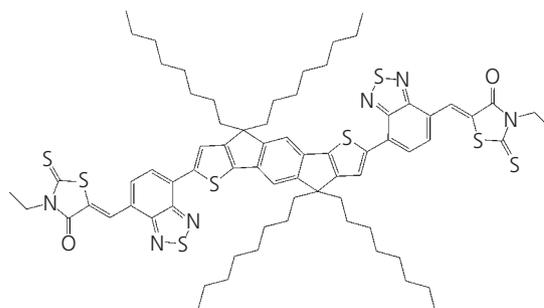

**Figure 7.229** Scission of the carbazole group in PCDTBT in the presence of light results in the production of carbazolyl and  $\text{CHR}_2$  ( $\text{R} = \text{C}_8\text{H}_{17}$ ) radicals. These can be trapped by the fullerene in the BHJ blend (left), or in the pure polymer, forming polycarbazoles indicated by the blue lines (right) (Tournebize et al., 2014).

© 2014 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

charge extraction. While the former requires an intimate and nearly homogeneous blend of donor and acceptor molecules, the latter property is optimized by the development of longer-range structural order within the bicontinuous D-A network. These apparently conflicting purposes and morphologies have led to the development of mixtures containing both amorphous and nanocrystalline, phase-separated regions. The separation of two solids from a blend into coexisting phases is known as *spinodal decomposition*. This is accomplished through the choice of molecular structures, the use of additives, thermal annealing, etc. The resulting morphologies are metastable. The addition of heat or illumination, therefore, can supply sufficient energy to cause structural reorganization. The concomitant rapid change in OPV characteristics due to spinodal decomposition has been observed in, for example, PffBT4T-2OD (also known as PCE11):PC<sub>61</sub>BM (1:1.2) active region OPVs (Li et al., 2017a). The separation of two solids from a blend into two coexisting phases is known as spinodal decomposition. This process appears to be active in the PCE11:PC<sub>61</sub>BM system.

The effects considered thus far are associated with fullerene acceptors. By replacing fullerenes with NFAs, dimerization, complexation, and morphological changes experienced by fullerenes are eliminated. This has been found to be the case for P3HT:IDTBR (Scheme 2) D-A OPVs. The aging data along with those of a P3HT:PC<sub>61</sub>BM BHJ are shown in Fig. 7.230. Both devices are fabricated by doctor-blade application of the active material blends in ambient. They form an inverted architecture with a ITO/ZnO bottom cathode, and a PEDOT:PSS/Ag

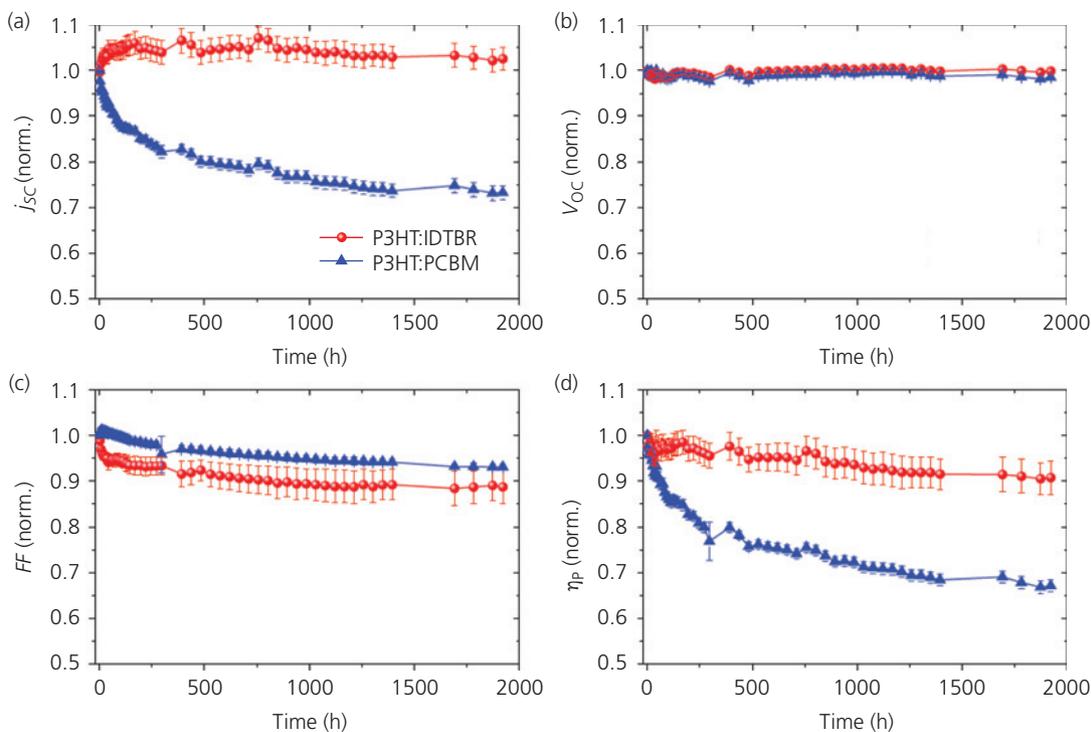

**Scheme 2**

anode (Gasparini et al., 2017). The burn-in transient that results in a 30% reduction in  $\eta_P$  of the PC<sub>61</sub>BM-based OPV during the initial 500 h of operation is absent in the IDTBR-based device. Almost all of the change responsible for the loss in PC<sub>61</sub>BM OPV efficiency is due to a reduction in  $j_{SC}$ , that we have previously shown is due to photo-oligomerization. While there is no burn-in loss in the NFAs, both devices suffer from a long term monotonic decay in *FF* and  $j_{SC}$ , resulting in  $T_{80} \sim 5000$  h for the NFA-based cell. Hence, reducing burn-in loss does not guarantee that the reliability of the devices will meet the demands required of practical solar cells.

## 7.8.2 Contacts and other interfaces

Contact stability is a key determinant of device operational lifetime. This has been shown to be true for OLEDs, and it is equally true for OPVs. Contacts must form a very low and stable injection barrier where the cell series resistance does not increase over time. The contact should not undergo reactions with the organic

**Figure 7.230** Comparison of (a)  $j_{SC}$  (b)  $V_{OC}$  (c)  $FF$ , and (d)  $\eta_P$  during aging of P3HT:PC<sub>61</sub>BM and P3HT:IDTBR BHJ OPVs (Gasparini et al., 2017).

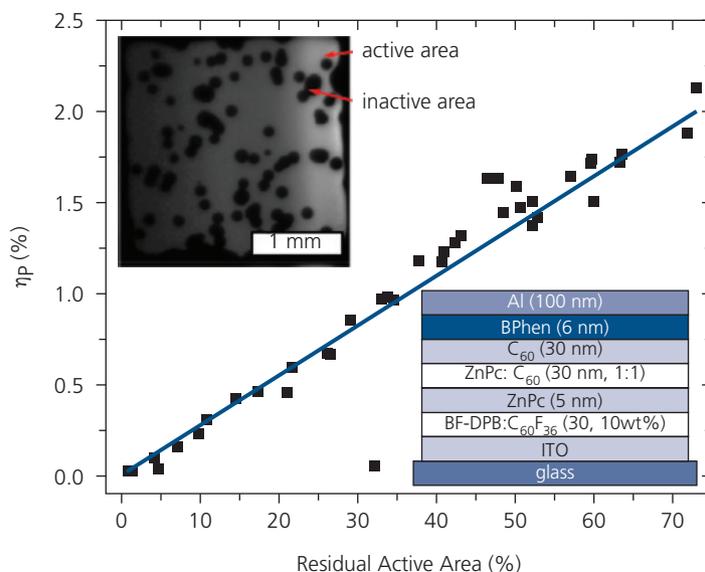

layers, it should be free of pinholes, physically robust (i.e. it should adhere strongly to the organic thin films), and should be resistant to change when exposed to trace contaminants remaining within the package following device fabrication. Since contact quality depends on so many factors, it is difficult to separate contact-related aging phenomena that are intrinsic (e.g. due to metal–organic interactions) or extrinsic (e.g. arising from contamination or physical defects). Hence, in studying OPV aging, its environment must be tightly controlled to enable a clear understanding of the mechanisms for degradation.

Contact diagnostics are similar to those employed in OLEDs (cf. Section 6.7.2). These include pulling or peeling off the contact using scotch tape, microscopic imaging to identify physical defects, thermal imaging to locate hot spots due to current crowding, and EL and PL imaging of the OPV active region. Dark regions under forward bias indicate a high rate of non-radiative recombination that do not generate photocurrent when reverse biased. Thus, monitoring the EL intensity over time provides a quantitative measurement of how the active OPV area is evolving. If the ratio of the time dependent photocurrent to EL intensity,  $EL(t)$ , given by  $R(t) = j_{SC}(t)/EL(t)$ , is constant, it is likely that the loss of contact area is the source of degradation in the OPV. In contrast, when  $R(t) < 1$ ,

then there are additional sources of EL loss due to recombination in the bulk of the active region beyond a simple reduction in contact area (Seeland et al., 2011). The photoluminescence intensity is also a function of bulk recombination, and hence PL imaging of the OPV can be used along with EL to separate contact from trap-related recombination within the BHJ.

Figure 7.231 shows a plot of  $\eta_P$  vs. the residual active area of a p-i-i ZnPC: C<sub>60</sub> cell with the structure shown in the inset after extended exposure to simulated solar illumination. The device is capped by a degassed, 175  $\mu\text{m}$  thick PET film attached to the glass substrate by a bead of UV-cured epoxy along its edges. As discussed in Section 6.7.5, PET and similar polymer films do not form a substantial barrier to atmospheric constituents, which undoubtedly account for many of the defects that grow during exposure. The residual area over time is determined from the total EL intensity obtained under forward bias. An image of an aged contact is shown in the top inset, Fig. 7.231. The linear relationship between  $\eta_P$  and the active area indicates that  $R(t) = 1$ . That is, the degradation in efficiency is due to the loss of active area, possibly due to infiltration of water through pinholes in the Al contact.

Example EL and thermal images of 0.5  $\text{cm}^2$  contacts to PCDTBT:PC<sub>61</sub>BM OPVs after aging are shown in

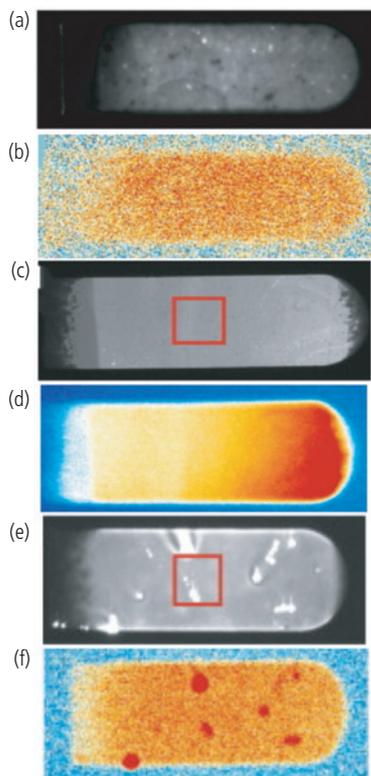

**Figure 7.231** OPV efficiency vs. active area determined via EL imaging under 1 sun intensity white illumination. Top inset: Example contact image showing dark spots. Bottom inset: p-i-i OPV structure used in the experiments. The BF-DPB layer is p-doped with C<sub>60</sub>F<sub>36</sub>. Adapted from Klumbies et al. (2014).

Fig. 7.232. Immediately following fabrication in a controlled, clean environment, the devices show featureless contact images, with no evidence for pinholes or hot spots that would arise from current non-uniformities (Seeland et al., 2011). However, numerous features emerge over time. They appear whether the devices are stored in the dark or operated at elevated temperatures. The integrity of the package and the choice of contact metal impact the degree and rapidity of defect formation. The packages comprised two glass layers bonded at their periphery using thermo-setting epoxy. It is found that a bare Al cathode exposed to air during aging exhibits several pinholes (dark spots, Fig. 7.232a) and hot areas (white regions, Fig. 7.232b), along with variations in EL intensity across the device. In contrast, packaged OPVs employing TiO<sub>x</sub>/Al cathodes are almost featureless after aging (Fig. 7.232c and d). The pinholes tend to grow with time since they allow water and oxygen to enter the active region, as well as by oxidizing the Al contact. This promotes photobleaching of the active region. This increases the contact resistance around the perimeter of the pinhole, causing an increase in local temperature and metal delamination. Preventing exposure to atmosphere in the packaged devices eliminates many of these problems. Interestingly, the devices close to the edges of the package (i.e. near the epoxy seal) had a noticeably higher defect density than devices near the center. This suggests the solar cells are vulnerable to environmental exposure; presumably

devices near the edge are contaminated by diffusion from water and oxygen sooner than are devices deeper within the package. Indeed, the devices near the edge may themselves get oxygen and water, fixing it at locations distant from the other, longer-lived OPVs.

The OPV characteristics do not age nearly as fast for the TiO<sub>x</sub>/Al cathodes as for the bare Al cathodes, even when packaged. Finally, TiO<sub>x</sub>/Ag contacts show a much higher concentration of non-uniformities than do the Al contacts. Silver rapidly migrates through the organic layers, creating current shunts that render large areas of the device inactive (Roesch et al., 2013, Song et al., 2015). The shunts result in the large bright regions across the device area in Fig. 7.232e and f.

The TiO<sub>x</sub> buffer placed immediately beneath the metal contact serves multiple purposes illustrated in Fig. 7.233. As described in Section 7.4.1, the buffer acts as an optical spacer, an exciton blocker and electron transporting medium, and it protects the active region from damage during metal contact deposition. The electron-conducting TiO<sub>x</sub> extends the device lifetime since it is considerably denser than the organic layers, and as such it forms a barrier to oxygen and water. Furthermore, since the layer is oxygen-deficient, it can scavenge oxygen from both the active region as well as from the interface with the metal contact (Lee et al., 2007). The metal oxide layer deposition from solution is illustrated in the right inset, Fig. 7.233. A precursor of Ti(IV) isopropoxide (TiOR = Ti[OCH(CH<sub>3</sub>)<sub>2</sub>]<sub>4</sub>) is

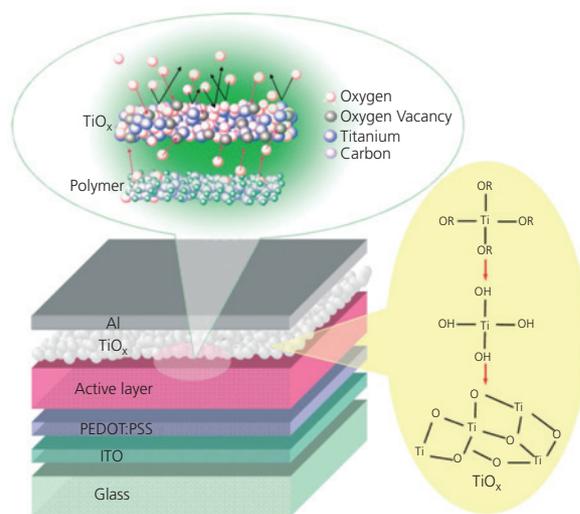

**Figure 7.232** Thermal (grayscale) and electroluminescent (color) images of 0.5 cm<sup>2</sup> PCDTBT:PC<sub>61</sub>BM OPV contacts following aging under different conditions. (a, b) Unpackaged devices employing TiO<sub>x</sub>/Al contacts aged for 1100 h at 1 sun intensity, (c, d) Packaged devices employing TiO<sub>x</sub>/Al contacts aged for 1150 h at 1 sun intensity. (e, f) Packaged devices employing TiO<sub>x</sub>/Ag contacts aged for 1150 h at 1 sun intensity. The temperature is highest in the white regions of the thermal images. The EL images range from red (most intense) to blue (no EL). Red boxes in (c) and (e) indicate regions where  $\eta_{\text{ext}}$  of the devices were measured (Roesch et al., 2013).

hydrolyzed by mixing with 1-methoxyethanol and ethanolamine. After spin casting the solution onto the OPV surface, it is annealed in air at 80°C for 10 min to form a 30–40 nm thick film.

The ability of TiO<sub>x</sub> to act as a barrier and as an oxygen getter is inferred from the data in Fig. 7.234, where TiO<sub>x</sub> was used to protect polyfluorene (PF) films that are highly vulnerable to photooxidation (cf. Fig. 7.225). The samples prepared for this test were: glass/PF, glass/TiO<sub>x</sub>/PF, glass/PF/TiO<sub>x</sub>, and glass/TiO<sub>x</sub>/PF/TiO<sub>x</sub>. Figure 7.234a, upper panel, shows the PL intensity of PF for the freshly prepared samples. The bare PF film shows the emergence of a strong, secondary emission peak at 550 nm after

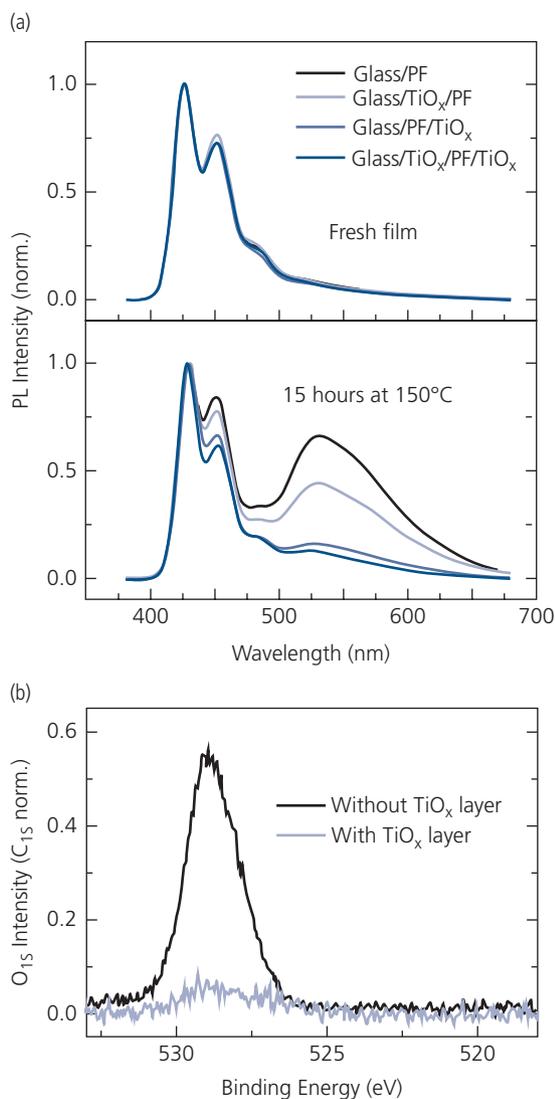

**Figure 7.233** Structure of a polymer OPV employing a TiO<sub>x</sub> cathode buffer layer. The top inset illustrates the ability of TiO<sub>x</sub> to form a barrier that prevents atmospheric contaminants from entering the active region, and also to scavenge O<sub>2</sub> at TiO<sub>x</sub> vacancies. The right inset shows the low temperature sol-gel process used to synthesize the TiO<sub>x</sub> layer (Lee et al., 2007).

exposure to air at 150°C (Fig. 7.234a, lower panel). The peak intensity is dramatically reduced, or even eliminated for the glass/PF/TiO<sub>x</sub>, and glass/TiO<sub>x</sub>/PF/TiO<sub>x</sub> samples. Hence, the TiO<sub>x</sub> cap retards oxidation. The peak intensity for the glass/TiO<sub>x</sub>/PF sample is below that of the bare PF film. Thus, even when oxygen permeates the PF, it can be captured and rendered inactive by TiO<sub>x</sub> buried beneath its surface. These findings are reinforced by the XPS spectra of the O<sub>1s</sub> peak normalized to C<sub>1s</sub> in Fig. 7.234b for bare and capped PF films after 48 h exposure at high temperature in air. The spectra were obtained after removal of the cap. They show that there is very little oxygen in the capped film compared to the bare PF, indicative of the barrier-forming properties of the buffer.

When the active region is heated above the glass transition temperature of a constituent material, the blend can locally separate, with one or more molecular constituents migrating toward the contacts. In some cases this introduces a barrier to charge extraction at the electrodes. Figure 7.235 shows the aging schedule of two PC<sub>61</sub>BM-based BHJ devices in the conventional, top cathode configuration. One device employs the donor P3HT with a  $T_g = 56^\circ\text{C}$ , and the other uses PCDTBT with  $T_g = 125^\circ\text{C}$  and  $130^\circ\text{C}$  for the thin film and bulk, respectively. In acquiring the data, the devices are brought to temperature and held for 3 h before the temperature is raised by another 10°C,

**Figure 7.234** (a) The PL intensity of as-deposited polyfluorene (PF) films and after 15 h exposure to air at 150°C. The legend shows the various film structures with and without a TiO<sub>x</sub> layer. (b) XPS spectrum of the O<sub>1s</sub> emission intensity of a bare PF film, and one capped by TiO<sub>x</sub> after 48 h exposure to air at 150°C (Lee et al., 2007).

all the while monitoring  $V_{OC}$ . When  $T \geq 57^\circ\text{C}$  for the P3HT-based OPV, there is a noticeable decrease in  $V_{OC}$  during the holding period. This is observed at 127°C for the device comprising PCDTBT. The changes in  $V_{OC}$ , therefore, occur at or very near to the  $T_g$  of the respective materials. By peeling off the cathode using scotch tape following the tests and then replacing it, the original device characteristics are recovered. The decrease in  $V_{OC}$  at  $T_g$  appears to be independent of cathode material, including MoO<sub>3</sub>/Ag and PEIE/Ag.

These findings suggest that the donor migrates to the cathode and forms a very thin barrier to electron

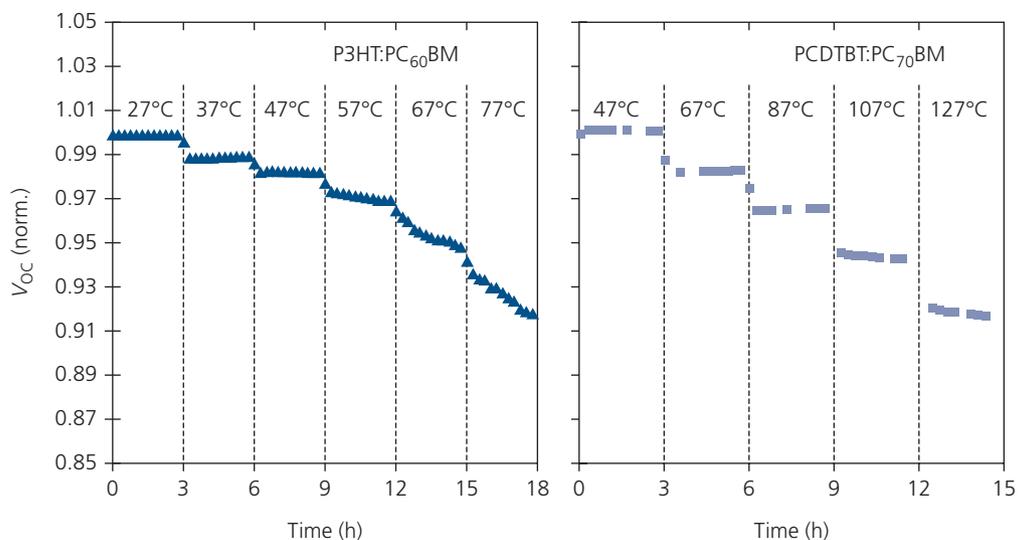

transport from the acceptor. However, this inference is not directly supported by spectroscopic evidence. It is notable that the changes in  $V_{OC}$  are not encountered in inverted devices, where the cathode is on the substrate surface. In that configuration, the donor would selectively migrate toward the top surface that is capped by the anode, thus eliminating the formation of the energy barrier to electrons at the cathode (Sachs-Quintana et al., 2014).

To summarize this discussion, the aging characteristics of OPVs are strongly influenced by the contacts, that can be protected by encapsulation impermeable to atmospheric exposure, particularly to O<sub>2</sub> and H<sub>2</sub>O. There are numerous pathways to failure originating from the choice of active region and contact metals, the chemical interactions at the interfaces between them, and their reaction with contaminants. Furthermore, combining materials with substantially different bulk moduli and coefficients of thermal expansion creates strain that results in morphological defects such as voids and fracture induced by changes in temperature or mechanical flexing. The effects of stress on various device regions are illustrated in Fig. 7.236. The value of organic electronic devices, and particularly OPVs, is partially due to their ability to be scaled to very large sizes, and to be fabricated on flexible, lightweight and often stretchable surfaces (Lipomi and Bao, 2011, Savagatrup et al., 2015). These substrates can introduce significant stresses on organic films and their encapsulants that are not ordinarily experienced by brittle, inorganic semiconductors.

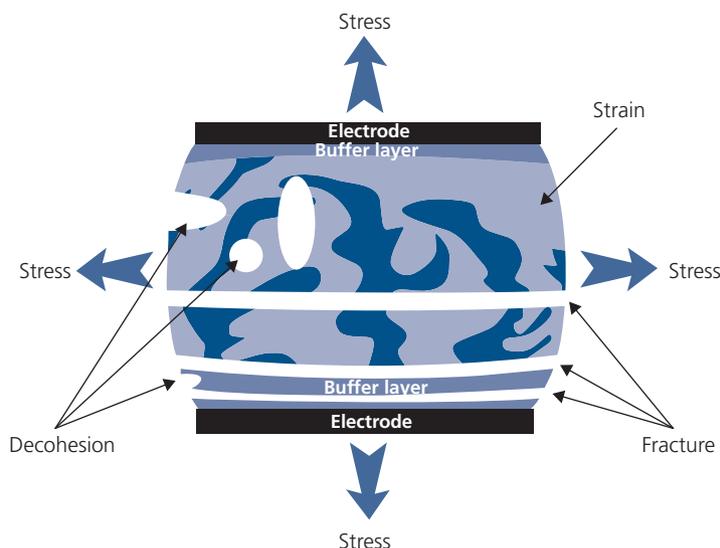

### 7.8.3 Encapsulation

While we have seen that materials, morphologies, device architectures, interfaces and contacts all play roles in determining reliability of OPV modules, ultimately, these features are vulnerable to deterioration if exposed to the environment. The modules must last for at least 20 years in environments that range from bitter cold ( $-40^\circ\text{C}$ ) to extremely hot ( $100^\circ\text{C}$ ), and from arid to tropical. The modules may be subjected to bombardment by sand and hail, and severe wind loads as well as heavy coatings of snow. The list of environmental hazards is extensive, placing extreme demands on organic thin film solar cells that are comprised of what are generally believed to be rather fragile, carbon-based semiconductor materials. Thus, cell and module packaging must withstand the most adverse circumstances while also being low cost.

Fortunately, a great deal of experience has been gained in packaging from the manufacture of

**Figure 7.235** Time dependence of  $V_{OC}$  using a step-wise increase in temperature of two BHJ OPVs employing a Ca (7 nm)/Al (150 nm) top cathode, and a ITO/PEDOT:PSS anode aged in  $N_2$  (Mateker and McGehee, 2017).

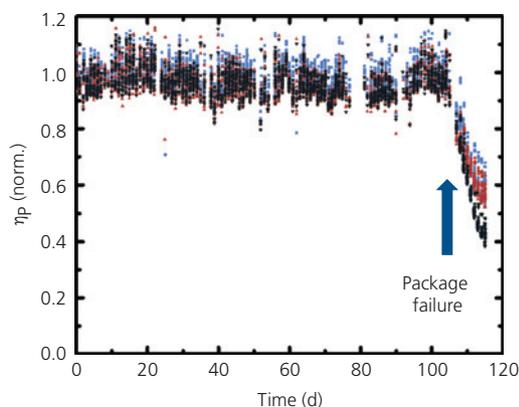

**Figure 7.236** Schematic of possible strains and failure modes introduced in an OPV subjected to stress, either from mechanical, optical, or thermal sources (Cheng and Zhan, 2016).

long-lived OLED displays and lighting appliances. Of course, the environments encountered by OLEDs are not nearly as challenging as for solar cells, but flexible and lightweight encapsulation schemes, along with sophisticated methods for their evaluation have been developed. Many of these solutions are described in Section 6.7.5. We extend that discussion here, focusing on technologies adapted specifically to packaging and large-scale manufacturing of OPVs.

Adverse environmental exposure can lead to catastrophic package failure. Figure 7.237 shows the

failure of a UV-cured, epoxy sealed glass package used to encapsulate small molecule OPVs in Fig. 7.220. The devices were continuously aged under open circuit conditions out-of-doors at Sde Boquer in the Negev Desert, Israel. The data from four devices shows a spread in diurnal efficiencies with the devices held at a fixed angle of  $30^\circ$  relative to the horizon. Rainfall on day 108 damaged the package seal, initiating a rapid decline in efficiency. This was due to a similarly rapid reduction in  $j_{SC}$ , with  $V_{OC}$  and  $FF$  largely unaffected by the package

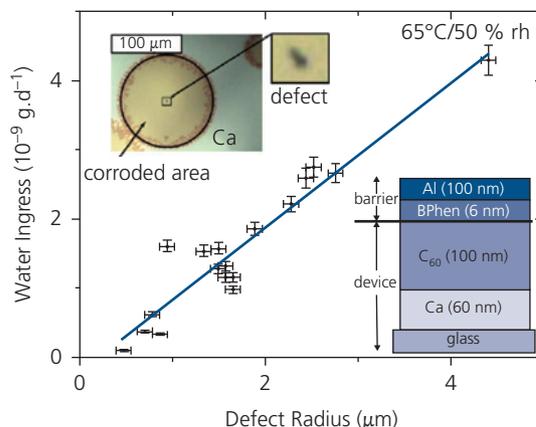

**Figure 7.237** Normalized  $j_p$  for a population of four DBP:PC<sub>71</sub>BM OPVs vs. time spent outdoors. Package failure occurred on day 108. After Burlingame et al. (2016).

failure. The vulnerability to variable weather events is but one of many challenges that must be overcome by environmentally robust, yet inexpensive encapsulation technologies.

Flexible packages must have at least one transparent surface. This can be provided by a plastic foil with an inorganic barrier layer that retards or eliminates penetration into the active device region (Dennler et al., 2006). In Sections 5.8 and 6.7.5, we discussed the process of contaminant ingress through multilayer barrier coatings embedded in polymer substrates. By interleaving impermeable, thin inorganic layers between organic layers, the contaminant must diffuse along an extended, circuitous path between defects in successive layers before it enters the cavity containing the active device (Graff et al., 2004). While the multilayer cannot prevent the eventual entry of contaminants since there is always a finite density of defects in every film, the time needed to reach the device may be sufficiently long to enable the intended application. An alternative, impermeable flexible encapsulant is very thin glass, although this is quite fragile and possibly unsuitable for solar cell applications. The second surface may or may not need to be transparent, and hence a second plastic barrier, or metal foil, respectively, can be employed for this purpose.

A coating is characterized by its *water vapor transmission rate (WVTR)* and *oxygen transmission rate (OTR)* (see Section 5.8). Suitable coatings for long-lived operation needed in OPVs have  $WVTR \sim 10^{-5}$ – $10^{-6}$  g/m<sup>2</sup>-d and  $OTR < 10^{-1}$  cm<sup>3</sup>/m<sup>2</sup> d atm. The *WVTR* of a package can be determined using a Ca sensor layer. A water sensitive test coupon comprises a thin Ca layer deposited on a glass substrate. In the example device in Fig. 7.238, top inset, the active region (here represented by a single C<sub>60</sub> layer, lower

**Figure 7.238** Water vapor transmission rate vs. defect radius. Upper inset: Micrograph of a defect in the center of a corroded area. The defect itself is much smaller than the yellow corroded area. Lower inset: Test coupon used to measure *WVTR*. After Klumbies et al. (2014).

inset), followed by the BPhen exciton blocker and Al contact are deposited on the Ca surface. Calcium corrodes by contact with two water molecules to form Ca(OH)<sub>2</sub> (Cros et al., 2006). The complete hydrolysis requires 1.4 g(H<sub>2</sub>O)/cm<sup>3</sup>(Ca). Thus, the 60 nm thick layer is converted to Ca(OH)<sub>2</sub> by 8.4 μg/cm<sup>2</sup> of H<sub>2</sub>O. Since Ca is a conducting, opaque metal, and Ca(OH)<sub>2</sub> is a transparent insulator, water penetration results in significant changes in both its optical and electrical characteristics.

The Ca test was used to investigate the barrier formed by the Al/Bphen layer of the devices in Fig. 7.231 when exposed to 50% relative humidity (RH) at 65°C. Figure 7.238, upper inset, shows a micrograph of the Ca layer (as viewed through the glass substrate) in the region surrounding a small defect in the Al cathode. The defect is apparently a pinhole located at the center of the corroded area that allows water to penetrate to the Ca layer, locally converting it to Ca(OH)<sub>2</sub>. The corroded area grows as the water content increases. Interestingly, the amount of water penetrating to the test layer is proportional to its radius, not the area of the defect. This results since the water molecules must diffuse laterally to reach areas not directly beneath the defect itself. The extent of the diffusion region, therefore, depends on the length of the defect periphery. Another finding is that the amount of water in the OPV active region at *T*<sub>50</sub> is 2.0 μg/cm<sup>2</sup>, independent of the exposure of the devices to a combination of temperatures between 38°C and 65°C and relative humidity between 11% and 90%. This is unsurprising since the damage to a constant volume of active material by H<sub>2</sub>O is ultimately

determined only by the concentration of  $\text{H}_2\text{O}$  within that volume (Klumbies et al., 2014).

Table 7.29 shows the *WVTR* of several different encapsulant lids that are epoxy-sealed to a glass substrate carrying the devices in Fig. 7.231. The device without an encapsulant only has BPhen/Al cathode as a barrier, whereas there are several different package lids employing different combinations of PET and reactively sputtered zinc-tin-oxide (ZTO). The triple barrier layer comprises two, 100 nm thick ZTO layers forming a sandwich with a 500 nm  $\text{SiO}_x\text{C}_y\text{H}_z$  plasma-deposited polymer layer. The package employing a glass lid has the lowest *WVTR* due entirely to water penetration of the thin UV-cured epoxy bead around its periphery.

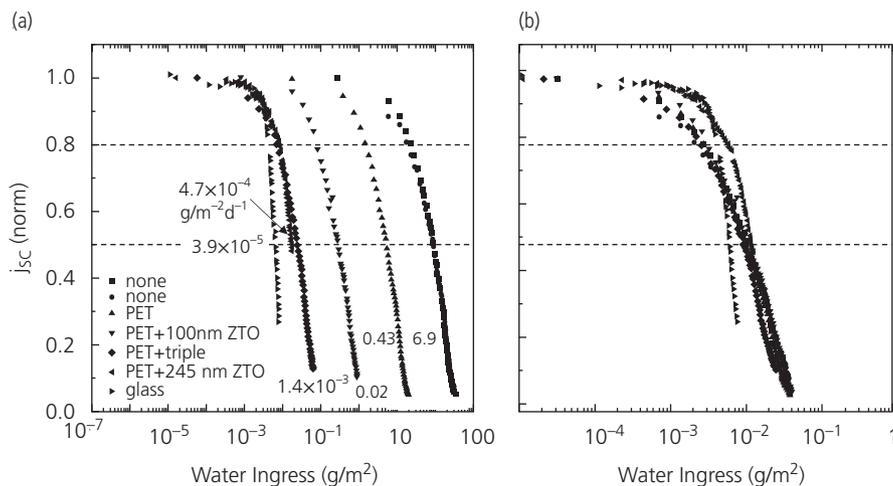

A population of devices encapsulated by these different lids were exposed to 1 sun intensity illumination at  $RH = 5.5\%$  using ISOS-L-1 conditions (i.e. at open circuit, see Table 7.28). The normalized

short circuit current vs. total water penetration for the devices is shown in Fig. 7.239a. There,  $j_{SC}(t)$  follows the stretched exponential of Eq. 7.212, indicating that there is no discernable difference between burn-in and long term degradation: the device performance monotonically depends on the amount of water to which it is exposed. In the figure, the *T50* of each device was different; curves to the left have lower *WVTR*, and hence have a larger *T50*, than curves to the right.

With only the exception of the glass lid device, the shape of the curves is approximately the same, with almost no change in  $j_{SC}$  until a threshold is reached, after which the device rapidly degrades. This suggests that once a threshold concentration of  $\text{H}_2\text{O}$  has entered the active region, rapid degradation follows. The water volume that is required to reach *T50* for each encapsulation is indicated in the plots. Degradation occurs at smaller water ingress as the *WVTR* of a package is reduced. For both the glass and 245 nm thick ZTO-coated PET, the amount of water penetrating to the device is insufficient to lead to complete degradation (i.e. to *T0*) over the 1150 h duration of the experiment. The thick, single layer ZTO is more effective than even the three-layer ZTO/organic/ZTO barrier. Presumably, when the ZTO reaches a critical thickness, the total defect area drops dramatically (da Silva Sobrinho et al., 2000). Nevertheless, some formation of defects is unavoidable. Thus, as expected, the best performance is obtained for the fully glass encapsulated OPV.

**Table 7.29** Water vapor transmission rates into the devices in Fig. 7.231 using different package lids (Hermenau et al., 2012)

Encapsulation	<i>WVTR</i> ( $\text{g}/\text{m}^2 \text{ d}$ )
None	6.9
125 $\mu\text{m}$ PET	0.43
125 $\mu\text{m}$ PET + 100 nm ZTO	0.02
125 $\mu\text{m}$ PET + triple barrier layer	0.0014
75 $\mu\text{m}$ PET + 245 nm ZTO	$3.7 \times 10^{-4}$
Glass	$3.9 \times 10^{-5}$

**Figure 7.239** (a) Normalized  $j_{SC}$  vs. total amount of water penetration into the packages encapsulated using a glass substrate and the lids in Table 7.29. The number associated with each curve is the total amount of water transmission at *T50*. The devices are the same as in Fig. 7.231. (b) The data in (a) adjusted for the effects of the water penetration of the BPhen/Al cathode such that only water penetration through the encapsulant is counted (Hermenau et al., 2012).

The result in Fig. 7.239a is counterintuitive. Why would a lower  $WVTR$  require less water to degrade the device (albeit over a longer time) than if the barrier to water penetration is reduced (i.e. in a device with no encapsulation)? This apparent contradiction is understood if there is more than the single barrier to water. One barrier (the encapsulation) is far more resistive to water penetration than the secondary barrier (the cathode). The time to penetrate the lid is much longer than to overcome the 100 nm thick Al cathode, and hence the former dominates the time to device failure. Once the moisture enters the package, however, it rapidly moves into the device active volume, since the cathode presents only a small additional time delay. Since  $WVTR$  is a measure of the conductance of the barrier to water, the total resistance to water penetration of the two barriers is simply:  $1/WVTR_{total} = 1/WVTR_{lid} + 1/WVTR_{Al}$ . Using  $WVTR_{Al} = 8 \times 10^{-4}$  g/m d, the data in Fig. 7.239a are replotted to account only for the transmission of the lid,  $WVTR_{lid}$ , as shown in Fig. 7.239b, where all the curves now overlap (Hermenau et al., 2012). This corroborates the hypothesis that the devices fail once a fixed amount of water has entered the package.

Encapsulations employing a plastic lid or substrate still fall well short of the performance of glass packages, with none showing the endurance required for operation longer than a few weeks or months when tested using ISOS-D-3, L-2, and L-3 conditions (Corazza et al., 2014, Voroshazi, 2014). Furthermore, sensitivity to UV light of many polymers results in their discoloration and embrittlement, leading to additional routes to package and device failure. We have seen that even the epoxy seal can fail catastrophically when exposed to adverse environments commonly encountered out-of-doors, and has a  $WVTR$  that in itself is too high for exterior use. Until these problems are solved, it is expected that OPVs will not be found in the most demanding conditions now dominated by commodity Si solar cells. There are many large niche applications, however, that do not require such a high degree of robustness. As discussed in previous sections, building integrated PV such as power generating windows, and even in some building applied PV applications, the harsh conditions faced by large power generating plants can be avoided. These niches are potentially enormous, and the low cost, lightweight, flexibility and most importantly, the semitransparency of OPVs are possibly the best choice for filling these needs.

## 7.9 Scaling up to modules

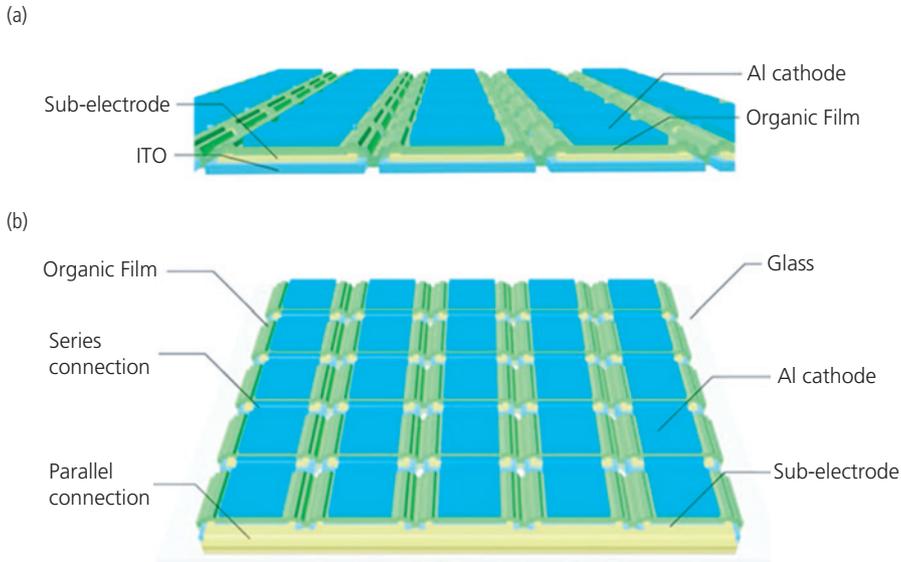

The primary challenges in scaling to modules are the reduction of series resistance, and the adaptability of the process to volume, low-cost and high yield manufacturing. We have briefly touched on both of these topics in previous sections. Series resistance primarily originates from the transparent contact. In Section 7.4.2 we have shown that there are several approaches to reducing series resistance while maintaining transparency, but none supersede the performance of ITO due to its combination of high transparency and conductivity. Yet ITO substantially limits the ability to scale the devices to modules due to both its high sheet resistance and cost. Furthermore, ITO is a brittle metal oxide, limiting the bending radius that can be tolerated before cracking. While deposition of OPVs on flat glass substrates may provide a solution for specialized applications, a considerable focus of research has been on developing continuous roll processes. While this is the path to realizing low cost, volume manufacturing, the flexible packaging required for R2R production are not sufficiently robust to withstand harsh exterior environments over long periods.

Here we discuss contact designs used for large modules, and some of the features of current R2R manufacturing. For this latter topic, we rely on the discussions of both Chapters 5 and 6, while in the following we describe only those issues that are specific to the scalable manufacture of organic solar cell modules in a continuous web environment. Batch manufacturing on large glass plates is a well-developed technology for the display industry.

In the context of multijunction cells in Sections 7.1.2 and 7.5, the power losses due to cell series resistance follow

$$\Delta P_{loss} = I^2 R_{ser}. \quad (7.220)$$

Thus, series-connected cells in modules are preferred over parallel-connected cells to minimize losses. An illustration of a typical cell arrangement in a module is shown in Fig. 7.240. The module consists of a  $5 \times 5$  array of individual cells in a series-parallel circuit. The series strings are along the columns, and are connected in parallel by the bus bars at the front and back of the module. Sub-electrode metal contacts overcoat the exposed ITO edges to minimize contact series resistance (Park et al., 2010b). The use of a combination of series and parallel connections prevents the voltage from getting so high that arcing, or difficulties in interfacing

**Figure 7.240** (a) Edge and (b) top views of an OPV module connected in a series-parallel circuit (Xiao et al., 2015).

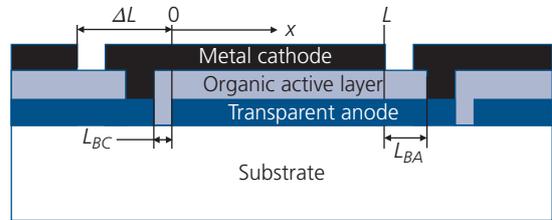

with the control circuitry, become problematic. Thus, for a single cell operating at its MPP voltage,  $V_M$ , the 25 OPV array output voltage is  $5V_M$ .

The series circuit is realized by connecting the anode of one OPV with the cathode of the adjacent device, as shown in detail in Fig. 7.241. The step made by the cathode from the bottom ITO contact on one cell to the top of the organic layer creates optically inactive regions that allow for alignment tolerances, and provide a sufficiently large anode-cathode contact to minimize series resistance. The aperture ratio, or *geometric fill factor*, is  $GFF = A_{cell}/A_{tot}$ , where  $A_{cell}$  is the active area of the cell, and  $A_{tot}$  is the total footprint occupied by each solar cell including inactive regions. For a cell of width,  $W$ , and length,  $L$ , then from Fig. 7.241 we have  $GFF = L/(L + \Delta L)$ , where  $\Delta L$  is the distance between cell active regions along the  $x$ -direction. The module power conversion efficiency is

$$\eta_{P,module} = \eta_{P,cell} \cdot GFF = \eta_{P,cell} \frac{L}{L + \Delta L}. \quad (7.221)$$

One of the challenges in module design and fabrication is to minimize  $\Delta L$ .

Power loss due to series resistance of an individual cell was calculated in Section 7.3.3. The analysis for a module extends that treatment to account for additional losses due to the layout of the series-connected array. In addition to the series resistance of the contacts of the individual cells, power losses in the module also must include contributions from the anode

**Figure 7.241** Schematic of the series connection of an OPV of active region length,  $L$ , to its neighbors. Note how the cathode must be deposited to connect the bottom transparent anode to the top of the organic active region.

and cathode bridges of lengths  $L_{BA}$  and  $L_{BC}$ , respectively, and the contact resistance of the cathode-anode contact (Hoppe et al., 2012).

If we consider the cell itself to be a distributed source generating an incremental current at point  $x$  (see Fig. 7.241) of  $dI(V, x) = j(V)Wdx$  where  $W$  is the contact width, then the total current at  $x$  is  $I(V, x) = j(V)Wx$ . It follows that the incremental change in resistance is  $dR = R_{\square}dx/W$ , yielding a total power loss from the contact sheet resistance,  $R_{\square}$ , of

$$\begin{aligned} \Delta P_{sheet} &= \frac{R_{\square}}{W} \int_0^L I(V)^2 dx = \frac{R_{\square}}{W} \int_0^L [j(V)Wx]^2 dx \\ &= I(V)^2 \left[ \frac{R_{\square}L}{3W} \right]. \end{aligned} \quad (7.222)$$

Thus the total sheet resistance from the contact of length  $L$  is

$$R_{sheet} = \frac{R_{\square}L}{3W}. \quad (7.223)$$

A similar analysis yields the bridge resistances of

$$R_{BA,C} = R_{\square A,C} \frac{\Delta L}{3W}, \quad (7.224)$$

where it is assumed that both the anode and cathode (subscripts  $A$  and  $C$ , respectively) bridge lengths are equal, but their sheet resistances,  $R_{\square A,C}$ , are not. The contact between the anode and cathode also contributes resistance,

$$R_C = \rho_C \frac{3}{W\Delta L}, \quad (7.225)$$

where  $\rho_C$  is the contact resistivity.

These resistances can be independently measured on the substrates used in the modules. Similarly, the device properties are derived from their  $j(V)$  characteristics. From the latter,  $\eta_{P,cell}$  is calculated in the usual manner. Finally, the module efficiency is found from Eq. 7.221.

This analysis is used to optimize the layout by minimizing both  $\Delta L$  and  $R_{\square}$  through appropriate materials choices, device structure, etc. It has been applied to P3HT:PC<sub>61</sub>BM solar cells to evaluate the performance of different anodes (ITO, PEDOT:PSS) and substrates (PET and glass). Table 7.30 lists measured values of  $R_{\square}$  and  $\rho_C$ . With these parameters in hand, along with the characteristics of the individual OPV cells, the module efficiency is calculated as a function of  $L$  and  $\Delta L$  assuming ITO bridge lengths of  $L_{BA} = \Delta L/3$  and  $W = 5$  cm. The results are plotted for  $R_{ser}$  (which is the sum of Eqs. 7.223–7.224),  $FF$  and  $\eta_P$  in Fig. 7.242. The result is for ITO on glass, with a maximum individual cell efficiency of 4%. The reduction in  $\eta_P$  with  $L$  and  $\Delta L$  is due to the reduction in  $FF$ , since both  $j_{SC}$  and  $V_{OC}$  are largely unaffected by the series resistance. The  $R_{ser}$  is almost entirely dominated by the ITO sheet resistance, increasing with the length of the anode bridge and the cell. It is noted that the cell efficiency in the module drops by over 30% as the cell length is increased to 2 cm, and the distance between cells to 0.5 cm. Not surprisingly in view of Table 7.30, the erosion in efficiency is far more pronounced for ITO on PET, and by using PEDOT:PSS to replace ITO (Hoppe et al., 2012).

Figure 7.243 shows data from a module comprising a  $5 \times 5$  array of  $1 \text{ cm}^2$  tandem cells in Section 7.3.3 (see Fig. 7.84 and 7.240). The dominant contribution to the series resistance from ITO is reduced using a Ag sub-electrode bus bar around 95% of the device perimeter (Park et al., 2010b), thereby reducing the total contact

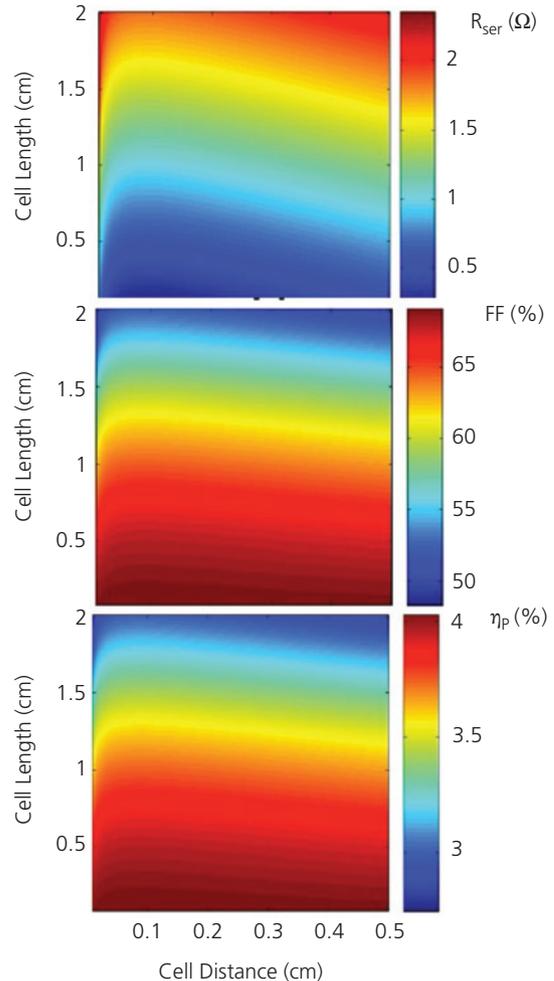

resistance to only 30% of that for a  $1 \text{ cm}^2$  cell without sub-electrodes. Furthermore, a sub-electrode is employed around each individual cell in the array.

**Table 7.30** Sheet and contact resistivities for common materials used in OPV modules (Hoppe et al., 2012)

Material	Layer thickness	$R_{\square}$ ( $\Omega/\text{sq.}$ )
Al	135	0.16
ITO on glass	150	12.5
ITO on PET	150	50
PEDOT:PSS PH1000	150	100

Material	$\rho_C$ with Al ( $\text{m}\Omega \text{ cm}^2$ )
ITO on glass	11
ITO on PET	17
PEDOT:PSS PH1000	200

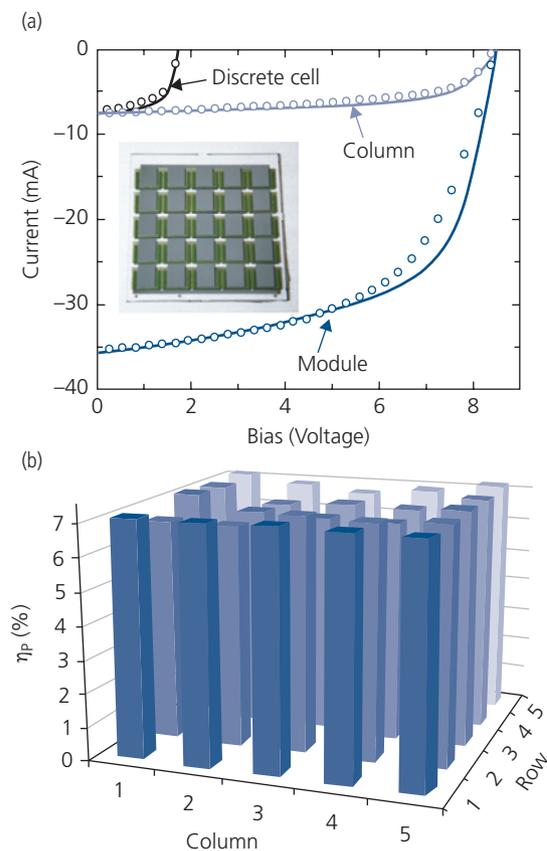

**Figure 7.242** Efficiency of P3HT:PC<sub>61</sub>BM solar modules as functions of individual cell lengths,  $L$ , and separation distances,  $\Delta L$ , assuming  $L_{BA} = 1/3\Delta L$  (Hoppe et al., 2012).

A photograph of the module fabricated by shadow mask patterning on a glass substrate is shown in the inset of Fig. 7.243a. For a column of five discrete cells connected in series,  $V_{OC} = 8.45$  V, which is within 0.5% of the sum of  $V_{OC}$  for 5 individual cells, while the short-circuit current of a column is 7.5 mA, the same as for the total discrete cell currents. The  $I$ - $V$  characteristics of these components measured under 1 sun, AM1.5G simulated illumination are shown in Fig. 7.243a. The characteristics indicate that resistive losses are minimal in the module compared to that of the individual cells due to a combination of the use of tandem cells, sub-electrodes, and an optimized circuit layout. The difference between the experimental and fitted  $I$ - $V$  characteristics for the module is due to differences in individual device performances from variations in film thickness and contact resistances across the module. Under simulated AM1.5G illumination at one sun intensity, the module output power is 162 mW with  $I_{SC} = 36$  mA,  $V_{OC} = 8.45$  V, and  $FF = 53\%$ , corresponding to  $\eta_p = 6.5\%$ . Correcting the efficiency for a  $GFF \approx 0.46$ , the module efficiency is  $\eta_{p,module} = 3.0\%$  (Xiao et al., 2015). The vacuum deposition process results in a 100% discrete cell yield, as shown in Fig. 7.243b. The efficiency of the discrete cells range from 6.7% to 7.2%, with a variation less than 10% across the module.

There are two principal remedies to closing the gap between the cell and module efficiencies. The individual cells must be kept as small as possible without unduly affecting  $GFF$  due to gaps between cells, and the anode resistance must be reduced. We found in Section 7.4.1 that there is not a lot of improvement expected by replacing ITO with alternative materials such as Ag nanowires. Hence, an attractive approach used in OLEDs and in OPVs is to embed a thin metal grid (laid out as streets and avenues, or honeycombs) in the ITO or PEDOT:PSS layer (Zhou et al., 2014). This can significantly reduce sheet resistance, although it increases fabrication complexity since the transparent layer added to the grid must planarize the surface to avoid non-uniformities in the subsequently deposited device active regions.

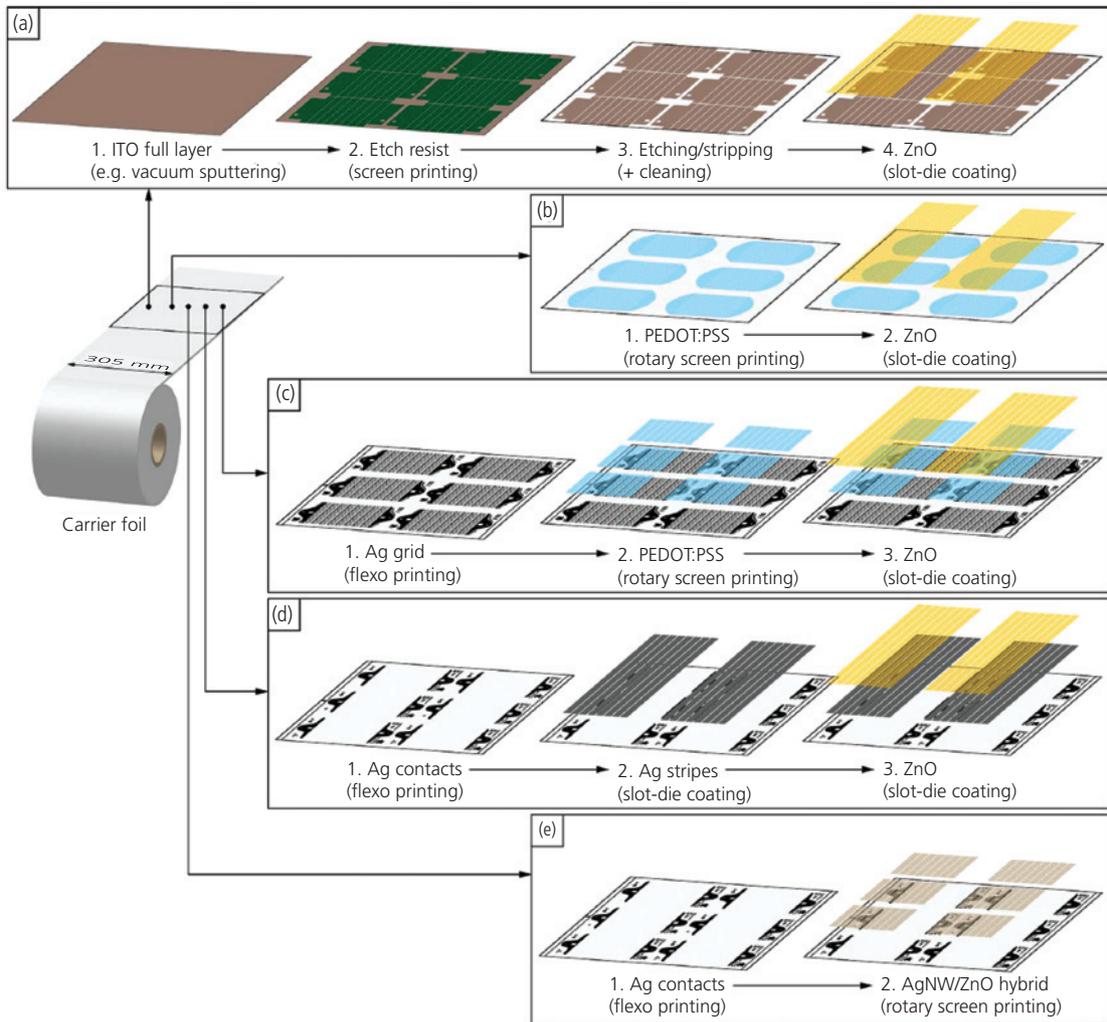

Large volume manufacturing that will ultimately make OPVs a viable technology has been extensively explored for solution-processed materials. Rapid module production is achieved by continuous R2R thin film deposition on flexible plastic (generally PEN or PET) substrates. Several solution-based R2R deposition methods have already been discussed in Chapter 5, and are reviewed elsewhere (Krebs, 2009). Patterning of the electrode on the substrate is the most

**Figure 7.243** (a) Experimental (circles) and calculated (solid lines)  $I$ - $V$  characteristics of a discrete,  $1\text{ cm}^2$  tandem OPV on the module (black), a column of 5 cells connected in series (light blue), and the entire module (dark blue) under 1 sun illumination. Inset: Photo of the OPV module. (b) Efficiency distribution of discrete OPV cells across the module (Xiao et al., 2015).

challenging step, since the other layers including the organic and counter-electrodes are deposited over the full surface. The final step is encapsulation, which also must be done in the R2R environment to avoid slowing the rate of material output. Indeed, continuous deployment of reels of substrate material requires that all layer depositions and patterns, independent of material or film thickness, must occur at the same rate, again to avoid slowing or intermittently halting the fabrication process.

Several example electrode patterning processes are shown schematically in Fig. 7.244. Transparent electrode processes are provided in Fig. 7.244a–c, and opaque substrates used for devices with transparent top contacts are in Fig. 7.244d and e. The layers are applied in ambient on a continuous, 305 mm wide PET web. The most common anode is ITO, which is also the most difficult to pattern. The substrate in Fig. 7.244a is supplied with a full surface

**Figure 7.244** Several processes for patterning either (a–c) transparent or (d, e) opaque reflective electrodes. The demonstrations of these methods are on a 305 mm wide PET web. Details of each process are provided in the text (Hösel et al., 2014).

coating of sputter-deposited ITO. Screen printing is used to apply an etch resist, which is stripped by wet chemical or dry processing, and then the remaining resist is removed, also via plasma processing. The ZnO cathode layer is applied from solution via slot-die coating. This, and other coating and patterning methods are described in Section 5.6. A simpler process employs only two layers (Fig. 7.244b). Here, PEDOT:PSS is applied via rotary screen printing, which comprises a cylinder with a screen whose pattern matches that to be transferred. The solution is continuously pushed through the screen with a squeegee, after which the film is dried. Again, the ZnO is applied by slot-die coating, with the pattern slightly offset from the underlying PEDOT:PSS to allow for contact to this layer. Figure 7.244c shows the

patterning of a Ag NP grid cathode. It begins by flexo-printing of the Ag NP or Ag nanowire solution. Flexo-printing employs a soft stamp whose raised areas define the pattern. Ink, in this case the Ag NP solution, is continuously applied to the stamp roller, and is transferred to the substrate as it is rolled through (Krebs, 2009). Then the PEDOT:PSS and ZnO layers are added as before.

Reflective substrate coatings start, as shown in Fig. 7.244d by application of Ag contacts on the edge of the sheet using flexo-printed Ag NPs. The cathode stripes are subsequently patterned using slot-die coating, and completed by a layer of ZnO. A simplified version of this process replaces the Ag stripes with a composite solution of Ag nanowires (NW), plus ZnO using rotary screen printing.

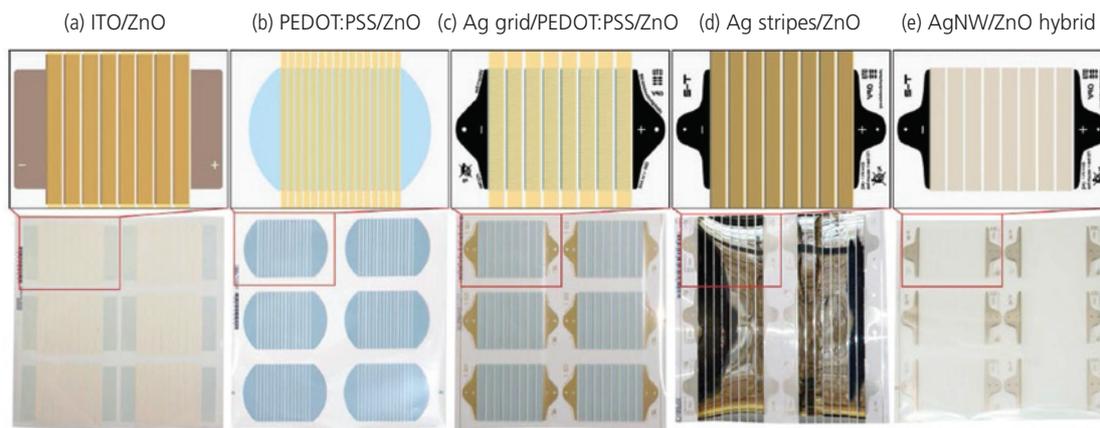

A further method of patterning that can be integrated into the R2R system is *laser scribing*. *Laser thermal ablation* can selectively remove layers at several stages of the fabrication sequence, depending on the layer absorption spectrum and the laser wavelength. This process can result in cuts only a few microns wide, potentially achieving  $GFF > 98\%$ . Laser ablation has been used to make small (3–10 devices) modules with a 500 kHz train of 350 fs pulses at peak energies of 16  $\mu\text{J}$  and 6.4  $\mu\text{J}$  at the fundamental wavelength of 1040 nm and the first harmonic at 520 nm, respectively. The two wavelengths are selectively absorbed within different layers of the structure. It is estimated that the laser can produce modules at a rate of 1 m/s in a volume manufacturing facility (Li et al., 2014).

Photographs of the results of each of the printing processes in Fig. 7.244 are shown in Fig. 7.245. There are six modules on each 12"  $\times$  12" sheet. Solution-processed R2R coating proceeds at rates that vary from  $< 1$  m/min to up to 100 m/min. The layer thickness control and patterning resolution tend to decline as the translation speed is brought into the upper range. As noted previously, the printing processes must be capable of dispensing adequate amounts of materials at the requisite web translation speed, and the equipment must be kept free of excess material accumulation and clogging during the manufacturing cycle. The rate of cell fabrication is limited by the slowest step in the continuous chain.

A compilation of performance of single devices and modules fabricated by the methods in Fig. 7.244 is provided in Table 7.31. The devices employ various transparent conductive electrodes and donor polymers. The active regions are BHJ blend

films with PC<sub>61</sub>BM as the acceptor. The performance of both the single cells produced on a laboratory scale "mini-roll coater", as well as the larger modules fabricated on the 305 mm system fall short of similar devices produced by batch mode processing. There are many reasons for the drop in efficiency, many of which have already been touched on. The increased contact resistance, loss of active area between cells, compromises made in choice of printable electrode materials and substrates, all conspire to decrease solar cell performance. Additionally, the R2R process proceeds in ambient. A consistent finding for all semiconductor devices, not just organics, is that ultrahigh purity source materials and an absence of contamination in the processing environment are essential ingredients for achieving high performance and long-term device stability. Exposing active materials to the atmosphere, which in itself is a poorly defined environment that changes from day to day, initiates the photooxidation process before the devices are encapsulated. The substrates, too, need to be baked out prior to use to eliminate moisture and other contamination that can outgas into the encapsulated device. Ultimately, this demand for high purity and avoidance of environmental contamination must be included at all stages of device fabrication up to, and including encapsulation.

There is considerably less information available for R2R processes based on vapor deposition of small molecules. There are a handful industry reports of production of OPVs by multiple, interconnected vacuum deposition chambers in a single R2R system. Active area efficiencies of 7.7% over areas of approximately 4600 cm<sup>2</sup> have been reported with a  $GFF = 66\%$  (Uhrich et al., 2017).

**Figure 7.245** Images of 12"  $\times$  12" motifs (bottom row) and details of modules on the motifs (top row) produced in ambient using the processes in Fig. 7.244 (Hösel et al., 2014).

**Table 7.31** Performance of OPV cells and modules fabricated by R2R processing in ambient based on patterned electrode and donor polymer compositions. Each device employs a PC<sub>61</sub>BM acceptor (Hösel et al., 2014)

Single cells, mini-rollcoater processed

An adaptation of R2R deposition is the integration of two different vapor deposition technologies into a single, laboratory system. The system combines high vacuum thermal evaporation with organic vapor phase deposition. This takes advantage of the versatility of VTE to grow complex layer systems, and the morphological control and very high deposition rates suitable for mass production using OVPD. A schematic illustration of the integrated system is shown in Fig. 7.246.

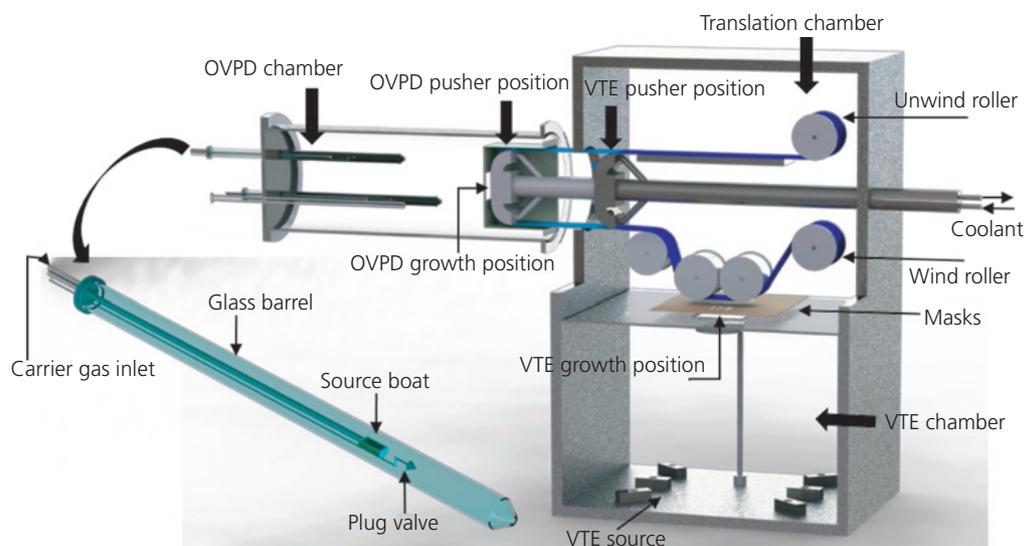

The system connects the VTE and OVPD systems via a translation chamber comprising a series of rollers that transports a 75 mm-wide flexible, tempered steel web. The use of steel eliminates problems of registration due to stretching, warping and heating of thermally sensitive substrates such as PET. This allows for attachment of a polymer or thin glass substrate onto the web without concern for its thermal or mechanical properties, nor whether it might be damaged during translation. The web is held stationary, or translated at up to 2.5 cm/s speed during deposition in either growth chamber. An actively cooled pusher arm is extended to shift the web from the translation chamber that contains the roller mechanism, into the OVPD growth position. A continuous coolant flow within the arm maintains the substrate at low temperature while in the hot OVPD chamber. The OVPD chamber itself comprises a cylindrical quartz reactor enclosed in a horizontal furnace. Quartz barrels contain the source boats. The organic source materials are volatilized by the flow of hot inert (N<sub>2</sub>) gas that

carries the molecules downstream where they are adsorbed on the cooled web film.

During VTE growth, the gate valve between the OVPD chamber and the translation chamber is closed, and the VTE chamber is pumped to 10<sup>-7</sup> torr. Before OVPD operation, the gate valve is opened and the pressure throughout the tool is equalized to the OVPD base pressure of 10<sup>-2</sup> torr. Shadow masks at both the VTE and OVPD growth positions allow for contact and film patterning.

This system has demonstrated an rms film roughness of only 0.40 nm even at growth rates of approximately 16 Å/s at translation speeds of 1.7 cm/s. Both single junction and tandem OPVs have been grown in this system, requiring web translation between the VTE and OVPD chambers twice for the tandem cells. A comparison of several devices (both single and tandem junction) grown while stationary and while translating at 0.3 cm/s is provided in Table 7.32. There is no significant difference between devices grown by R2R with the PET substrate either translating during growth, or halted at the growth position before moving on to the next. Also, the device characteristics are comparable to those grown by conventional VTE. All devices, however, are somewhat inferior to those grown on glass substrates due to the lower sheet resistance of ITO on glass compared with PET.

While this is only an early demonstration of R2R growth using vapor deposited small molecules in an integrated system, it is encouraging that very

**Figure 7.246** Cross-section schematic of the roll-to-roll (R2R) system integrating VTE with OVPD. A magnified view of OVPD source barrel containing the organic source boat and plug valve is shown (Qu and Forrest, 2018).

**Table 7.32** Device performance of single and tandem junction OPVs fabricated by conventional VTE growth, and in the R2R system combining VTE and OVPD (Qu and Forrest, 2018)

Substrate	Dep.	No. of junctions	Trans. speed (mm/s)	$j_{sc}$ (mA/cm <sup>2</sup> )	$V_{oc}$ (V)	FF	$\eta_p$ (%)
Glass	VTE	1	0	15.1	0.92	0.70	9.7
PET	VTE	1	0	14.7	0.92	0.65	8.8
PET	R2R	1	0	14.5	0.92	0.65	8.6
PET	R2R	1	3	14.4	0.92	0.64	8.5
PET	R2R	2	0	8.6	1.77	0.58	8.9

different growth processes can be integrated in a single deposition tool. Combining solution and vacuum deposition in a continuous web-based growth line provides additional opportunities to realize high efficiency devices that are hybrid combinations of several different processes (Griffith et al., 2016). Indeed, we have seen that the combination of solution and vapor processed subcells in a tandem architecture can lead to high fabrication yields and efficiencies (Che et al., 2018b). Thus far, however, hybrid solution and vapor-grown systems have not enabled the continuous throughput of substrates as has been done in fully solution or vapor deposition R2R systems. It is possible to extend the laboratory system in Fig. 7.246 into a continuous process (as opposed to one where the substrate moves back and forth between growth chambers). Further, it is feasible to integrate high vacuum and solution-processed deposition systems using differentially pumped plenum chambers between system modules operating at different pressures. However,

significant challenges related to device performance, encapsulation and contact resistance must first be overcome before large volume manufacturing of OPVs via R2R technologies becomes practical.

## 7.10 Summing up

In this chapter, we have shown that organic thin film materials are ideally suited for high performance optical detection in applications requiring flexibility, light weight, and low cost. Intense and narrow exciton spectra enable thin organic active regions that only absorb in selected wavelength bands. This is distinct from the behavior of inorganic semiconductors whose broad energy bands absorb from the band edge, deep into the shorter wavelength spectral regions. The narrow absorption spectra of organics opens up new possibilities for use of OPDs as wavelength selective sensors designed to capture only those regions of the spectrum needed for a

given application, while otherwise being transparent. OPDs have other characteristics that are superior to their inorganic counterparts. Their thin active regions lead to short charge transit times that allow for very high bandwidth, high quantum efficiency operation. And the ability to deposit films on a variety of flexible, large area substrates makes them useful as position sensors. The range of applications that can benefit from the unique attributes of OPDs is limitless.

While OPDs have these distinctive features, a preponderance of effort in exploiting the optical detection properties of organics has focused on their use as solar cells. Their selective absorption spectra makes them attractive for application to power-generating windows that are semitransparent in the visible, yet absorb strongly in the UV and NIR. Thus, high efficiency coupled to semitransparency, long lifetime, flexibility and low cost on large substrates has driven intense worldwide interest in OPVs as a potentially important contributor to solving humankind's clean energy supply crisis. Of no less importance is the environmental sustainability of OPVs. The materials used in the cells and modules are often recyclable, and do not present undue toxic hazards that are frequently drawbacks of other solar technologies. Use of toxic materials in solar panels creates a disposal challenge at the end of their useful life; concerns that are largely absent in OPVs. The very low temperatures used in OPV fabrication compared to those required for thin film inorganic semiconductor processes coupled with the relatively low cost of source materials, suggests that OPVs will eventually be cost competitive with Si (Mulligan et al., 2015, Gambhir et al., 2016).

The efficiencies of OPVs are also fast becoming competitive with far more mature solar cell technologies, and their long-term stability also appears to be reaching toward the 10–20 year benchmark required for low cost solar energy generation. All of these features suggest that there is indeed a very promising future for OPVs. To date, however, this promise has not been realized. The fabrication of solar cell modules based on either solution or vapor deposited materials has yet to yield performance that is near to that obtained on the laboratory bench. This is due to the many compromises that are made in the choice of materials, processes, and encapsulants when moving to large volume manufacturing. Many years of research and development still need to be invested to completely overcome these hurdles. Moreover, this is not the type of research that can be done in small laboratories. It will

take significant investment by industry and/or governments to resolve many of the most challenging manufacturing issues. The investments needed are of a scale similar to those made in moving OLEDs from laboratory curiosities into today's massive organic global display market. The outstanding, differentiating attributes of OPVs makes these investments almost inevitable. We just do not know when.

Finally, and perhaps most important of all, is that research on OPVs and OPDs has revealed the richness of the phenomena involved in photo-induced charge generation in disordered media. The multistep process that starts with the absorption of a photon to generate an exciton, followed by its diffusion to an energy discontinuity at the donor–acceptor HJ, leading to efficient charge transfer, and finally the generation of a free PP have been a subject of deep fascination since long before the first efficient bilayer OPV was demonstrated. The linkages found between the physical processes of optical absorption, energy transport and charge generation with materials composition and thin film morphologies, have impacts on our understanding of disordered solids that go far beyond their particular applications in photodetection. Indeed, many of the insights developed in understanding light generation in OLEDs have furthered our understanding of the complementary process of light detection in organic detectors. It is this foundation of knowledge that will ultimately open doors to devices and applications that have yet to be imagined. Thus, for practical and fundamental reasons alike, the pursuit of high efficiency OPDs and OPVs has created a watershed of knowledge that will continue to grow in the years ahead, all the while bringing this exciting technology closer to a transformative new generation of devices that will help to provide abundant, clean energy to fill humankind's ever increasing demands.

## Problems

1. In Section 7.1 we showed that photogeneration in an excitonic photoconductor results in a charge density given by Eq. 7.20, viz.:

$$n_{ph} = \frac{j_{rec}}{k_{rec}D} \left\{ 1 - \frac{2dq n_i}{D} (1 - \eta_{IQE}) - \left[ \left( 1 - \frac{2dq n_i}{D} (1 - \eta_{IQE}) \right)^2 + 4q \eta_{IQE} \frac{j_X}{j_{rec}} \right]^{\frac{1}{2}} \right\}$$

- (a) Derive this expression.
- (b) Derive an expression for  $n_{ph}$  in a doped semiconductor with  $n_0 > p_0$  and  $\mu_e \approx \mu_p$ .
- (p) Plot  $n_{ph}$  vs.  $D$  and for  $n_0/p_0$  from 1 to  $10^5$ .
2. The expressions such as in Problem 1 are for the charge density in steady state.
- (a) Set up the time dependent rate equations for  $n_{ph}(t)$  assuming that the illumination is a harmonic function at frequency  $\omega$ . Assume that the semiconductor is intrinsic.
- (b) What is the characteristic time constant for the return to equilibrium of the photoconductor for a step function optical pulse that terminates abruptly at  $t = 0$ ? Plot the decay transient. What variables is it most sensitive to?
- (c) What is the gain-bandwidth product of the photoconductor in (a) and (b)?
3. The expressions for noise in photoconductors in Section 7.1.1 assume a single charge carrier (electrons) and deep traps that act as recombination centers. Derive expressions for the shot and Johnson noise for two cases:
- (a) The electron and hole mobilities are equal.
- (b) The traps are shallow, that is, they reside close to a frontier energy level, at or just below the Fermi energy.
4. For a symmetric heterojunction, that is, where the trap density of states ( $H_{TA}$ ,  $H_{TD}$  with characteristic trap temperatures of  $T_{tA}$ ,  $T_{tD}$ ) are equal on each side of the junction,
- (a) Derive the ideal diode equation for a symmetric heterojunction, including an expression for the saturation current,  $j_{sym0}$ , assuming that the HOMO and LUMO densities of states are equal to  $N_S$ .

- (b) Show that the open circuit voltage for the symmetric junction is given by

$$qV_{OC} = \Delta E_{HL} - n_S k_B T \ln \left[ \left( \frac{k_{rec} k_{PPr}}{k_{PPd} + k_{PPr}} \right) \frac{q a_0 N_S^2}{j_{ph}} \right]$$

5. The transfer matrix method in Section 7.1.4 was developed for light incident normal to the substrate.
- (a) Derive the scattering and phase matrices,  $I_{jk}$  and  $L_j$ , respectively, for light incident at an angle,  $\theta$ , from normal.
- (b) Plot the total light absorbed in a layer of thickness 10 nm sandwiched between an Al contact and a 0.1 mm thick glass substrate as a function of angle,  $\theta$ . The layer has  $\tilde{n} = 1.7 + i1.0$  at the wavelength of  $\lambda = 500$  nm.
6. Derive the generalized transfer matrices  $I_{jk}$  and  $L_j$  for:
- (a) Layers with an rms surface roughness,  $\sigma$ .
- (b) Layers with an rms index inhomogeneity,  $\Delta n$ .
- (c) Layers with both surface roughness and index inhomogeneities as in (a) and (b).
7. Plot the first, second, and third order transitions vs. diameter for quantum dots in air composed of:
- (a) InP
- (b) InAs
- (c) In Fig. 7.52, verify that the three peaks correspond to the 1S–1S, 1P–1P, and 1D–1D transitions for a spherical PbSe dot of diameter  $2\rho = 6.5$  nm. The effective masses of electrons and holes in PbSe are approximately  $m_e^* = 0.12m_0$  and  $m_h^* = 0.07m_0$ , respectively. (See Fig. 7.50 for the definition of the transitions.)
8. By integrating over the relevant half space, show that the étendue is given by  $f_\omega = \pi \sin^2 \theta_{sum}$ .
9. Calculate the approximate spectral mismatch factor for the OPV in Fig. 7.79a (denoted  $S_T$ ) using:
- (a) A Si detector with a KG3 filter (see Fig. 7.81).
- (b) A Si detector with a KG5 filter.
- (c) Assuming that the device has  $j_{SC} = 15$  mA/cm<sup>2</sup>,  $FF = 0.72$ , and  $V_{OC} = 0.92$  V at SRC measured under a solar simulator whose spectrum is given in Fig. 7.79b using a KG3 filter, what is its power conversion efficiency?
- (d) For the device in (c), what is its peak external quantum efficiency and responsivity?
10. The  $j$ - $V$  characteristics of inorganic and organic junctions are governed by two different equations; the Shockley equation for the former and the excitonic ideal diode equation for the latter. The power conversion efficiency of a photodiode operated in the photovoltaic mode is proportional to the fill factor,  $FF = \frac{V_M I_M}{V_{OC} I_{SC}}$ , where  $V_M$  and  $I_M$  are the voltage and current at the maximum power point, and  $V_{OC}$  and  $I_{SC}$  are the open circuit voltage and short circuit current taken from the  $j$ - $V$  data in the fourth quadrant. Assume a saturation current density of  $j_{sat}$ .
- (a) Write an approximate expression for the maximum fill factor expected for a Shockley diode as a function of ideality factor,  $n$ .

- (b) Plot the maximum  $FF$  vs.  $n$  over the domain  $n = [1,3]$ .
- (c) As in part b, for an excitonic diode over  $n = [1,4]$ , assume that the polaron pair dissociation efficiency is approximately given by Frenkel-Poole emission.

That is,  $k_{ppd} = K \text{Fexp}\left(\frac{\sqrt{q^3 F / \pi \epsilon}}{k_B T}\right)$ . Here,  $K$  is a

constant, and the electric field is given by  $F = |V - V_{bi}| / d$ , where  $V_{bi}$  is the built-in potential and  $d$  is the total HJ layer thickness. Which device (organic or inorganic) has a higher  $FF$  and thus power conversion efficiency? For simplicity, assume only one type of charge trap exists in the non-ideal ( $n > 1$ ) case.

11. Rewrite Problem 10a for:
  - (a) A device with series resistance,  $R_{ser}$ .
  - (b) Now recalculate  $FF$  vs.  $R_{ser}$  for  $n = 2$ .
  - (c) What is the difference in shape of the reverse  $j$ - $V$  characteristics of an excitonic HJ assuming Onsager-Braun or Frenkel-Poole emission theory for  $k_{ppd}$ . Be quantitative (i.e. calculate these curves and plot on a normalized scale of  $j/j_0$  over a voltage domain of 0 to  $-5$  V). Consider both the voltage and temperature dependences.
12. In Section 7.3.1, we considered the effects of series and shunt resistance on solar cell efficiency. Starting with the ideal diode equation of excitonic junctions,
  - (a) Derive an expression for  $V_M$  in Eq. 7.126, including the effects of  $R_{ser}$  and  $R_{shunt}$ .
  - (b) Plot in the  $j$ - $V$  characteristics in the limit of  $R_{ser} = 0$  and  $R_{shunt} = \infty$  in the 4th quadrant for  $k_{ppd}/k_{ppr} = 10$  and 100, with  $n_s = 1.5$  and  $V_{OC} = 1$  V, and  $j_{SC}/j_0 = 10^2$  and  $10^4$  with  $j_{SC} = 10$  mA/cm<sup>2</sup>. How do these differ from the curves in Fig. 7.71?
  - (c) Derive the expression for  $FF$  in Eq. 7.131.
13. A D-A heterojunction detector has  $\Delta E_{FL} = 0.3$  eV. Assuming equal masses for electrons and holes, and a density of states of  $N = 10^{21}$  cm<sup>-3</sup> eV<sup>-1</sup> for both the donor and acceptor, for a device whose characteristics are dominated by generation and recombination in the dark:
  - (a) Plot the fourth quadrant  $j$ - $V$  characteristics of the OPV in the dark and under 1 sun illumination assuming a uniform  $\eta_{ext} = 70\%$  from  $\lambda = 400$  nm to 1  $\mu$ m, and  $\eta_{ext} = 0$  elsewhere. Assume the work functions of the cathode and anode contacts are equal.
  - (b) Now assume that there is a second internal junction within the device whose polarity is opposite to the first junction (perhaps due to a second HJ, or a poor contact). Assuming the saturation current of this second junction is  $j_{02} = 0.1j_{01}$ , where  $j_{0(1,2)}$  are the saturation currents of the respective junctions, plot the  $j$ - $V$  characteristics under the same illumination conditions as in (a).

14. Figure 7.100 suggests that the  $j$ - $V$  characteristics of a double junction formed by a multistep cascade have an "S" shaped appearance that can be modeled as two back-to-back diodes.
  - (a) Draw the full equivalent circuit of the double junction, assuming that one junction has saturation

current,  $j_{01}$  and the other has current  $j_{02}$ . Each has a shunt resistance,  $R_{shunt1}$  and  $R_{shunt2}$  and the internal resistance of the layer connecting the two junctions is  $R_{ser}$ . Make sure you include an element for the photocurrent,  $j_{ph}$ .

- (b) Show that the  $j$ - $V$  characteristics are given by:

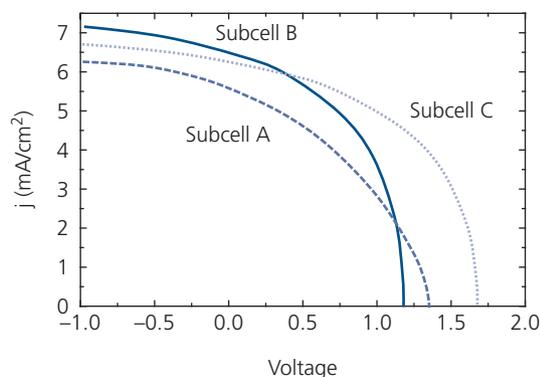

$$j = j_{01}[\exp(qV_1/n_1k_B T) - 1] + \frac{V_1}{R_{shunt1}} - j_{ph} \\ = -j_{02}[\exp(qV_2/n_2k_B T) - 1] + \frac{V_2}{R_{shunt2}}.$$

For this expression, we assume that  $V_a = V_1 + V_2 + jR_{ser}$ , and that only junction 1 generates photocurrent. Here, subscripts 1 and 2 refer to the different junctions.

- (c) In the special case where  $jR_{shunt2} \gg V_2$ , show that:

$$j = j_{01} \left[ \left( 1 - \frac{j}{j_{02}} \right)^{n_2/n_1} \exp(qV_a/n_1k_B T) - 1 \right] \\ + \frac{V_1}{R_{shunt1}} + \frac{n_2k_B T}{qR_{shunt1}} \ln \left( 1 - \frac{j}{j_{02}} \right) - j_{ph}$$

- (d) Letting  $R_{shunt1} \rightarrow \infty$  plot the  $j$ - $V$  characteristics over the domain  $V = (-1,1)$  V of a device with  $j_{01} = 10$   $\mu$ A/cm<sup>2</sup>,  $j_{02} = 0.1$  mA/cm<sup>2</sup>,  $j_{ph} = 5$  mA/cm<sup>2</sup>, and  $n_1 = n_2 = 2$ . Does it show an "S" like characteristic? Why or why not?
15. Consider a series-connected multijunction OPV with three different absorbing cells with Gaussian absorption profiles centered at 500 nm, 750 nm, and 900 nm. The charge recombination zone is both electrically and optically lossless, and the saturation current is  $10^{-6}$  A/cm<sup>2</sup> for each subcell. Assuming that the peak external quantum efficiencies are 65%, 80%, and 90% with FWHMs of 50 nm, 100 nm, and 125 nm, respectively, then calculate:
    - (a) The efficiency of the triple junction cell assuming that the optical fields are centered within the appropriate subcell, assuming  $FF = 70\%$  and  $E_{loss} = 0.5$  eV for each subcell.
    - (b) From front to back, what is the optimal position for each cell?
    - (c) What is the optimal thickness of each subcell to maximize light absorption? For this, assume that each device is a mixed or bulk heterojunction structure.
  16. In Fig.P7.16 are shown the fourth quadrant  $j$ - $V$  characteristics under 1 sun, AM1.5G illumination of three subcells used in a multijunction cell.
    - (a) Make a table that lists the  $j_{SC}$ ,  $V_{OC}$ ,  $FF$ ,  $j_M$ ,  $V_M$ , and  $P_M$  of each cell.
    - (b) Consider a tandem cell comprised of Subcells A and B. Construct the  $j$ - $V$  characteristics of the tandem and put its  $j_{SC}$ ,  $V_{OC}$ ,  $FF$ ,  $j_M$ ,  $V_M$ , and  $P_M$  data in your table. Also list the power penalty,  $\Delta\eta_P$  for the tandem. Which cell limits the performance?
    - (c) Repeat (b) for a triple junction cell comprised of subcells A, B, and C.

**Figure P7.16** The  $j$ - $V$  characteristics of three subcells used in multijunction OPVs.

17. Singlet fission results in the generation of three possible correlated triplet pair states,  $^1(TT)$ ,  $^3(TT)$ , and  $^5(TT)$ .
- Using bracket notation, write down the spin wavefunctions for the 9 possible triplet pair states. Clearly define the meaning of all of the notations used.
  - Derive Eqs. 7.202 and 7.203 for the change in photocurrent and fission efficiency as functions of magnetic field.
  - Plot the functions in (b) vs. magnetic field, from  $B = 0$  to the saturation field (i.e. where  $\delta$  and  $\eta$  become approximately independent of  $B$ ).

*"God made the bulk; the surface was invented by the devil."*

**Wolfgang Pauli, Nobel Laureate in Physics**

Organic materials are excitonic materials. In this regard, they would seem to be ideally suited for optoelectronic devices, such as OLEDs, OPVs, and photodetectors. But what about their uses as purely electronic materials? Specifically, do organics hold promise as a platform for thin film transistors useful solely for electronic applications? In this chapter we address just this question.

As the epigram to this chapter implies, organic thin film transistors (OTFTs) differ from the other devices that we have considered in that they are controlled by the surface, rather than the film bulk. By this we mean that the charge flows between source and drain contacts along the organic semiconductor/dielectric interface. From many decades of engineering of conventional semiconductors, it is indisputable that surface physics, and particularly surface charge transport is far more complex than analogous phenomena in the bulk. The complications are inherent in the 2D nature of interfaces, introducing defects and lattice reconstruction that occurs at surfaces. Hence, the understanding and optimization of OTFTs necessarily implies that we examine the complex microscopic properties of organic semiconductor/gate insulator interfaces.

The chapter opens by introducing basic transistor architectures and the theory of their operation. This discussion relies on the understanding of charge transport in organics that was developed in Chapter 4, and is now extended to consider interface transport. Next, we elucidate all of the many forms that OTFTs take, since the positions of the gate, source and drain contacts relative to each other and to the films on which they are deposited determine the device attributes. Also, we take this opportunity to discuss several different variants, such as split and dual gate OTFTs, and a different type of transistor altogether: the vertical transistor that is analogous to a vacuum tube triode. Unlike the OTFT, vertical transistor properties depend on the film bulk rather than its surface, making it more akin to the devices in the previous two chapters.

Our discussion of transistor operating principles and architectures is followed by consideration of the phototransistor. While this hybrid between a transistor and a photodetector can exhibit optical responsivity considerably greater than a photodiode owing to its inherent gain, enhanced photosensitivity comes at the expense of a smaller bandwidth of operation and a somewhat more complex structure. However, its ability to be integrated into circuits with increased functionality beyond that of a simple photodetector can make it attractive for specialized applications where bandwidth is not a dominant concern. The treatment of phototransistors necessarily draws heavily on discussions and definitions used in understanding photodetectors. Hence, the reader is referred to Chapter 7 to fully appreciate the phototransistor discussion presented here.

The performance of organic transistors, like all electronic devices, depends almost entirely on the materials used. The OTFTs are operated with few exceptions in the accumulation mode, whereby charges are drawn

into the channel by the potentials determined by the gate and drain voltages. The carrier type can be either electrons or holes, depending on the metal/channel work functions, and which carrier type has the highest mobility. We find that nearly equal performance has been obtained for n- and p-channel devices, and indeed ambipolar transistors supporting both carrier types have been demonstrated and employed in high performance circuits. We will discuss the introduction of materials with high mobilities and low voltages that have been employed in complementary logic circuits and oscillators, and that operate in the kilohertz to megahertz regimes with acceptable noise margins.

No discussion of devices is complete without considering stability, that is, the ability of the OTFTs to maintain high performance over long periods of operation, in adverse environments and under stressful conditions. Many of the electrical characteristics of OTFTs, such as threshold voltage, drain current, field effect mobility, and output conductance, drift over time. In most cases, exposure of the gate insulator, the channel, and the insulator/channel interface to a humid environment is responsible for many, but not all, of the device instabilities. Encapsulation can delay, but not completely eliminate water from entering the device active regions, hence providing only a limited degree of device stability over time.

We close out our discussion of OTFTs with a description of a few of the impressive applications and circuits that have been demonstrated. In the relatively short time since their introduction, the performance of OTFTs has surpassed even that of amorphous Si devices in terms of mobility, stability, and operating voltage. However, to be adopted in practical applications, we must clearly define the competitive advantage that OTFTs offer over conventional thin film solutions such as amorphous or polycrystalline Si, or metal oxide transistors. Without such clarity of purpose, OTFTs simply become yet another “technological solution looking for a problem!” In this context, OTFTs have a considerable potential to occupy new application spaces that are inaccessible to incumbent inorganic transistor solutions as a result of their ability to be fabricated on ultrathin ( $\sim 1 \mu\text{m}$ ) substrates over very large areas by volume, roll-to-roll (R2R) fabrication processes. In our discussion, we therefore focus on applications that require large area circuits such as for tactile, gas and optical sensing, and for the emerging area of imperceptible, biocompatible devices for medical diagnostics, entertainment, and robotics. In spite of this promise, we must keep in mind that OTFTs have yet to be adopted on any significant scale by the electronics manufacturing industry; a situation different from that experienced by OLEDs, and to a much lesser extent by organic solar cells.

Ultimately, the widespread adoption of organic transistor technology remains uncertain. This is not a question that can or should be answered in this book: that is left to the marketplace and the consumer to decide. Independent of that question, however, there is little doubt that research and engineering of OTFTs has led to a deeper understanding of charge transport in organics, and to the development of highly sophisticated small molecule and polymer conductive media. This in itself has led to improvements in optoelectronic devices such as OLEDs and OPVs that rely on highly conductive charge transport layers to achieve high performance.

For the ensuing discussions, we assume that the reader has at least a passing acquaintance with the basics of transistor design and operation. There are many excellent texts available that can provide that background knowledge, as well as affording a deeper appreciation for this very broad topic than can be presented here. Some of these references are found in *Further reading*.

## 8.1 Thin film transistor basics

The organic thin film transistor (OTFT) is a *metal–insulator–semiconductor field effect transistor*, or MISFET, whose basic configuration is shown in Fig. 8.1. It is a three terminal device comprising a source (S) and a drain (D) contact made to a thin film semiconducting channel. An insulating layer (the gate insulator) is in contact with at least one surface of the semiconductor. The gate contact (G) is located on the opposite side of

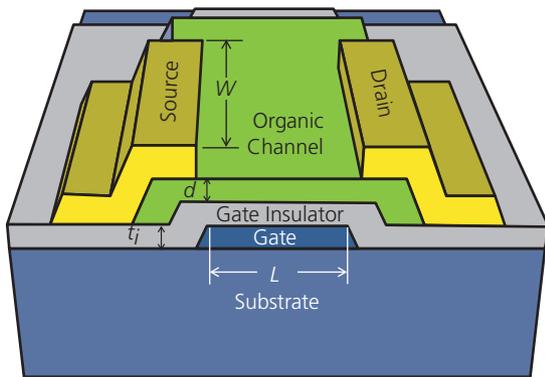

the insulator, bridging the gap between S and D. Figure 8.1 also defines several important geometric factors: the gate width ( $W$ ) is typically much larger than its length ( $L$ ). The channel thickness is  $d$ , and the insulator thickness is  $t_i$ . Charge is introduced into the channel by injection from the source contact due to a potential difference from the source to the gate,  $V_{GS}$ . Then conduction in the channel occurs by applying a voltage between source and drain,  $V_{DS}$ . Since the

amount of charge injected into the channel depends on the gate voltage, the source-drain current,  $I_D$ , is modulated by the magnitude of  $V_{GS}$ . Thus, field effect transistors are essentially gate-controlled resistors.

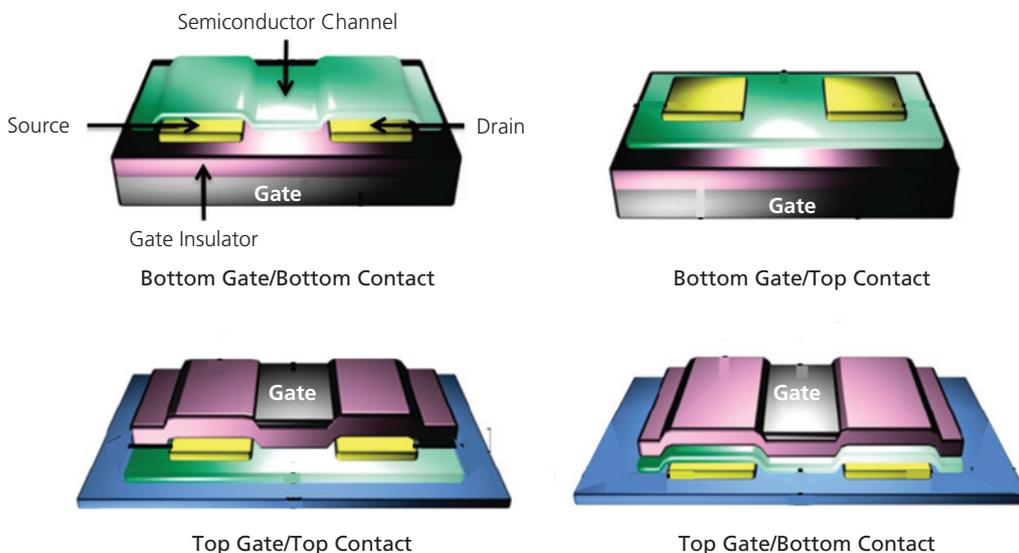

The sign of the charge that carries the drain current determines whether the OTFT is a p- or n-channel device. In most organics, the channel itself is undoped, although it may have a residual concentration of holes or electrons that determine the position of the Fermi energy at equilibrium (see Chapter 4). This is a different operating regime than for an inorganic MISFET where the channel region is doped n- or p-type, and hence the semiconductor bulk, or body, supplies the carriers at the insulator/semiconductor interface. For example, the high hole mobility in pentacene makes this material useful in p-channel OTFTs. A negative voltage at the

gate draws holes to the semiconductor/insulator interface, while a negative voltage at the drain leads to conduction within the channel. These are the same bias conditions used for an inorganic p-channel MISFET. The density of charge in the channel is largely unrelated to the background charge concentration. Indeed, in OTFTs it is important that the background charge concentration be very small such that, at  $V_{GS} = 0$  (corresponding to the transistor "off" state), the channel leakage is also very small. Hence, the OTFT operates in the charge *accumulation mode*. It is normally off, that is, in the absence of a negative gate voltage there is ideally no charge in the channel, and hence no current can flow from source to drain. A normally off transistor is known as an *enhancement mode* device.

The device pictured in Fig. 8.1 has a bottom gate-top source-drain contact configuration, or briefly, it is a *bottom-gate/top-contact* (BG/TC) transistor. However, as shown in Fig. 8.2, many other possible architectures realized by placing the gate and channel contacts on either the same or opposing sides of the channel semiconductor. The BG/TC transistor is possibly the easiest to fabricate, and hence is the most common architecture since it allows the S and D contacts to be deposited through a shadow mask. We have found in Chapter 4 that deposition of metals onto organics can damage the metal/organic interface, introducing traps that can lower the injection barrier, and hence the contact resistance. Another commonly employed architecture is the bottom gate/bottom contact (BG/BC) configuration. This

**Figure 8.1** Schematic perspective of an organic thin film transistor.

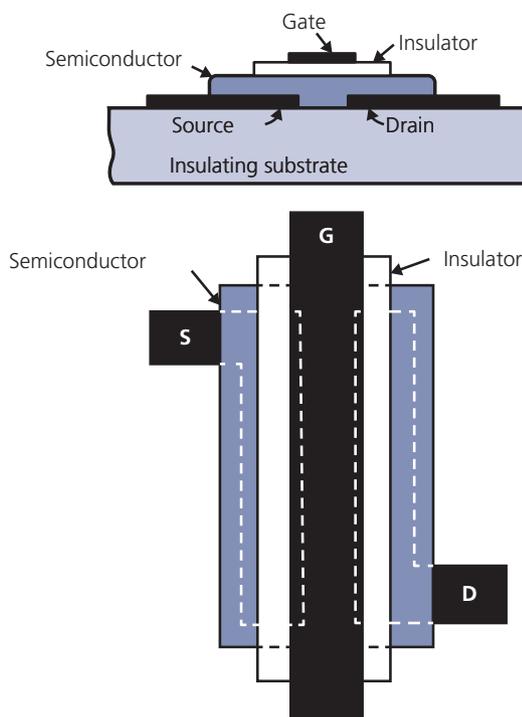

**Figure 8.2** Possible OTFT configurations. Clockwise from top left: bottom gate/bottom contact (BG/BC), BG/TC, TG/BC, and TG/TC.

places all contacts on the same surface of the semiconductor, which allows for photolithographic patterning to achieve very short gate geometries. The gate contact is accessed by extending it beyond and parallel to the source and drain contacts. The selection of a particular architecture is ultimately based on the choice of materials, the patterning method, and the demands placed by the circuit on its intended application (e.g. high current, high bandwidth, low noise, etc.).

## 8.2 A brief history of OTFTs

We begin our tour through the history of OTFTs with the invention of the field effect transistor itself. This can be traced to a patent by Lilienfeld who proposed, but did not demonstrate a “device for controlling electric current” employing CuS as the channel material, and  $\text{Al}_2\text{O}_3$  as the gate insulator (Lilienfeld, 1933). The first realization of a thin film transistor grown on an insulating substrate employed a vapor deposited microcrystalline film of CdS as the semiconductor, Au as the gate electrode, and  $\text{SiO}$  as the gate insulator. This TG/BC structure was fabricated on a glass substrate. As shown in Fig. 8.3, it bears all of the attributes of modern OTFTs (Weimer, 1962).

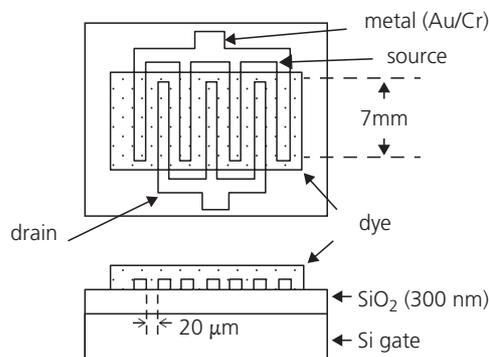

**Figure 8.3** Microcrystalline CdS TFT on a glass substrate in cross-sectional (top) and plan (bottom) views. Note how the gate contact overlaps the source and drain to minimize channel resistance (Weimer, 1962).

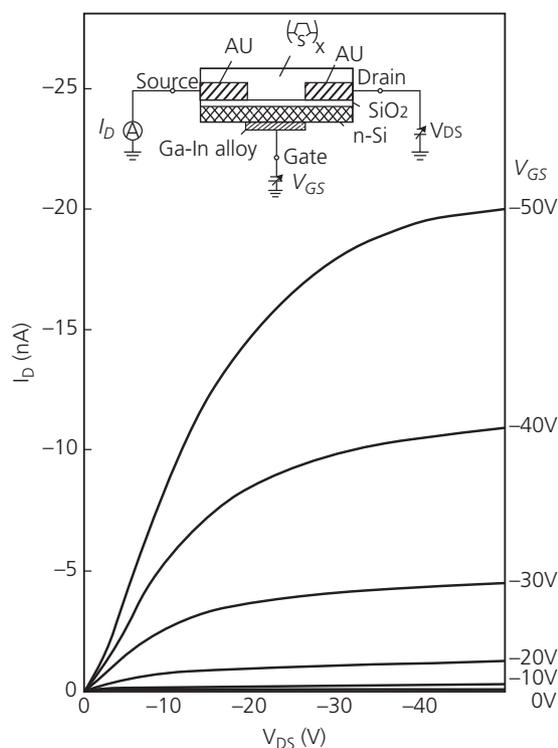

The door to OTFTs was opened by depositing a merocyanine channel on interdigitated S and D contacts patterned onto a 300 nm thick  $\text{SiO}_2$  gate insulator. This combination of materials used a 1  $\Omega$  cm p-Si substrate that served as the gate electrode. The BG/BC configuration is shown in Fig. 8.4 (Kudo et al., 1984). The device dimensions were  $L = 20 \mu\text{m}$ ,  $W = 7 \text{ mm}$ , and  $d = 40 \text{ nm}$ . The device did not enter the saturation regime, nor did the channel pinch off, even at +15 V, indicating excessive background conduction of the merocyanine dye. A small hole *field effect mobility* of  $\sim 10^{-5} \text{ cm}^2/\text{V s}$  was extracted from the device characteristics in the unsaturated, or linear regime. Hence, while this device has the elements of an OTFT, it did not show clear transistor operation.

Apparently, the first report of an OTFT that showed all of the characteristics of a functioning transistor exhibiting both linear and saturated drain current characteristics, used a conjugated polythiophene thin film channel in a BG/BC configuration (see Fig. 8.5) (Tsumura et al., 1986). The polythiophene film was deposited on a  $\text{SiO}_2$  gate insulator ( $t_i = 300 \text{ nm}$ ) on a 4–8  $\Omega$ -cm n-Si substrate gate contact. The film was electrochemically de-doped in solution to ensure a non-conducting channel in the “off” state. The enhancement mode OTFT had dimensions of  $L = 10 \mu\text{m}$ ,  $W = 2 \text{ mm}$ , and  $d = 140 \text{ nm}$ . The drain-current characteristics have three characteristics that are expected of all practical enhancement mode FETs: (i) a linear onset of  $I_D$  vs.  $V_{DS}$  extending up to  $V_{DS} \approx V_{GS}$ . (ii) At higher  $V_{DS}$ , the  $I_D$  becomes independent of  $V_{DS}$  as the transistor enters the saturation regime at pinch-off. (iii) The drain current,  $I_D \rightarrow 0$  as  $V_{GS} \rightarrow 0$ . A hole mobility of  $\sim 10^{-5} \text{ cm}^2/\text{V s}$  is inferred from analysis of these characteristics.

Within three years, a vacuum-deposited (vs. solution processed) small molecule thin film of  $\alpha$ -sexithiophene ( $\alpha$ -6T) OTFT was demonstrated (Horowitz et al.,

**Figure 8.4** Plan (top) and cross-sectional views of the merocyanine OTFT (Kudo et al., 1984).

**Figure 8.5** Polythiophene p-channel OTFT drain current characteristics showing linear and saturation regions of operation, as well as a negligible “off” current at  $V_{GS} = 0$  (Tsumura et al., 1988).

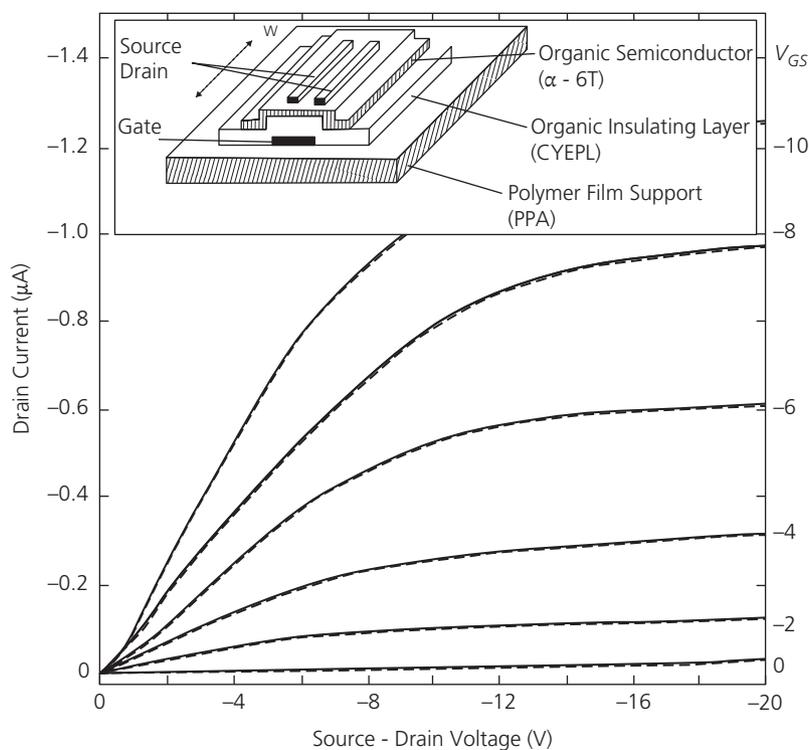

1989). The devices were in a BG/TC configuration, again using n-Si as the gate contact and substrate, and a 300 nm thick  $\text{SiO}_2$  gate oxide. The OTFT had dimensions of  $L = 90 \mu\text{m}$ ,  $W = 310 \mu\text{m}$ , and  $d = 70 \text{ nm}$ . The as-deposited films exhibited excessive channel conductivity, and hence required de-doping by heating in air for 3 h at  $120^\circ\text{C}$  after deposition. Following de-doping, the enhancement mode transistors exhibited a saturation-regime mobility of  $\sim 10^{-4} \text{ cm}^2/\text{V s}$ , which was the highest reported up to that time.

The next significant advance in OTFTs was made by replacing the Si gate coated with an  $\text{SiO}_2$  gate insulator by a metal electrode and an organic dielectric, cyanoethylpullulan (CYEPL) in the structure shown in Fig. 8.6, inset (Garnier et al., 1990). The BG/TC structure starts with a  $25 \mu\text{m}$  thick, flexible poly(parabanic acid) (PPA) substrate. A 1 mm wide by 20 mm long Au gate contact stripe is then vacuum deposited, followed by solution drop deposition of CYEPL. Depositing an  $\alpha$ -6T channel and Au S and D electrodes completed the  $L = 50 \mu\text{m}$ ,  $W = 5 \text{ mm}$ , and  $d = 50 \text{ nm}$  OTFT. This structure has several characteristics that distinguished it from previous work. A metal strip replaced the conducting substrate used previously as the gate contact. This allows for

applying different gate biases to different transistors integrated on the same substrate, which is required in almost all electronic circuit designs. Further, the use of a plastic substrate allows for bending and twisting without changing the device characteristics, as shown in Fig. 8.6. This takes advantage of the inherent flexibility of van der Waals bonded solids, arguably one of the most important characteristics of organic electronic devices. And finally, the high quality of the organic insulator/channel interface resulted in an unprecedented high hole field effect mobility of  $0.43 \text{ cm}^2/\text{V-s}$ . This represents at least a 100-fold improvement over previously demonstrated devices, and indeed made this OTFT competitive with amorphous Si thin film transistors then in use in LCD back-planes. The high mobility also leads to a low  $V_{GS} \sim 10 \text{ V}$  compared with previous devices where  $V_{GS} \sim 50 \text{ V}$  was common (cf. Fig. 8.5). This early, high performance OTFT considerably heightened interest in the technology, and subsequently led to its further rapid development.

As seen in Chapter 4, charge mobility in organics is strongly dependent on disorder. Dynamic disorder that arises from coupling of phonons to the molecular solid presents an intrinsic limitation to the bulk mobility of  $1\text{--}5 \text{ cm}^2/\text{V s}$  in molecular solids. Static disorder due to structural defects or impurities, however, has an exogenous origin, and can reduce the charge mobility even further. This led, in subsequent years to, finding deposition conditions and pure materials that generated more ordered thin films, and even single crystals to achieve high field effect mobilities. We will show below, however, that field effect mobilities obtained in single crystal OTFTs are not significantly higher than in polycrystalline organic transistors. While single crystal OTFTs have been helpful in understanding the limits to performance of organic electronic devices, practical devices must be manufactured over large substrate areas using conventional thin film deposition from the solution or vapor phases.

The introduction of pentacene, which readily forms crystalline regions under a wide range of deposition conditions, has led to significant increases in field effect mobilities in OTFTs (Lin et al., 1997a). Indeed, a dependence of mobility and transistor on-off current ratio (i.e. the ratio of the drain current in the transistor “on” state in saturation to the “off” state where no charge is accumulated under the gate, see Section 8.3.2) is directly traced to both pentacene nanomorphology and the purity of the source material. When deposited onto a substrate at elevated temperatures ( $60\text{--}120^\circ\text{C}$ ), pentacene molecules tend

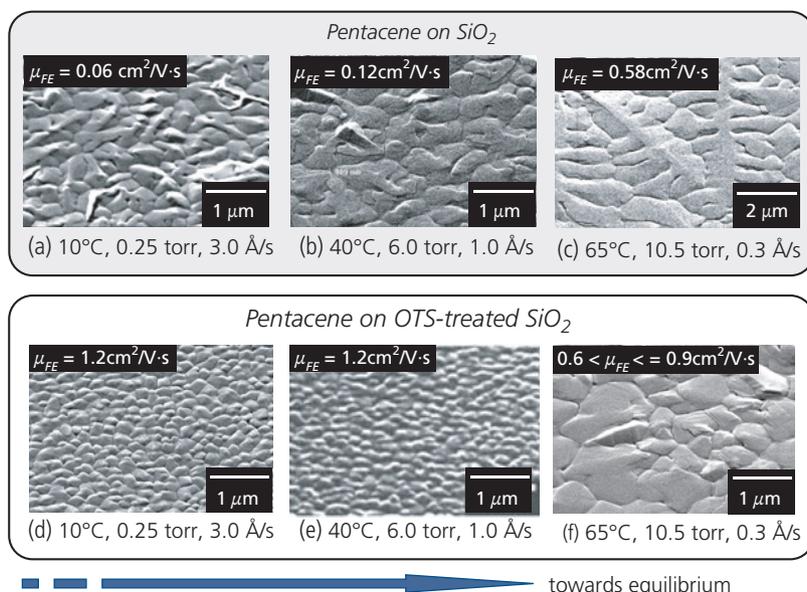

**Figure 8.6** Drain current characteristics of a BG/TC OTFT obtained in air. The solid lines are for an as-fabricated device, and the dashed lines are the transfer characteristics after bending and twisting of the device on its flexible substrate. Inset: Perspective illustration of the OTFT featuring a polymer substrate, and small molecule organic insulator and channel layers (Garnier et al., 1990).

to stand up, forming  $\pi$ -stacks along the in-plane direction. This orientation results in a high hopping mobility between molecules along the channel. The pentacene BG/TC OTFT employing a  $\text{SiO}_2$  insulator and a doped Si substrate gate contact showed a hole mobility of  $0.7 \text{ cm}^2/\text{V s}$ . Importantly, the on-off current ratio of the transistor was increased from previous reports of from  $\sim 10^3$ – $10^4$  to  $10^8$ . A high on-off current ratio is essential for obtaining large display backplane arrays that deliver a suitably high contrast between the pixel on and off states, as well as a large noise margin in logic circuits (see Section 8.3.4).

High mobility was attributed to nanocrystalline order achieved via vacuum deposition on heated substrates, and the on-off ratio to the high purity (and hence a low background charge density) of the material that reduced the off-state leakage current. This result was improved by functionalizing the  $\text{SiO}_2$  surface with a self-assembled, space-filling monolayer of octadecyltrichlorosilane (OTS) prior to deposition of a 30 nm thick pentacene channel onto the heated ( $90^\circ\text{C}$ ) substrate. The OTS reduces the surface energy relative to pentacene. Growth on OTS produces dendritic crystals separated by grain boundaries that are at a lower density and

perhaps smaller than achieved by pentacene growth directly on  $\text{SiO}_2$ . The gaps are filled in by subsequent deposition of an additional 20 nm of pentacene after the substrate is cooled to room temperature. This BG/BC  $\text{SiO}_2$  gate insulator OTFT showed a mobility of  $1.5 \text{ cm}^2/\text{V s}$  and an on-off drain current ratio of  $10^8$  (Lin et al., 1997b).

The dependence of mobility on surface and bulk morphologies was demonstrated for pentacene-based OTFTs grown by organic vapor phase deposited (OVPD, see Section 5.4.2) on a  $\text{SiO}_2$  insulator, with and without an OTS monolayer. Growth by OVPD allows for considerable control over morphology via variations in the chamber temperature and pressure, source temperature and gas flow rates. Hence, it provides an ideal platform for studying the effects of morphology on device parameters. Figure 8.7 shows scanning electron micrographs of 70–100 nm thick pentacene films grown by OVPD on a thermally grown  $\text{SiO}_2$  on an n-Si substrate, with and without an OTS layer pre-deposited onto the oxide surface (Shtein et al., 2002). The crystallite size increases from 0.5 to  $>5 \mu\text{m}$  as equilibrium growth conditions are approached at high substrate temperatures, high chamber pressures and low growth rates. Under these

**Figure 8.7** Scanning electron micrographs of pentacene thin films grown by OVPD on (a–c) thermally grown  $\text{SiO}_2$  and (d–f) OTS pretreated  $\text{SiO}_2$ . The conditions for OVPD growth for each film (left to right) are substrate temperature, chamber pressure and growth rate. The films on the right are grown closer to thermodynamic equilibrium than on the left (Shtein et al., 2002).

conditions, arriving molecules have more freedom to move along the surface, where they find low energy attachment sites before being buried by subsequently arriving molecules. The crystallite boundaries are readily apparent in the images of Fig. 8.7a–c.

OVPD growth was used in fabricating BG/TC OTFTs whose resulting hole field effect mobilities are shown in the figure. Increasing the grain size results in at least a tenfold increase in mobility due to the reduction in the number of grains, and possibly the width of the grain boundaries. In addition, the purified pentacene channels yielded a drain current on-off ratio of  $\sim 10^5$ . However, even the largest crystallites grown near equilibrium do not extend all the way across the gate length of  $45 \mu\text{m}$ . If this were the case, even higher mobilities might be achieved.

Growth on an OTS-functionalized surface results in a considerably smaller-scale surface texture but higher mobilities. Indeed, non-equilibrium growth results in mobilities of up to  $1.6 \text{ cm}^2/\text{V s}$  compared to the device grown near equilibrium with a field-effect mobility of  $\mu_{FE} = 0.6\text{--}0.9 \text{ cm}^2/\text{V s}$ . Both of these mobilities are higher than for films grown on bare  $\text{SiO}_2$ . The on-off ratio also increased to  $\sim 10^7$  compared to the bare  $\text{SiO}_2$  devices. Apparently, the textures on the film surfaces in Fig. 8.7d and 8.7e are not due to grain boundaries. X-ray diffraction analysis of the films shows that the OTS forces the first few monolayers of pentacene to lie flat on the substrate plane, as well as creating denser films with fewer grain boundaries.

The flat-lying pentacene may lead to improved order in the subsequently deposited layers that ultimately transport charge within the channel.

Higher mobility OTFTs employed organic polymer gate insulators with a vacuum deposited pentacene channel. The BG/TC transistors used a Si gate contact and substrate, followed by either cross-linked PVP or PVP-co-HEM. The pentacene channel and contacts were deposited on the polymer surface. Transistors with dimensions of  $L = 130 \mu\text{m}$  and  $W = 170 \mu\text{m}$ , yielded a hole field effect mobility of approximately  $\mu_{FE} = 3 \text{ cm}^2/\text{V s}$  for both insulators as compared to similar devices employing  $\text{SiO}_2$  (Klauk et al., 2002).

In this brief history, we have only discussed high mobility in hole conducting channels. In Section 8.6 we discuss several polymers and small molecules leading to both hole and electron dominated OTFTs.

### 8.3 Operating principles and definitions

The previous sections have described several prominent features of OTFTs. We have provided the basic layouts and several operating parameters such as the field effect mobility and on-off current ratio that characterize the most basic device attributes. In this section, we develop the theory of operation of the thin film transistor. The treatment provides the relationships between device geometry, materials characteristics and equivalent circuit performance in both transient and steady-state modes of operation.

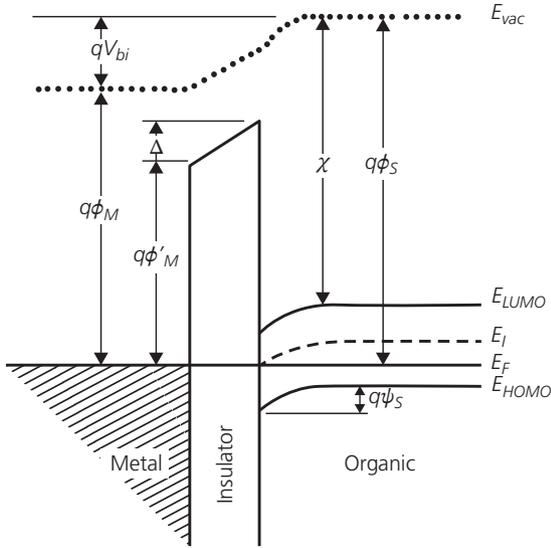

The usefulness of a transistor technology, whether it is based on inorganics such as Si or GaAs, metal oxide transistors, nanostructures such as carbon nanotubes (CNTs), or OTFTs, depends entirely on the application it is intended to serve. The application places several demands on the transistor, including:

- (i) *Current capacity.* Is the current that can be delivered by the transistor per gate area consistent with the needs of the load? For example, for the OTFT to drive an OLED in a display backplane, the transistor circuit must have a footprint no greater than that of the emitting device ( $\leq 10^4 \mu\text{m}^2$ ) while delivering sufficient current to achieve the required display brightness ( $\geq 1 \text{ mA/cm}^2$  for a luminance  $L > 1000 \text{ cd/m}^2$ ). The relationship between output (i.e. drain) current, and device and materials parameters is therefore a central consideration in transistor design.
- (ii) *On/off current ratio.* When used as a switch, and even in analog circuit applications, the drain current in the on state must be several orders of magnitude higher than in the off state. For digital circuits, this ensures reliable, low noise operation of a logic circuit consisting of a cascading chain of gates. That is, the transistor must be capable of distinguishing between a high vs. a low input state without error, to ensure that its output responds accordingly for the next gate in the chain. The distinction between on and off (or logical high and low states) is quantified by the circuit *noise margin* (Section 8.3.4). Further, the off state is determined by the channel leakage current. This sets the *noise floor* in both analog and digital circuits below which an output signal cannot be reliably detected.
- (iii) *Operating voltage.* Most low power dissipation circuits today operate at  $\sim 5 \text{ V}$  or less. The supply voltage can be higher than this, although the transistor can be assigned only a portion of the total available voltage to allow for other circuit elements to function.
- (iv) *Uniformity.* Device turn-on, or threshold voltage, must be confined to an acceptably small variance from device to device in large circuits, otherwise the margin for failure that depends on triggering logic gates becomes too small for reliable operation. The primary quantities that determine the operating point are the transistor *threshold voltage*, *sub-threshold slope*, and *transconductance*.
- (v) *Gain.* In both analog and digital circuits, the voltage gain of each stage must be sufficient to compensate for losses, and to drive subsequent circuits. The transistor transconductance, as determined by the charge mobility in the channel, must be sufficiently high for this purpose.
- (vi) *Frequency response.* Determined by both the transistor geometry (e.g. gate area and hence gate capacitance) and the transconductance, the transistor must operate at frequencies sufficient to deliver the required circuit bandwidth.
- (vii) *Noise.* The transistor noise in an analog circuit is amplified at each stage, and can eventually overwhelm the small input signal. For example, the input current noise of a transimpedance amplifier must be smaller than the smallest detectable signal of a photodiode designed to detect a small photon fluence. In a digital circuit, the output noise current of a transistor should not be so high as to mistakenly trip the logic state of the following gate. The *dynamic range* of the amplifier is the ratio of the lowest detectable signal determined by the input transistor noise floor, to the maximum signal before the amplifier deviates significantly from a linear response.
- (viii) *Stability.* The transistor must be stable over time, otherwise at some point the output characteristics drift outside of the margins where the circuit can reliably operate.

In this section, we establish a theoretical framework for determining whether or not a particular transistor architecture or material meets the demands of its target application. Our discussion begins at the most general level, considering all operational modes of MISFETs. However, as previously noted, OTFTs primarily (but not exclusively) operate in the accumulation-enhancement regime, and hence the discussions primarily focus on this common situation. Within this framework, we identify the applications that are most suitably addressed by OTFTs, and which can be better served by alternative transistor technologies.

### 8.3.1 Metal–insulator–semiconductor contacts

The key to understanding OTFT operation is the *metal gate–insulator–semiconductor* (MIS) capacitor. In Fig. 8.8 we show the energy level diagram for a MIS capacitor comprising a metal contact and

**Figure 8.8** Equilibrium energy level diagram of a metal–insulator–organic contact where the organic is p-type.

semiconductor with work functions,  $\phi_M$  and  $\phi_S$ , respectively. In this example,  $\phi_M < \phi_S$ . When the metal, insulator and semiconductor are brought into contact, charge flows until equilibrium is established. Then the Fermi energy,  $E_F$ , across the device is level, resulting in bending of  $E_{LUMO}$ ,  $E_{HOMO}$ , and the vacuum level,  $E_{VAC}$ , near the dielectric/semiconductor interface. This induces a dipole of energy,  $\Delta$ , in the insulator, and depletion of holes within the semiconductor. From inspection of this diagram:

$$\phi_{MS} = \phi_M - \phi_S = \phi_M - \frac{1}{q}(\chi + (E_{LUMO} - E_F)) = qV_{bi}, \quad (8.1)$$

where  $\chi$  is the electron affinity of the semiconductor and  $V_{bi}$  is the *built-in potential*. It is convenient to define the surface potential,

$$q\psi_S = q\phi_{MS} - \Delta = qV_{bi} - \Delta, \quad (8.2)$$

as the band bending at the semiconductor/insulator interface. In the special case where  $\phi_M = \phi_S$ ,  $V_{bi} = 0$  and the bands are flat throughout the semiconductor channel. This is known as the *flat-band condition*. The device in Fig. 8.8 achieves flat-band when the potential applied to the metal (i.e. the gate potential in a transistor) is  $V_{GS} = \psi_S$ .

In MIS systems, there are several sources of trapped charge both within the insulator and at the interfaces. Specifically, trapped charges per area due to fixed ( $\Delta Q_F$ ) and mobile ( $\Delta Q_M$ ) ions in the insulator bulk, and interface traps ( $\Delta Q_{IT}$ ), contribute to a change in gate voltage. The presence of charge traps in

equilibrium also contributes to the energy level bending, and hence affects the surface potential in the channel. Defining the sum of all charges trapped at defects both within the bulk and at the surfaces of the insulator as  $\Delta Q_i = \Delta Q_F + \Delta Q_M + \Delta Q_{IT}$  (each term of which can be either positive or negative, depending on the polarity of the trap at equilibrium), the built-in potential becomes

$$V'_{bi} = V_{bi} + \Delta V_{bi} = \phi_{MS} + \frac{\Delta Q_i}{C_i}, \quad (8.3)$$

where the insulator capacitance per area in the absence of traps is

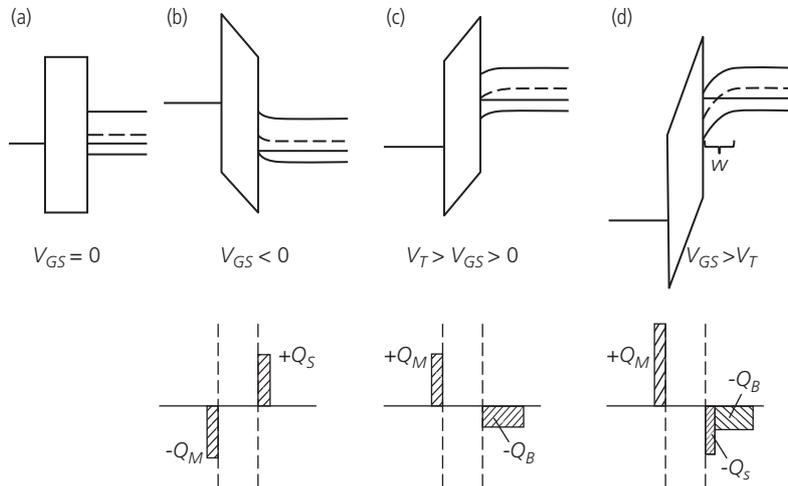

$$C_i = \frac{\epsilon_i \epsilon_0}{t_i}. \quad (8.4)$$

Here, both  $Q$  and  $C$  are normalized to the contact area, and  $\epsilon_i$  and  $\epsilon_0$  are the relative dielectric constant of the insulator and the permittivity of free space, respectively.

Control of the channel charge and potential by the gate voltage in an MIS capacitor is shown in Fig. 8.9, assuming  $\phi_M = \phi_S$  and  $\Delta Q_i = 0$ . The energy level diagrams are shown at the top of the figure, and the charge distributions are shown at the bottom. Generally, the charge density in the organic is small, but rarely is it zero. In the MIS capacitor, we assume the organic is infinitely thick with a background hole density,  $p > 0$ .

At  $V_{GS} = 0$ , the device is at thermal equilibrium and the bands are flat. At  $V_{GS} < 0$ , holes accumulate at the surface at density  $+Q_S$ . This is the *accumulation regime*. Under a small positive bias less than the threshold voltage, that is, at  $V_{GS} < V_T$ , charge is depleted from the insulator/semiconductor interface, leaving only fixed bulk charge,  $-Q_B$ , due to the residual holes in the channel. At  $V_{GS} > V_T$  the Fermi level in the semiconductor moves above mid-gap and the minority charge concentration at the surface surpasses the majority carrier concentration. In this case, the semiconductor is said to be *inverted*, where the number of electrons,  $n > p$ . Note that this description is general. However, due to the low background charge concentrations in undoped organics, typically only the accumulation regime is accessed by applying a negative gate voltage.

The inversion condition occurs when the free charge at the interface (i.e. electrons in Fig. 8.9) equals the holes in the bulk, and therefore creates a neutrality condition. This is the depletion-inversion transition point, and from inspection of Fig. 8.8, occurs when  $q\psi_S = 2(E_F - E_I)_{bulk}$  where the last term refers to the values of  $E_F$  and  $E_I$  in the channel bulk. Here,  $E_I$  is the

**Figure 8.9** Gate voltage control of hole concentration at the organic/semiconductor interface in an MIS capacitor. (a) Flat band condition (thermal equilibrium) where  $\phi_M = \phi_S$ . (b) Accumulation, (c) depletion, (d) inversion at  $V_{GS} > V_T$ , the threshold voltage. Diagrams at bottom show the charge at each side of the insulator.

intrinsic level energy. The gate voltage at the transition point is the threshold voltage,  $V_T$ , and is defined by satisfying the condition for the total surface charge:

$$Q_S = -C_i(V_{GS} - V_T) = 0. \quad (8.5)$$

In the absence of channel doping, then

$$V_T = \frac{2}{q}(E_F - E_i)_{bulk} = 2\psi_B, \quad (8.6)$$

where  $\psi_B$  is the Fermi energy relative to the intrinsic level in the bulk of the semiconductor. The charge density in the bulk of the semiconductor is given by (see Eq. 4.266ff.)

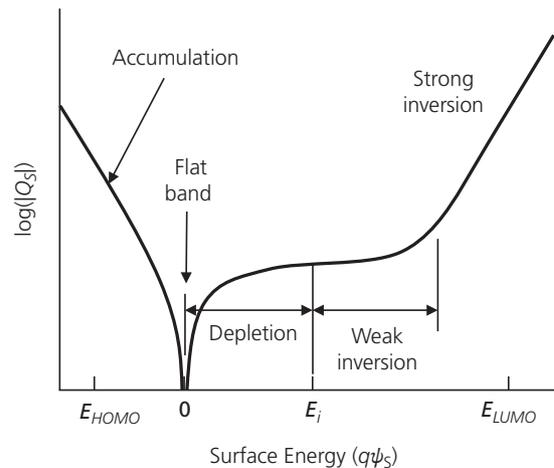

$$Q_B = -qN_A w = -\sqrt{2qN_A \epsilon_S \epsilon_0 (2\psi_B)}, \quad (8.7)$$

where  $N_A$  is the density of residual acceptors in the bulk. The total threshold voltage is thus

$$V_T = 2 \left( \psi_B + \frac{\sqrt{qN_A \epsilon_S \epsilon_0 \psi_B}}{C_i} \right) \approx 2\psi_B + \frac{qN_A d}{C_i}. \quad (8.8)$$

The expression to the far right is valid for a lightly doped organic of thickness  $d$  that is completely depleted at  $V_{GS} = 0$ . This situation is the most commonly encountered in organic semiconductors.

A qualitative plot of the surface charge,  $\log(|Q_S|)$ , vs. the surface energy  $q\psi_S$  for an MIS capacitor is provided in Fig. 8.10. This plot shows how the gate potential controls the charge density at the semiconductor/insulator interface. The electron surface charge density for an MIS capacitor with an electron-rich semiconductor bulk follows

**Figure 8.10** Surface charge vs. surface energy for a p-type MIS capacitor.

$$Q_S = qn_s = qn_{pS0} \exp(-q\psi_S/k_B T), \quad (8.9)$$

where  $n_s$  is the surface electron density, (with the total charge density in the channel of  $n_B = n_s \Delta y$  where  $\Delta y$  is the width of the charge layer at the insulator/semiconductor interface), and  $n_{pS0}$  is the electron surface charge density at equilibrium. For an undoped semiconductor,  $Q_S$  increases exponentially in both the accumulation and strong inversion regimes. In weak inversion, the charge density increases only slowly with  $\psi_S$ , whose exact functional dependence is found from a solution to Poisson's equation in the channel (Sze, 1981). Importantly, at flat band, the semiconductor is in equilibrium where the number of

thermally generated holes and electrons are equal, thus resulting in the absence of a net charge at the interface.

The capacitance of the gate under accumulation is simply the geometric capacitance of the insulator in Eq. 8.4. At high frequencies where the surface charge cannot respond to the a.c. signal,  $C_i$  is added in series to the capacitance of the depletion region in the channel bulk,  $C_B$ . Then, the total capacitance is

$$C_T = \frac{\epsilon_S \epsilon_i \epsilon_0}{\epsilon_S t_i + \epsilon_i w}, \quad (8.10)$$

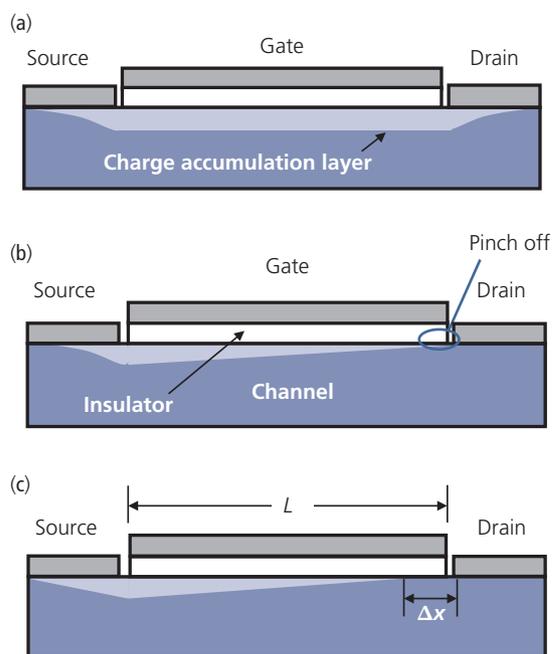

where  $\epsilon_S$  is the semiconductor dielectric constant, and  $w$  is the depletion region width. As is often the case in organics, the background charge density is small, and the thin semiconductor is completely depleted ( $w \rightarrow d$ ). At low frequency, the interface charge follows the variation in voltage, and the capacitance returns to  $C_i$  once inversion is reached.

### 8.3.2 OTFT operation

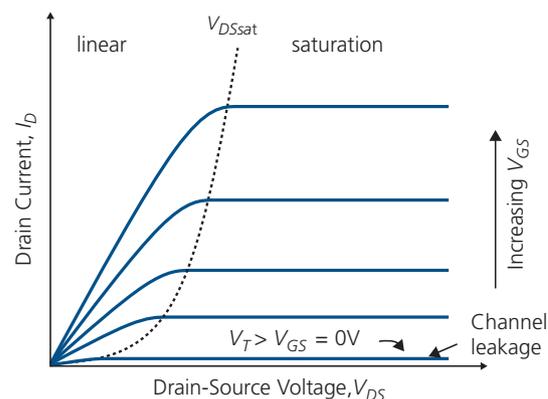

Figure 8.9 illustrates several bias regimes at a MIS junction. Since organics have a low background charge density, charge is drawn into the channel via injection from the S contact by applying a bias,  $|V_{GS}| > |V_T|$ . Furthermore, the channel is “normally off” when no charge exists at  $V_{GS} = 0$ . This corresponds to enhancement mode operation. For the unusual case where the channel is heavily doped, it can be conducting at  $V_{GS} = 0$ , in which case it is “normally on.” This is the depletion mode of operation, which is rarely exploited in OTFTs due to the difficulty in obtaining sufficiently high free charge concentrations via doping.

In the accumulation-enhancement mode, at  $|V_{GS}| > |V_T|$ , injected charge in the channel diffuses along the insulator interface to the drain. Figure 8.11 shows the OTFT along the length of the gate at different  $V_{DS}$ . The illustration shows the extent of the conduction region from  $V_{DS} = 0$  (Fig. 8.11a), to  $V_{DS} = V_{DSsat}$  (Fig. 8.11b), that is, the point at which the drain potential leads to a pinch-off of the charged layer at the drain. At small  $V_{GS}$ , therefore, the channel current is in the linear regime when  $I_D$  vs.  $V_{DS}$  approximately follows Ohm’s law. In this regime, the channel resistance is relatively independent of  $V_{DS}$ . At  $|V_{DS}| = |V_{DSat}|$ , the current demanded by the drain potential can no longer be supplied by the source without increasing  $V_{GS}$  needed to increase the charge density at the insulator interface. This creates a depletion region between the pinch-off point and the source, preventing the drain current from increasing further.

Thus, when  $|V_{DS}| > |V_{DSat}|$ , the free charge recedes a distance,  $\Delta x$ , from the drain (Fig. 8.11c). The drain current is pinned at  $I_{DSat}$  assuming there is no series resistance contributed by the depleted gate region. Since the drain current is constant at higher voltages, this is known as the *saturation regime*. The various current regimes along with the  $I_D$  vs.  $V_{DS}$  characteristics of an  $n$ -channel OTFT (where both  $V_{GS}$  and  $V_{DS}$  are positive) are shown in Fig. 8.12.

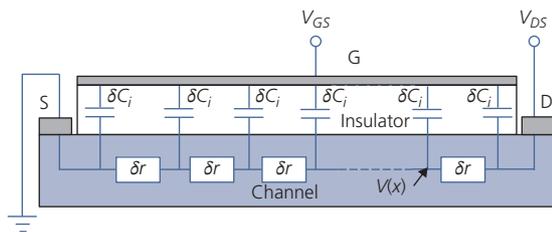

**Figure 8.11** Channel conduction (accumulation) layer under different  $V_{DS}$  for  $V_{GS} > V_T$ , that is, the area under the gate has a high density of charge that enables drain current flow from the source. (a)  $V_{DS} = 0$ , (b)  $V_{DS} = V_{DSsat}$  at pinch-off, and (c)  $V_{DS} > V_{DSsat}$ . The undoped channel bulk is depleted beyond the accumulation region.

**Figure 8.12** Drain current characteristics of an  $n$ -channel OTFT for various gate and drain voltages. The voltage at the onset of saturation is shown by the dotted line.

The OTFT operation can be modeled using the distributed resistive/capacitance network in Fig. 8.13. The equivalent circuit approximates the channel by a series of  $N$  incremental resistances,  $\delta r$ . Similarly, the gate dielectric consists of a parallel network of incremental insulator capacitances,  $\delta C_i$ . The voltage at point  $x$  from the source along the channel of length,  $L$ , is  $V(x)$ . For simplicity, we ignore the effects of S and D contact resistances, which can be significant (see below).

For calculating device characteristics, we make several assumptions. (i) The charge mobility at the interface, that is, the field effect mobility,  $\mu_{FE}$ , is independent of electric field under all bias conditions. We have found in Chapter 4 that this is in fact not the case in disordered organic solids where a density of conductive states extends from the HOMO or LUMO into the energy gap. As the charge density increases with  $V_{GS}$  and  $V_{DS}$ , the filling of these tail states pushes the mobility edge toward the frontier orbital energies, resulting in an increase in  $\mu_{FE}$ . Hence, it is widely observed that  $\mu_{FE}$  is higher than the bulk mobility of the channel material that is typically measured at much lower charge densities than exist at the insulator/channel interface. (ii) Only drift current is considered; diffusion current contributions are ignored. (iii) The channel is lightly doped, or undoped, that is,  $E_F \approx E_I$  at  $V_{DS} = 0$ . This condition also implies that, in the absence of gate leakage, the channel leakage is negligible when the transistor is in the “off” state. (iv) The electric field normal to the gate contact (in the  $y$ -direction) is considerably larger than from source to drain. This is the *gradual channel approximation* that applies when  $t_i \ll L$ , which is almost always true for OTFTs. (v) We start by assuming ambipolar conduction in the channel (Schmechel et al., 2005). Ambipolar implies that both electrons and holes can transport current. Except in special cases where the material has a nearly equal electron and hole field effect mobility, that is, where  $\mu_{FEh} \approx \mu_{FEp}$ , or in blends of electron and hole conducting constituents, the OTFT shows unipolar conduction where  $I_D$  is carried

**Figure 8.13** Equivalent circuit used in calculating the large signal OTFT operating characteristics.

by only a single charge type. Once the full ambipolar treatment is developed, it is readily simplified to model unipolar operation.

In an ambipolar OTFT, the total charge at the insulator/channel interface at  $x$  is

$$Q_S(x) = q(p_S(x) - n_S(x)) = C_i(V(x) - V_{GS}). \quad (8.11)$$

Here,  $p_S(x)$  and  $n_S(x)$  are the respective surface charge concentrations (cf. Eq. 8.9). At this point, we neglect the threshold voltage and assume that  $|V_{GS}| \geq |V_T|$ . This simplification allows us to consider a different threshold for electrons ( $V_{Tn}$ ) and holes ( $V_{Tp}$ ); factors that will be included below.

Since the channel in the linear regime behaves as a resistor with total resistance  $R_{tot}$ , then from Fig. 8.13 it follows that

$$V(x) = V_{DS} \frac{R(x)}{R_{tot}}, \quad (8.12)$$

where the resistance at  $x$  as measured from ground (i.e. from the source contact) is

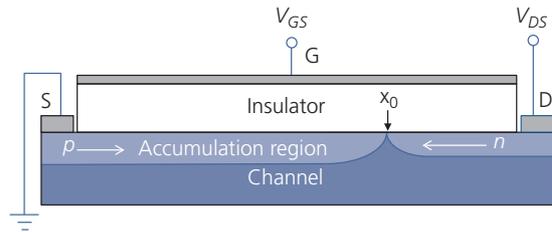

$$R(x) = \int_0^x \frac{dx}{qW [\mu_{FEp} p_S(x) + \mu_{FEh} n_S(x)]} \quad (8.13)$$

and  $R_{tot} = R(L)$ . Substituting Eqs. 8.12 and 8.13 into Eq. 8.11 yields the change in surface charge vs. distance along the channel:

$$\frac{dQ_S(x)}{dx} = \frac{C_i V_{DS}}{R_{tot}} \frac{1}{qW [\mu_{FEp} p_S(x) + \mu_{FEh} n_S(x)]}. \quad (8.14)$$

Figure 8.14 illustrates the accumulation region for holes injected from the source and electrons from the drain (i.e.  $V_{DS} < 0$ ). To good approximation, we can assume that all electrons and holes that meet at point  $x_0$  recombine. Hence, we have the following conditions for the charge distributions:

$$\begin{aligned} Q_S(x) &= qp_S(x) & 0 \leq x < x_0 \\ Q_S(x) &= -qn_S(x) & x_0 \leq x < L \end{aligned} \quad (8.15)$$

**Figure 8.14** Ambipolar OTFT showing the accumulation region under bipolar charge injection.

That is, the accumulation region is divided into two zones, one that conducts only holes and the other, electrons. With this, we can simplify Eq. 8.14 in the region  $x < x_0$ :

$$\frac{dQ_S(x)}{dx} = \frac{C_i V_{DS}}{R_{tot}} \frac{1}{qW\mu_{FEp}Q_S}, \quad (8.16)$$

with an analogous relationship for electrons at  $x \geq x_0$ . Integrating Eq. 8.16 up to the point  $x$  gives

$$|Q_S(x)| = \sqrt{(C_i V_{GS})^2 \pm \frac{2C_i V_{DS}}{\mu_{FE} R_{tot}} x}, \quad (8.17)$$

where the “+” sign refers to holes (in which case  $\mu_{FE} = \mu_{FEp}$ ), and “−” to electrons (where  $\mu_{FE} = \mu_{FEp}$ ). Since  $V(L) = V_{DS}$ , and using Eqs. 8.11 and 8.17 we can eliminate  $Q_S(L)$ :

$$R_{tot} = \frac{2L}{\mu_{FE} WC_i |2V_{GS} - V_{DS}|}. \quad (8.18)$$

Finally, we calculate the drain current characteristics using Ohm’s law,  $I_D = V_{DS}/R_{tot}$ , along with our solution for  $R_{tot}$  in Eq. 8.18. First, let us consider the case of a unipolar transistor where  $\mu_{FE} = \mu_{FEh} \gg \mu_{FEp}$ . Then electrons populate the inversion region when  $V_{GS}$ ,  $V_{DS} > 0$ . Including the threshold voltage,  $V_T$ , we obtain in the linear region:

$$I_D = \frac{W}{L} \mu_{FEh} C_i \left( V_{GS} - V_T - \frac{V_{DS}}{2} \right) V_{DS}, \quad (8.19)$$

$$\left( \begin{array}{l} 0 \leq V_{DS} \leq V_{DSsat} \\ V_{GS} > V_T \end{array} \right).$$

Equation 8.19 describes the unipolar drain current characteristics of the OTFT in the linear regime at  $V_{DS} < V_{GS} - V_T$ . In this regime, the drain current follows Ohm’s law, that is,  $I_D \sim (V_{GS} - V_T)V_{DS} \propto V_{DS}$ .

The saturation current at  $V_{DS} > V_{DSsat} = V_{GS} - V_T$  is fixed at its value at  $V_{DSsat}$ . Since the conduction is unipolar, saturation occurs when  $x_0 = L$  and

$$I_{Dsat} = \frac{W}{2L} \mu_{FEh} C_i (V_{GS} - V_T)^2, \quad \left( \begin{array}{l} V_{DS} > V_{DSsat} \\ V_{GS} > V_T \end{array} \right). \quad (8.20)$$

The saturation current scales linearly with the dielectric capacitance, and not surprisingly, the mobility. The capacitance is proportional to the ratio  $\epsilon_r/t_i$ . Therefore, the choice of both the organic semiconductor and dielectric determines the magnitude of the current, and ultimately the gain that the transistor can source.

Two further quantities are useful in characterizing transistor performance. The first is the *transconductance*,  $g_m$  (units of  $[A/V] = [S]$ ), which quantifies the modulation of the drain current due to changes in  $V_{GS}$ . The transconductance is related to the transistor gain. Thus, for a constant  $V_{DS}$ ,

$$g_m = \left. \frac{\partial I_D}{\partial V_{GS}} \right|_{V_{DS}} = \begin{cases} \frac{W}{L} \mu_{FEh} C_i V_{DS} & V_{DS} \leq V_{DSsat} \\ \frac{W}{L} \mu_{FEh} C_i (V_{GS} - V_T) & V_{DS} > V_{DSsat} \end{cases}. \quad (8.21)$$

As noted, high gain is also dependent on materials, requiring a high  $C_i$  and  $\mu_{FE}$ . The second quantity is the *output*, or *drain conductance*,  $g_D$ , equal to the slope of the  $I_D$  vs.  $V_{DS}$  characteristics. The output conductance ultimately determines the output impedance of the transistor, and hence the maximum circuit gain that can be achieved. In the absence of drain or source contact resistances:

$$g_D = \left. \frac{\partial I_D}{\partial V_{DS}} \right|_{V_{GS}} = \begin{cases} \frac{W}{L} \mu_{FEh} C_i (V_{GS} - V_T - V_{DS}) & V_{DS} \leq V_{DSsat} \\ 0 & V_{DS} > V_{DSsat} \end{cases}. \quad (8.22)$$

In realistic devices, it is not possible to have a vanishing output conductance in saturation. Diffusion, generation-recombination, and other parasitic currents such as gate insulator leakage contribute to the channel current originating within the transistor depletion region. Leakage depends on both  $V_{GS}$  and  $V_{DS}$ , and hence  $g_D \rightarrow g_{Dsat}(V_{GS}, V_{DS})$  at  $V_{DS} > V_{DSsat}$ , where  $g_{Dsat}$  is the output conductance in the saturation region. Furthermore, the source ( $r_S$ ) and drain ( $r_D$ ) resistances differ from zero. Their inclusion in the analysis leads to expressions for the *measured values* of  $g_m$  and  $g_D$  ( $g'_m$  and  $g'_D$ , respectively) of (Chou and Antoniadis, 1987)

$$g'_m = \frac{g_m}{1 + r_S g_m} \quad (8.23)$$

and

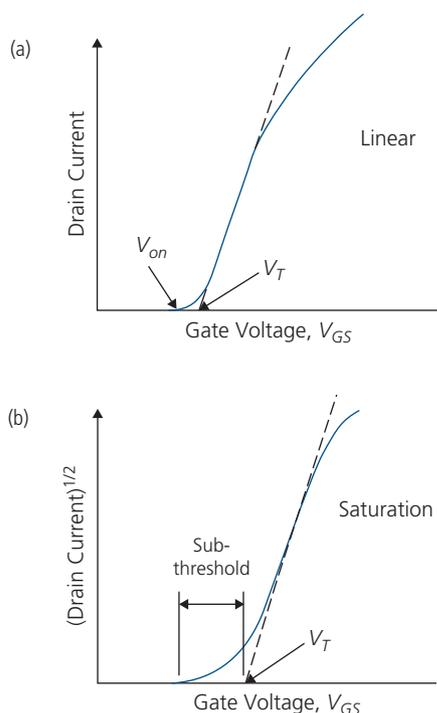

$$g'_D = \frac{g_D}{1 + (r_S + r_D) g_D}. \quad (8.24)$$

Thus, for  $r_S \rightarrow 0$ , then  $g'_m \rightarrow g_m$ . In contrast, in the saturation regime for large leakage (corresponding to  $g_{Dsat}$  large), then  $g'_D = (r_S + r_D)^{-1}$ , that is, the output conductance is limited by sum of the source and

drain resistances that includes a combination of both undepleted channel and contact resistances.

From the expressions for  $I_D$  in both the linear and saturation modes, we can extract several important features of the OTFT. The dependence of  $I_D$  on  $V_{GS}$  at fixed  $V_{DS}$  (known as the transistor *transfer characteristics*) in these two modes is shown in Fig. 8.15. According to Eq. 8.19,  $I_D$  in the linear regime at fixed  $V_{DS}$  is proportional to  $V_{GS}$  with an intercept at  $V_{GS} = V_T$ , and a slope equal to  $g_m$  (cf. Eq. 8.21). The field effect mobility, therefore, is extracted from  $g_m$ . Similarly, in the saturation regime (Eq. 8.20), a plot of  $\sqrt{I_{Dsat}}$  vs.  $V_{GS}$  yields  $\sqrt{\mu_{FEH}}$  with an intercept of  $V_T$ . In practice, the mobility should be obtained from the saturation rather than the linear regime data, since the latter may be diluted by series resistance and channel leakage that are less significant as the current is increased into saturation. Deviations at high  $I_D$  in both plots are due to series resistance, field-dependent mobility and other non-ideal effects.

The value of  $\mu_{FE}$  can alternatively be obtained from a plot of  $g_D$  vs.  $V_{GS}$  at  $V_{DS} = 0$ . From Eq. 8.22, the slope is  $\frac{W}{L} \mu_{FEH} C_i$  and the intercept at  $V_{GS} = 0$  gives  $V_T$ . This measurement is reliable only if the interface charge density is small, since charging or discharging of traps

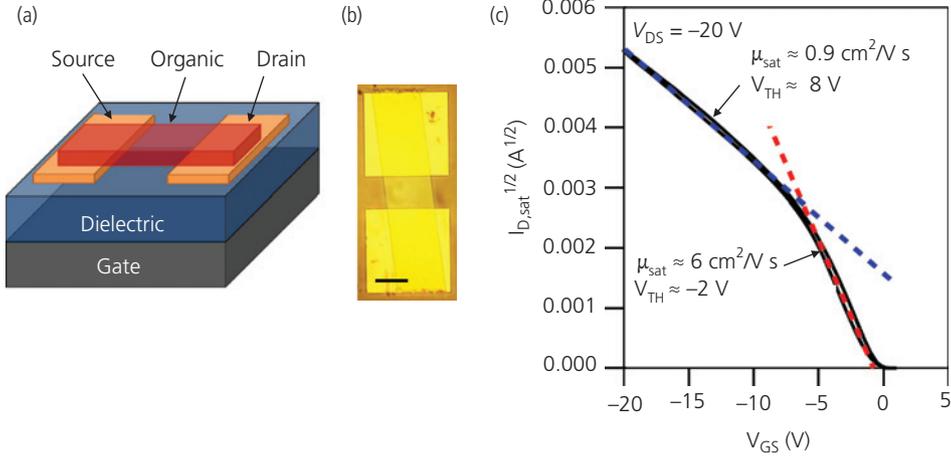

**Figure 8.15** Drain current vs.  $V_{GS}$  in the (a) linear and (b) saturation regimes of an enhancement mode OTFT. Also shown are the threshold voltage,  $V_T$ , and linear extrapolations to the characteristics (dashed line).

as the Fermi energy is swept through the energy gap with  $V_{GS}$  reduces the slope, affecting the mobility measurement.

We have noted previously in this discussion as well as in Section 4.4.3, that the field effect mobility is not the same as the bulk mobility for several reasons that should be apparent from the foregoing analysis. The field effect mobility is associated with conduction along the organic/insulator interface, and hence is influenced by the presence of charge trapped at the interface. It is also influenced by contact resistances (Eqs. 8.23 and 8.24), the exceptionally high density of charge in the OTFT that leads to filling of the Gaussian density of states (DOS), and static disorder within the channel. This has led to numerous reports of unphysically high single crystal mobilities extracted from the transistor transconductance.

The accuracy of the measurements have been studied using rubrene single crystal OTFTs whose structure is shown in Fig. 8.16a, and a photograph is shown in Fig. 8.16b. The rubrene crystal was grown by physical vapor deposition in flowing Ar in a heated reactor tube. The crystal was attached to the  $\text{SiO}_2$  gate dielectric pretreated with OTS, used to improve its adherence to the dielectric. The  $I_{Dsat}^{1/2}$  vs.  $V_{GS}$  characteristics in the saturation regime ( $V_{DS} = -20$  V) are shown in Fig. 8.16c. There is a noticeable kink in the characteristics at  $V_{GS} = -6$  V, which differs from expectations from the theory of Eq. 8.20. The mobility extracted from the data at  $V_{GS} < -6$  V gives  $\mu_{FEp} = 0.9$   $\text{cm}^2/\text{Vs}$ , which is more than six times lower than  $6$   $\text{cm}^2/\text{Vs}$  at  $-6$  V  $< V_{GS} < 0$ . A survey of the literature shows that the discontinuity in the transfer characteristics can result in differences of greater than a factor of ten in the field effect mobilities measured using the d.c. output characteristics. This finding is independent of whether the device is based on single crystals or polymers, and for both carrier types (Bittle et al., 2016, Choi et al., 2018).

Figure 8.17 shows fits to the  $I_D$  vs.  $V_{DS}$  characteristics in both the linear and saturation regimes of transistors employing the two different values of the field effect mobility from Fig. 8.16. The fits to the lower mobility obtained at a more negative gate voltage (Fig. 8.17a) are considerably more faithful to the data than using the higher mobility, suggesting that this latter value is significantly overestimated. Analysis of the transistor performance based on voltage-dependent mobility measurements and admittance spectroscopy indicates that the transition from the high to low mobility regimes is accompanied by an abrupt decrease in contact resistance. At low gate bias,

**Figure 8.16** (a) Schematic illustration of a single crystal OTFT. (b) Micrograph of a single crystal of rubrene overlaying the S and D and G (not shown) contacts forming the single crystal OTFT. The scale bar is 100  $\mu\text{m}$ . (c) The transfer characteristics of the rubrene transistor in the saturation regime at  $V_{DS} = -20\text{V}$ . After Bittle et al. (2016).

the contact resistance is dominated by thermionic emission of charge at the source contact, and is approximately equal to the channel resistance. As the gate voltage is increased, a high density of charge accumulates under the contact, reducing the injection barrier by the onset of field emission into the channel. With further increases in gate voltage, the resistance remains constant, at value of more than two orders of magnitude smaller than the channel resistance. In this case, the contact resistance no longer significantly impacts the mobility measurement. Indeed, when contact resistance effects are included, the mobility is independent of voltage equal to its value at  $V_{GS} < -6\text{V}$ . The anomalous differences between the field effect and bulk mobilities are thereby reduced, although these two quantities characterize two very different conduction regimes. Hence, it should be apparent that measurements of very high mobilities from the d.c. transistor characteristics should be treated with considerable caution (Choi et al., 2018).

Returning to the more general solution for ambipolar conduction, the recombination point,  $x_0$ , is determined by modeling the accumulation region as a voltage divider comprising two resistances,  $R_p$  and  $R_n$  (Schmechel et al., 2005):

$$\begin{aligned} R_p &= \frac{2x_0}{\mu_{FEp} WC_i |V_{GS}|}, \\ R_n &= \frac{2(L - x_0)}{\mu_{FEn} WC_i |V_{DS} - V_{GS}|} \end{aligned} \quad (8.25)$$

with a total channel resistance of  $R_{tot} = R_p + R_n$  and  $|V_{GS}|/R_p = |V_{DS} - V_{GS}|/R_n$ . Thus,

$$x_0 = \frac{LV_{GS}^2}{V_{GS}^2 + \frac{\mu_{FEn}}{\mu_{FEp}} (V_{DS} - V_{GS})^2}. \quad (8.26)$$

As expected,  $x_0$  depends on the relative magnitudes of  $\mu_{FEn}$  and  $\mu_{FEp}$ . Here we have assumed that holes are injected at  $x = 0$  and electrons at  $x = L$ . As  $\mu_{FEn}$  increases relative to  $\mu_{FEp}$ ,  $x_0$  decreases until  $\mu_{FEp} \rightarrow 0$ , corresponding to  $x_0 \rightarrow 0$ , that is, the electron-rich accumulation region extends across the entire channel.

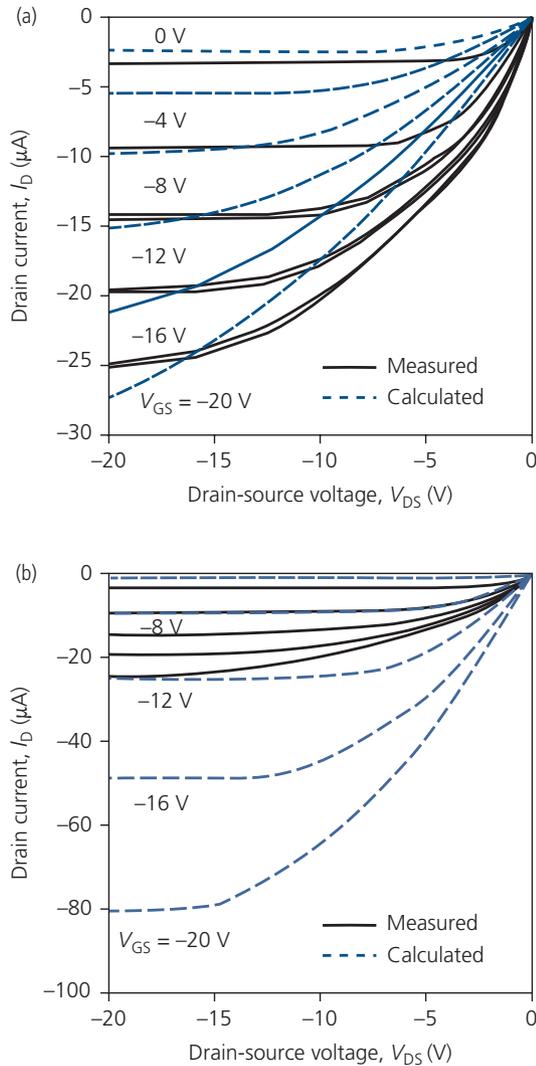

A plot of the charge density distribution for various ratios of  $\mu_{FEp}/\mu_{FEn}$  is given in Fig. 8.18. When the mobilities are equal,  $x_0 = L/2$ , but as  $\mu_{FEp}$  increases, the point where the charge density vanishes moves toward the drain. Unipolar conduction corresponds to  $\mu_{FEp}/\mu_{FEn} = 100$ .

With expressions for  $R_n$ ,  $R_p$ , and  $x_0$ , we can calculate a general solution to the drain currents for ambipolar OTFTs. The characteristics are similar to those for a unipolar device in the linear regime in Eq. 8.19, although at higher drain voltages ( $V_{DS} \geq V_{GS}$ ), the  $I_D$  vs.  $V_{DS}$  characteristics follow

$$\begin{aligned} I_{Dsat} &= \frac{WC_i}{2L} \left[ \mu_{FEn} (V_{GS} - V'_T)^2 \right. \\ &\quad \left. + \mu_{FEp} (V_{DS} - V_{GS} + V'_T)^2 \right], \end{aligned} \quad (8.27)$$

$$\left( \begin{array}{l} V_{GS} < V_{DS} \leq V_{DSsat} \\ V_{GS} > V'_T \end{array} \right).$$

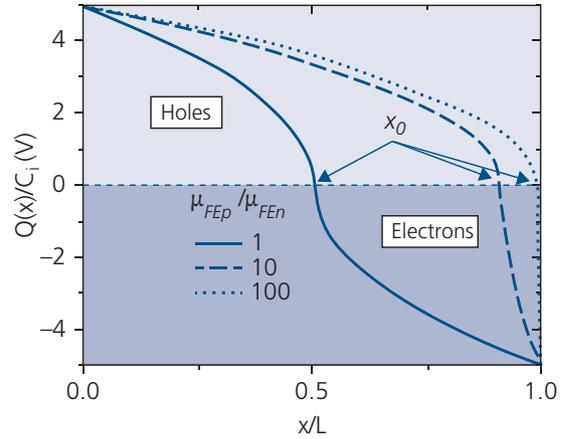

There are several differences between this expression and that for unipolar conduction in Eq. 8.20. For  $\mu_{FEn} \gg \mu_{FEp}$ , the conduction is in fact unipolar, and Eq. 8.27 is the same as Eq. 8.20. Further, the threshold voltage  $V_T$  is replaced by  $V'_T$ , allowing for the

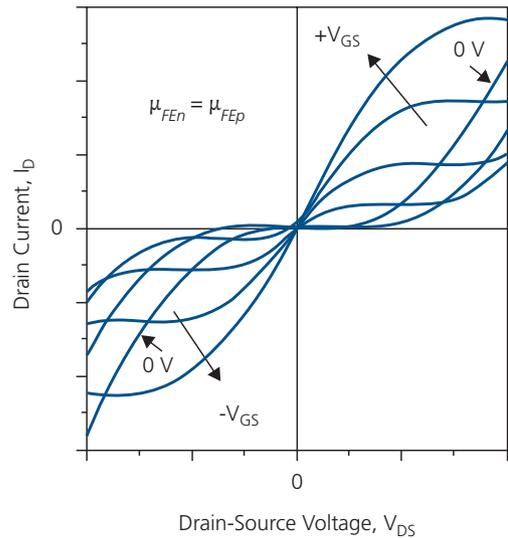

**Figure 8.17** Measured and simulated drain current characteristics using the mobility obtained at (a) high and (b) low negative gate voltages from Fig. 8.16 (Bittle et al., 2016).

possibility of two thresholds; one for electrons and the other for holes. This is discussed further below. And finally, there is no current saturation regime. The last term on the right indicates that the current increases quadratically with  $V_{DS}$  when  $V_{DS} > V_{GS}$ .

The drain current characteristics for an ambipolar OTFT with  $\mu_{FEh} = \mu_{FEp}$  and  $V_T' = 0$  V are illustrated in Fig. 8.19. The onset of the  $I_D \propto V_{DS}^2$  dependence is at  $V_{DS} = V_{GS}$ , as predicted by Eq. 8.27. Hence, a notable characteristic of the curves is that they cross over each other and exhibit saturated behavior over a larger range of  $V_{DS}$  with increasing  $V_{GS}$ . Furthermore, they are expected to lose their symmetry about  $V_{DS} = 0$  when the electron and hole mobilities and threshold voltages significantly differ.

**Figure 8.18** Charge density and location of the recombination point,  $x_0$  vs. the relative electron and hole field effect mobilities,  $\mu_{FEp}$  and  $\mu_{FEh}$  respectively. Here,  $V_{GS} = -15$  V,  $V_{DS} = -10$  V, and  $V_T = 0$  V. After Schmechel et al. (2005).

**Figure 8.19** Ambipolar OTFT drain current characteristics for  $\mu_{FEp} = \mu_{FEh}$ . The threshold voltage for both is  $V_T = 0$  (Zaumseil and Sirringhaus, 2007).

Ambipolar transistors have a comparatively low output conductance,  $g_D$  at low  $V_{GS}$ , making them less useful than unipolar OTFTs as voltage amplifiers. The transconductance of ambipolar devices is inferred from the  $I_D$  vs.  $V_{GS}$  characteristics in Fig. 8.20. When there is a large asymmetry in the mobilities, the transfer characteristics are similar to those in Fig. 8.15. However, as the difference in mobilities is reduced, an inflection in the drain current is observed near  $V_{GS} = 0$  V, which becomes more pronounced with increasing  $\mu_{FEp}$ . Inspection of Eq. 8.27 shows that at small  $V_{GS}$ , the second term dominates and the slope inverts.

The drain current expression assumes a single threshold voltage,  $V_T$ . In most devices, however, different threshold voltages,  $V_{Tn}$  and  $V_{Tp}$ , are required to achieve electron or hole accumulation, respectively. We now write the explicit expressions for  $I_D$  for the example of  $V_{Tp} \leq V_{Tn}$ . The ambipolar transistor has three regimes of operation. In the linear regime,

$$I_D = \frac{WC_i}{L} \mu_{FE_n} \left( V_{GS} - V_{Tn} - \frac{V_{DS}}{2} \right) V_{DS}, \quad (8.28)$$

$$\left( \begin{array}{l} 0 \leq V_{DS} \leq V_{DSsat} \\ V_{GS} > V_T \end{array} \right).$$

Beyond the linear regime, the transistor enters the saturation regime, where

$$I_D = \frac{WC_i}{2L} \mu_{FE_n} (V_{GS} - V_{Tn})^2, \quad \left( \begin{array}{l} V_{DS} \geq V_{GS} - V_{Tn} \\ V_{DS} \leq V_{GS} - V_{Tp} \end{array} \right). \quad (8.29)$$

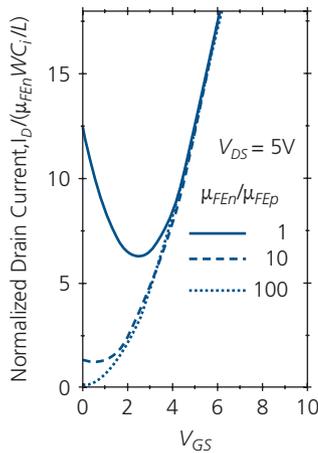

Finally, in the ambipolar (quadratic) regime, we have

$$I_D = \frac{WC_i}{2L} \left\{ \mu_{FE_n} (V_{GS} - V_{Tn})^2 + \mu_{FE_p} (V_{DS} - V_{GS} + V_{Tp})^2 \right\}, \quad (8.30)$$

$$V_{DS} \geq V_{GS} - V_{Tp} \geq V_{GS} - V_{Tn}.$$

Analogous expressions are obtained for  $\mu_{FE_n} < \mu_{FE_p}$  and  $V_{Tp} > V_{Tn}$ .

These drain current characteristics are easily reduced to the equivalent unipolar expressions by simply allowing the mobility of the less mobile carrier to vanish. Since nearly all high performance OTFTs operate under unipolar injection, for clarity we will confine

**Figure 8.20** Transfer characteristics of an ambipolar OTFT in the saturation regime for various ratios of electron to hole mobility (Schmechel et al., 2005).

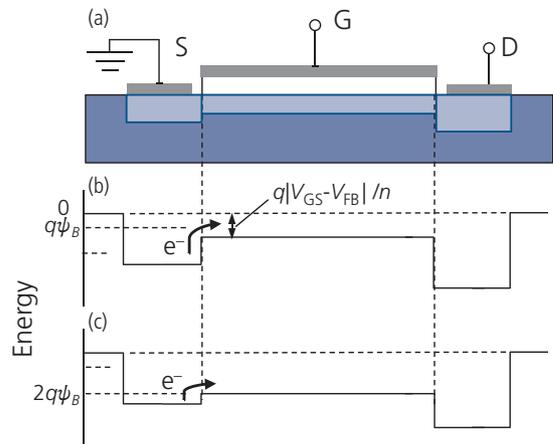

the rest of our discussion here to unipolar devices. Example ambipolar transistors, and their application to electronic circuits is found in Section 8.4.4.

In Fig. 8.15, the drain current deviates from zero at  $V_{GS} < V_T$ . A high performance transistor is characterized by a small drain current below threshold, as well as an onset (called the *switch-on voltage*,  $V_{on}$ ) very near to  $V_T$ . An abrupt current onset enables a small voltage swing to switch the OTFT from the off to the on state. The rate of change of the current at  $V_{on} < V_{GS} < V_T$  is known as the *sub-threshold slope*, defined as

$$S = \frac{\partial V_{GS}}{\partial (\log_{10} I_D)}. \quad (8.31)$$

For example, for a Si MOSFET  $S \sim 60$  meV/decade of drain current, and for a-Si TFTs,  $S = 0.3\text{--}1.5$  V/decade. This larger value for amorphous Si is likely due to states that extend into the band gap (tail states) due to structural disorder or defects. A similar situation exists in organics, where both dynamic and static disorder lead to a high density of tail states. It is therefore unsurprising that  $S$  is large, and for OTFTs it can be as high as 4–5 V/decade (Lin et al., 1997b), although with improved crystalline order in the channel and a reduced interface charge density of states (DOS),  $S = 0.5$  V/decade has been obtained for pentacene/SiO<sub>2</sub> OTFTs (Klauk et al., 2002).

The sub-threshold current is due to thermally excited charge that surmounts the energy barrier between the injecting source contact and the gate, as illustrated in Fig. 8.21 for an OTFT in weak and strong accumulation. Figure 8.21a shows depletion region (shaded area), where there is a barrier with a

**Figure 8.21** Energetic landscape under sub-threshold conditions. (a) Profile of the OTFT. The lightly shaded area under the gate is the depletion region. (b) Energy along the channel under weak accumulation, and (c) energy under strong accumulation. The energy barrier height between source and gate is  $qV_{GS}/n$ .

built-in potential at each contact. In Fig. 8.21b, the energy barrier between source and gate decreases with gate voltage as  $q|V_{GS} - V_{FB}|/n$ , where  $V_{FB}$  is the flat band voltage ( $V_{FB} = 0$  in Fig. 8.21b), and  $n$  is the ideality factor for the injection current. We have shown previously that, in the absence of trapped charge,  $V_{FB} = \Delta/q$ . At  $V_{GS} < V_T$ , charge surmounts the barrier by thermionic emission, resulting in a drain leakage current of

$$I_D = I_{D0} \exp(q|V_{GS} - V_{FB}|/nk_B T) = I'_{D0} \exp(qV_{GS}/nk_B T), \quad (8.32)$$

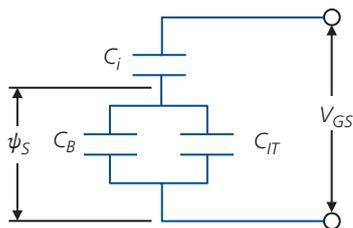

where  $I_{D0}$  and  $I'_{D0}$  are constants. That is,  $I_D$  increases exponentially as the barrier height decreases. In Fig. 8.21c, the barrier is significantly reduced near threshold as  $V_{GS} \rightarrow 2\psi_B$ , improving charge injection into the channel.

The expressions developed thus far, and in particular those leading to Eqs. 8.20 and 8.32, are based on treatments of conventional transistors that operate in the inversion mode. Since OTFTs operate in the accumulation mode, the relationships between the threshold voltage, and the turn-on voltage,  $V_{on}$  (and hence,  $V_{FB}$ ) are simply empirical models. Nevertheless, Eq. 8.32 is in good agreement with OTFT operation in the sub-threshold regime. And while  $V_T$  extracted from these characteristics is not identically equivalent to that obtained for inversion-mode FETs, it is nevertheless useful for describing OTFT performance.

The ideality factor is the fraction of the gate voltage dropped across the semiconductor, that is,  $n = V_{GS}/\psi_S$ . This is calculated by inspection of the gate equivalent circuit in Fig. 8.22. In the presence of traps, the circuit consists of the series/parallel combination of the capacitances of the insulator, depletion region ( $C_B$ ), and interface traps,  $C_{IT}$ . The voltage divider thus yields

$$n = 1 + \frac{C_B + C_{IT}}{C_i} \approx 1 + \frac{C_{IT}}{C_i}, \quad (8.33)$$

where, on the right, we assume that  $C_B \rightarrow 0$  in an organic where the dopant concentration is very

**Figure 8.22** Equivalent circuit of the MIS gate region in the presence of interface traps.

small. The interface capacitance is  $C_{IT} = qN_{IT}$ , where  $N_{IT}$  is the interface charge DOS. Then we obtain  $n \geq 1$ .

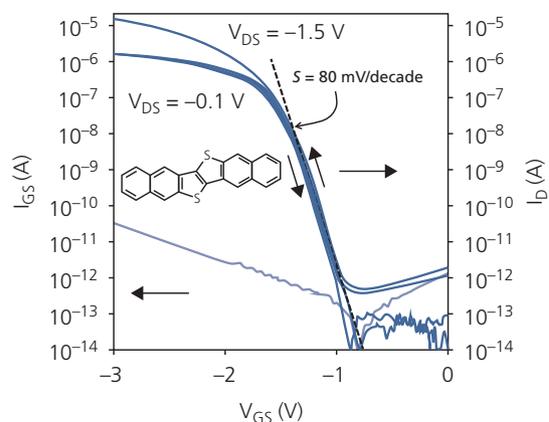

Using Eq. 8.32 in Eq. 8.31, we obtain

$$S = 2.3 \frac{nk_B T}{q}. \quad (8.34)$$

For an ideal MISFET,  $n = 1$  and thus the smallest possible sub-threshold slope at room temperature is  $S = 60$  mV/decade. The trapped charge density is obtained from  $S$  using Eq. 8.33.

The sub-threshold characteristics of a DNNT, p-channel OTFT are shown in Fig. 8.23. The device has a BG/TC configuration. The  $\text{AlO}_x$  gate dielectric is a 3.6 nm layer grown by oxygen plasma vapor deposition (PVD). Prior to vacuum depositing DNNT, the insulator surface is treated with a solution of alkylphosphonic acid that forms a *self-assembled monolayer* (SAM) that modifies the surface energy, and/or surface trap density. Further discussion of the use of SAMs in influencing OTFT characteristics is found in Section 8.6.1.

Figure 8.23 is a semi-log plot from which the sub-threshold slope of  $S = 80$  mV/decade is obtained from the exponential characteristics in both the linear and saturation regimes at  $V_{DS} = -0.1$  V and  $-1.5$  V, respectively. The threshold at  $V_{GS} = V_T = -1.4$  V is obtained from the transition of the current from an exponential to a linear increase in  $I_D$  at  $V_{GS} = V_T$ . The value of  $S$  is remarkably close to the theoretical minimum of 60 meV/decade for  $n \approx 1$  (Eq. 8.34). An interface trap density of  $N_{IT} = 2 \times 10^{12} \text{ V}^{-1} \text{ cm}^{-2}$  is inferred from the measured  $n$  and using Eq. 8.33.

**Figure 8.23** Sub-threshold drain and gate leakage current characteristics of a DNNT, p-channel OTFT with dimensions of  $L = 10 \mu\text{m}$  and  $W = 100 \mu\text{m}$ . The characteristics in the linear and saturation regimes at  $V_{DS} = -0.1$  and  $-1.5$  V, respectively, are shown. The sub-threshold slope (dashed line) is obtained at low  $I_D$ . Inset: Molecular structural formula of DNNT (Klauk, 2010).

At  $V_{GS} < V_T$ , the drain current is due to emission over the source contact-channel barrier, recombination within the channel, shunt and other parasitic leakage paths, and leakage through the gate dielectric. The sum of the leakage currents determines the off current of the transistor. The gate leakage current is also plotted in Fig. 8.23, and is  $\sim 1$  pA in the saturation regime. The channel resistances,  $r_D + r_S$ , limit the on current. The transistor performance as a switch depends on the ratio of on-to-off current ratio,  $I_{on}/I_{off} = 10^6 - 10^7$ , and by  $S$  which sets the minimum voltage needed to swing the transistor between these logic states.

### 8.3.3 Frequency response

The equivalent circuit for the small signal a.c. response of an OTFT is shown in Fig. 8.24. It is customary to use lower case variables (e.g.  $i_D$  vs.  $I_D$ ,  $v_{DS}$  vs.  $V_{DS}$ , etc.) to denote the small signal values of the corresponding parameters. Now the small signal drain current is

$$i_D(v_{DS}, v_{GS}) = I_D(V_{DS} + v_{DS}, V_{GS} + v_{GS}) - I_D(V_{DS}, V_{GS}). \quad (8.35)$$

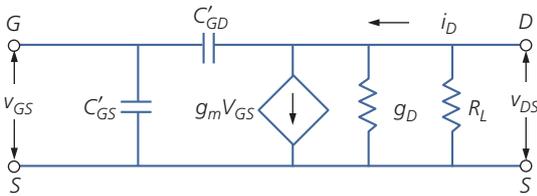

This expression is expanded in a Taylor series to give, to first order,

$$i_D = \left. \frac{\partial I_D}{\partial V_{DS}} \right|_{V_{GS}} v_{DS} + \left. \frac{\partial I_D}{\partial V_{GS}} \right|_{V_{DS}} v_{GS}, \quad (8.36)$$

which, using the definitions in Eqs. 8.21 and 8.22, yields

$$i_D = g_D v_{DS} + g_m v_{GS}. \quad (8.37)$$

Both the gate-to-source ( $C_{GS}$ ) and gate-to-drain ( $C_{GD}$ ) capacitances contribute to the a.c. input impedance. These capacitances are the sum of the geometric dielectric capacitance (Eq. 8.4) and the parasitic gate-source and gate-drain capacitances that result from overlap between the gate and the channel contacts. Under a.c. gate voltage modulation, the reactance from these capacitances shunts the gate voltage. The total equivalent gate capacitance is, therefore,

**Figure 8.24** OTFT small signal a.c. equivalent circuit. Here,  $C'_{GS}$  and  $C'_{GD}$  are the total gate-source and gate-drain capacitances, respectively.

$$C_G = C_{GS} + C_{GD}(1 + A_v), \quad (8.38)$$

where  $A_v$  is the voltage gain. In an a.c. circuit, the external load resistance,  $R_L$ , appears across the drain, and hence  $A_v$  is simply

$$A_v = \frac{\partial v_{DS}}{\partial v_{GS}} = \frac{\partial v_{DS}}{\partial i_D} \frac{\partial i_D}{\partial v_{GS}} = \left( R_L \parallel \frac{1}{g'_D} \right) g_m, \quad (8.39)$$

where, in the a.c. equivalent circuit of a common source amplifier, the transistor output resistance,  $1/g'_D$ , is in parallel with  $R_L$ . For circuits with moderate voltage gain,  $R_L < 1/g'_D$ , leading to  $R_L \parallel \frac{1}{g'_D} \rightarrow R_L$ . The drain capacitance in Eq. 8.38 appears at the OTFT input, and hence  $A_v$  amplifies its effect on the output impedance. The total drain capacitance

$$C_M = C_{GD}(1 + A_v) \quad (8.40)$$

is known as the *Miller capacitance*, and its amplification is known as the *Miller effect*. The difficulty in precise patterning and alignment of the gate within the channel can result in a significant dependence of the OTFT a.c. response on  $C_{GD}$ , and therefore the parasitic capacitances of the source and drain to the gate cannot be ignored.

For a sinusoidal input angular frequency,  $\omega$ , the small signal input current is purely reactive:

$$i_{GS} = WLC_G \frac{\partial v_{GS}}{\partial t} \Big|_{V_{DS}} = j\omega(WLC_G)v_{GS} = j2\pi f(WLC_G)v_{GS}, \quad (8.41)$$

where  $f$  is the modulation frequency of the gate. Also,  $j = \sqrt{-1}$  indicates that the gate current and voltage are phase-shifted by  $\pi/2$ . Similarly, the current at the drain is, from Eq. 8.21,

$$i_D \simeq g_m v_{GS}, \quad (8.42)$$

resulting in a current gain of

$$\left| \frac{i_D}{i_G} \right| = \frac{g_m}{2\pi f(WLC_G)}. \quad (8.43)$$

Since the reactive current  $i_G$  is linear in  $f$ , whereas  $i_D$  is frequency independent, we define the maximum frequency of practical operation as the *cutoff*, or *transfer frequency*,  $f_T$ , which is defined at the point where  $|i_D/i_G| = 1$ . Thus,

$$f_T = \frac{g_m}{2\pi WLC_G} = \frac{g_m}{2\pi WL(C_{GS} + C_M)}. \quad (8.44)$$

Apparently,  $f_T$  decreases approximately inversely with  $A_v$  in high gain transistor circuits, with the maximum frequency response at  $A_v \sim 1$ . This is an

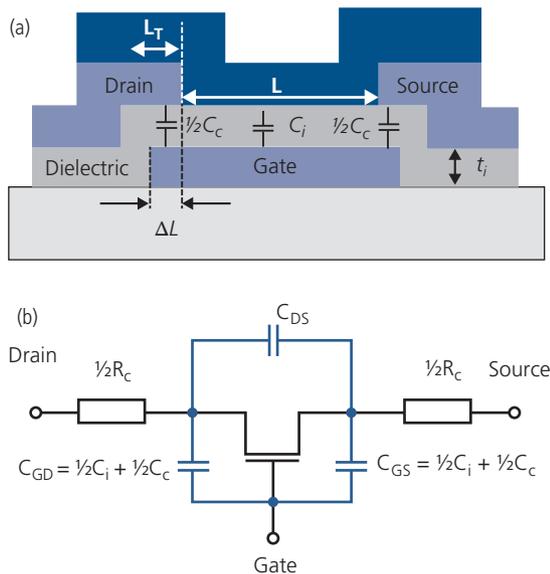

expression of the gain-bandwidth product introduced in the context of photodetectors in Section 7.1.1.

The geometric relationship between capacitances and the electrode configuration that is helpful in analyzing a BG/TC OTFT is shown in Fig. 8.25a. For convenience, we assume a symmetrical device where the insulator and parasitic contact capacitances ( $C_i$  and  $C_c$ , respectively) are shared equally between the source and drain. The *transfer length*,  $L_T$ , is the overlap of the drain and source contacts with the channel that participates in current injection into the channel. The d.c. equivalent circuit in Fig. 8.25b shows that  $C_{GS} = C_{GD}$  for this particular device geometry.

Using Eq. 8.21 in the saturation regime, we obtain

$$f_T = \frac{g_m}{2\pi W(L + \Delta L)C_i} = \frac{\mu_{FEac}(V_{GS} - V_T)}{2\pi L(L + \Delta L)}. \quad (8.45)$$

Here, we assume that the *total* overlap of both the gate and drain contacts with the source is  $\Delta L$ . Then the total insulator geometric capacitance is increased by  $L + \Delta L$ . We have shown above that the current is limited by both the contact and channel resistances. At high frequencies, the contact resistance can significantly impact the frequency response as well. Indeed, in Eqs. 8.23 and 8.24 we found that  $g_m$  decreases with increasing resistance. Since  $\mu_{FE}$  is determined from a measurement of the transconductance, this implies that the measured mobility, and hence  $f_T$ , are also dependent on resistance. To calculate contact

**Figure 8.25** (a) Cross-sectional view of a BG/TC OTFT showing the various capacitive circuit elements and geometric factors; (b) d.c. equivalent circuit of the OTFT. The contact capacitance and resistance are  $C_c$  and  $R_c$ , respectively.

resistance effects, we replace  $V_{DS}$  in the linear regime with  $V_{DS} - I_D R_C$ , where  $R_C$  is the total contact resistance that is the sum of the contributions from both source and drain (Benor and Knipp, 2008). Then, from Eq. 8.19, we have

$$I_D = \frac{W}{L} \mu_{FE0} C_G \left( V_{GS} - V_T - \frac{1}{2} (V_{DS} - I_D R_C) \right) \times (V_{DS} - I_D R_C), \quad (8.46)$$

where the insulator capacitance is replaced by the total gate capacitance,  $C_G = C_{GS} + C_{GD}$ , and  $\mu_{FE0}$  is the channel mobility in the absence of contact resistance. For small  $V_{DS}$ , Eq. 8.46 simplifies to

$$I_D = \frac{W \mu_{FE0} C_G (V_{GS} - V_T) V_{DS}}{L + W \mu_{FE0} C_G (V_{GS} - V_T) R_C}. \quad (8.47)$$

Comparison with Eq. 8.19 suggests that the effective mobility measured in an OTFT whose contact resistance is comparable to that of the channel resistance is expressed as

$$\mu_{FEeff} = \frac{\mu_{FE0} L}{L + W \mu_{FE0} C_G (V_{GS} - V_T) R_C}. \quad (8.48)$$

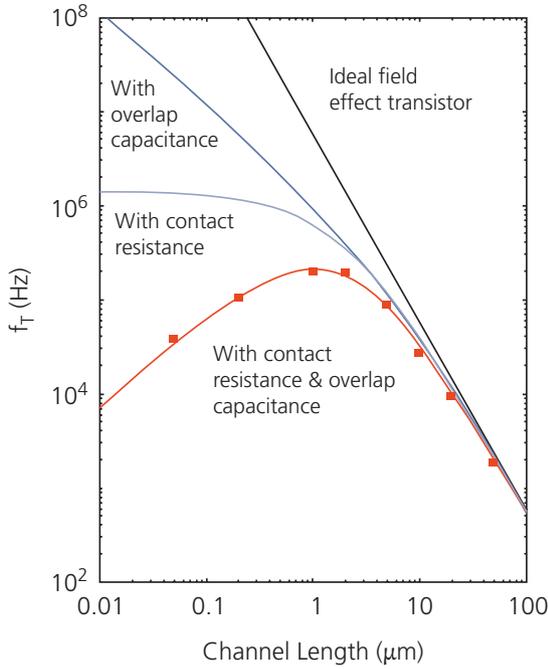

An analogous expression can be derived for the effective mobility in the saturation region starting with Eq. 8.20. In the presence of both parasitic capacitance and resistance, the foregoing yields

$$f_T = \frac{\mu_{FE0} (V_{GS} - V_T)}{2\pi L (L + \Delta L)} \left[ \frac{1}{1 + W \mu_{FE0} C_G (V_{GS} - V_T) R_C / L} \right]. \quad (8.49)$$

Now  $f_T \sim (V_{GS} - V_T) / L^2$ , and decreases with both  $R_C$  and  $C_G$ . Thus, as the voltage increases, so does the charge density in the channel, allowing for more rapid charging and discharging of the gate capacitance in response to a small signal input.

The cutoff frequency vs. channel length is calculated for BG/TC DH7T OTFTs in Fig. 8.26, showing the individual contributions from contact resistance and overlap capacitance. The organic channel is deposited onto a  $\text{SiO}_2$  dielectric first coated with an HMDS SAM. The transfer length,  $L_T = 2\text{--}3 \mu\text{m}$ , and  $\Delta L = 5 \mu\text{m}$  were obtained for the photolithographically patterned gate with lengths as small as 50 nm. The devices have a mobility of  $\mu_{FE0} = 0.02 \text{ cm}^2/\text{V s}$ , and the fits to the data (points) including all parasitic effects including overlap capacitances, yields a contact resistance of  $R_C W = 3.5 \text{ k}\Omega \text{ cm}$  (Hoppe et al., 2010).

A maximum frequency response of 200 kHz is obtained at  $L = 1 \mu\text{m}$ . As the gate length decreases, the contact resistance exceeds the channel length, limiting

**Figure 8.26** Cutoff frequency vs channel length and the separate contributions to the response due to overlap capacitance and contact resistance for BG/TC DH7T OTFT. The fit (red line) to the data (points) is obtained using  $R_c W = 3.5 \text{ k}\Omega \text{ cm}$  (Hoppe et al., 2010).

$f_T$ . Indeed, Eqs. 8.48 and 8.49 indicate that the frequency response, even for very high mobility materials, is ultimately limited by contact resistance which, for OTFTs, is rarely below  $100 \text{ }\Omega\text{-cm}$ . Thus the prospect for achieving  $f_T > 100 \text{ MHz}$  when  $\mu_{FE0}$  is as high as  $10 \text{ cm}^2/\text{V s}$  and  $V_{DS} \sim 10 \text{ V}$ , is unlikely unless a considerable reduction in  $R_c W$  below current values of several hundred  $\Omega \text{ cm}$  are realized (Klausk, 2018).

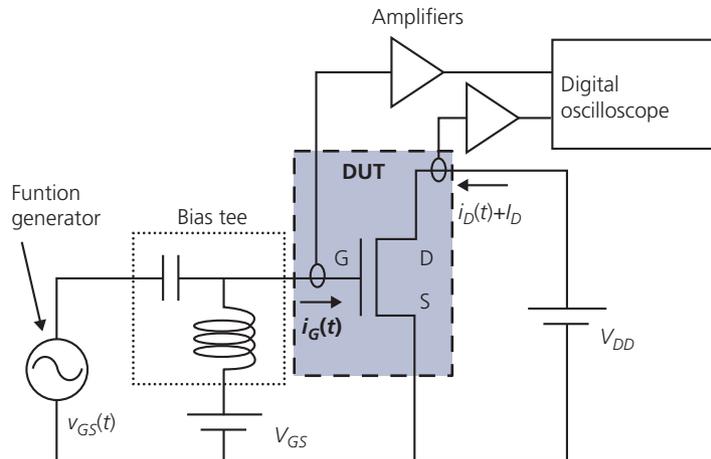

Finally, it is important to distinguish the mobility measured under a.c. and d.c. conditions. The mobilities thus obtained are not generally equal, since the small signal response under a.c. modulation may be limited, in part, by the trapping and detrapping of charge that follows the input signal. The a.c. mobility is loosely analogous to a time of flight measurement of the bulk mobility ( $\mu_{TOF}$ , see Section 4.4.3), except that the values may significantly differ, since  $\mu_{FEac}$  is influenced by the morphology and charge density at the insulator/semiconductor interface, whereas  $\mu_{TOF}$  is a property of the bulk.

To understand the scale of  $\mu_{FEac}$  in OTFTs, we return to the device characteristics in Fig. 8.23. In that example,  $C_i = 0.8 \text{ }\mu\text{F}/\text{cm}^2$ ,  $\Delta L = 10 \text{ }\mu\text{m}$ , giving a total input capacitance of  $25 \text{ pF}$ . A transconductance of  $g_m = 15 \text{ }\mu\text{S}$  was measured from the saturation characteristics at  $V_{DS} = -3 \text{ V}$ , yielding  $f_T \sim 100 \text{ kHz}$

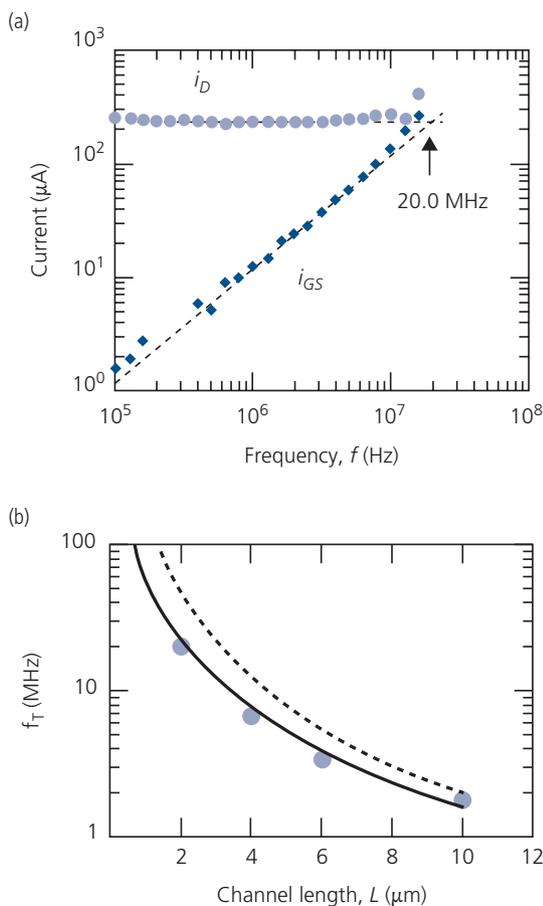

(Klausk, 2010). The best determination of  $f_T$ , however, is by direct measurement rather than via inference from the transconductance in Eq. 8.44. That is,  $g_m$  is obtained from the d.c. transistor characteristics, which may not accurately extrapolate into the a.c. domain.

A typical test setup for measuring  $f_T$  is shown in Fig. 8.27. The operating point of the device under test (DUT) is set by the two power supplies,  $V_{GS}$  and  $V_{DD}$ . Both a d.c. bias and the oscillating test signal ( $v_{GS}(t)$ ) are applied to the gate through a bias tee. The tee capacitively couples the a.c. signal to the gate, which is isolated from ground by the inductive choke between the  $V_{GS}$  supply and the gate. The gate and drain a.c. currents are measured using current amplifiers and a fast digital oscilloscope or spectrum analyzer. The a.c. input signal is typically a sine wave, although a fast pulse, approaching that of a delta function can be used in conjunction with a spectrum analyzer. The fast pulse has a uniform frequency spectrum, and hence its roll-off at high frequency to the point corresponding to  $|i_G(t)/i_D(t)| = 1$  from its d.c. value provides a direct measurement of  $f_T$ . The disadvantage of the fast-pulse technique is that the pulse magnitude must be sufficient to detect the current signal across the entire spectrum up to  $f_T$ .

Results of frequency response measurements on an n-channel,  $C_{60}$  OTFT are shown in Fig. 8.28a. The device has a BG/TC configuration, with  $L$  varied from  $2 \text{ }\mu\text{m}$  to  $10 \text{ }\mu\text{m}$ . Overlap between the gate and the output contacts of  $\Delta L = 1\text{--}2 \text{ }\mu\text{m}$  gives rise to a parasitic capacitance,  $C_p$ . The other transistor dimensions are  $W = 1 \text{ mm}$ ,  $d = 100 \text{ nm}$ , and  $t_i = 200 \text{ nm}$ . The data are obtained in the saturation regime with  $V_{DS} = 25 \text{ V}$  and  $V_{GS} = 20 \text{ V}$ , leading to a linear increase in  $i_{GS}$  with  $f$  that is consistent with reactive coupling through  $C_G$  in Eq. 8.41. In contrast,  $i_D$  is relatively frequency independent until  $f = f_T = 20 \text{ MHz}$ . The frequency dependence of  $i_D$  is more pronounced as  $L$  increases due to the increased parasitic  $C_{GD}$ . The steady-state calculations of  $f_T$  based on  $g_m$  and measurement are shown in Fig. 8.28b (dashed line and data, respectively). Here,  $g_m$  is obtained using an electron mobility of  $\mu_{FE0}$  between  $0.86$  and  $1.1 \text{ cm}^2/\text{V s}$ , which is a fitting parameter applied to achieve agreement with the measured cutoff frequency. The difference between theory and experiment is largest at large  $f_T$ , corresponding to a short gate length. This is attributed to a parasitic capacitance,  $C_p$ , not entirely accounted for by the measured gate/drain overlap. A fit to the data assuming an average value for  $C_p$  for all gate lengths is shown by the solid line in Fig. 8.28b (Kitamura and Arakawa,

**Figure 8.27** Setup for testing the frequency response of a transistor. The shaded region highlights the device under test (DUT).

**Figure 8.28** (a) Small signal drain and gate currents vs. frequency for an  $n$ -channel  $C_{60}$  OTFT. The crossing point corresponds to  $f_T = 20$  MHz for a gate length of  $L \approx 2 \mu\text{m}$ . Dashed lines are fits to the data. (b) Cutoff frequency vs. gate length. The dashed line is a calculation using the transconductance (Eq. 8.44), and the solid line includes a parasitic capacitance that provides the best fit to the data (Kitamura and Arakawa, 2009).

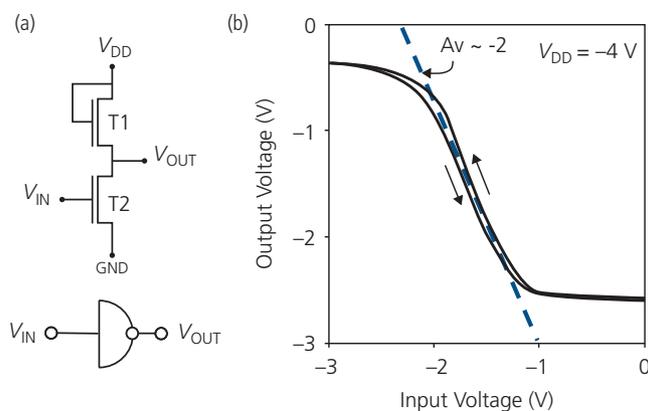

2009). If the overlap between input and output electrodes is decreased using self-aligned patterning and gate lengths of  $L \rightarrow 1 \mu\text{m}$ , and a decreased contact resistance,  $f_T$  may exceed 50 MHz.

A dual transistor, unipolar inverter consists of a load (T1) and a drive (T2) transistor in a common source (i.e. source ground) configuration. The load comprises a transistor whose gate and drain are shorted. This active load is in saturation since  $V_{GS} = V_{DS} = V_{DD}$ , the supply voltage. The drive transistor source is grounded, and the output is across the load, and is supplied at the drain of T2. The approximate voltage gain of the stage is

$$A_v = \frac{\partial V_{OUT}}{\partial V_{IN}} = -\frac{g_{m2}}{g_{m1}} = -\sqrt{\frac{(W_2/L_2)}{(W_1/L_1)}}, \quad (8.50)$$

where the last expression follows from Eq. 8.21 for  $g_m$  in saturation. Here,  $g_{m1,2}$  refers to transistors T1, T2 in Fig. 8.29, respectively. For the data in Fig. 8.29b,  $A_v = -2$ . Each stage must have  $|A_v| > 1$  to fully regenerate the signal from the previous stage. The inverter has an approximate voltage swing of  $\Delta V_{IN} = 0.7$  V. For linear operation, the gate voltage of T2 is biased midway within its linear regime, that is, at  $V_{IN} \approx -1.7$  V. Importantly, the circuit voltage never swings completely between 0V and  $V_{DD} = -4$  V, indicating that even in the quiescent, switched state, the circuit dissipates power. We show below that this limits the number of unipolar stages due to the maximum current that can be sourced, and by circuit heating. Quiescent power dissipation is eliminated via the use of complementary logic.

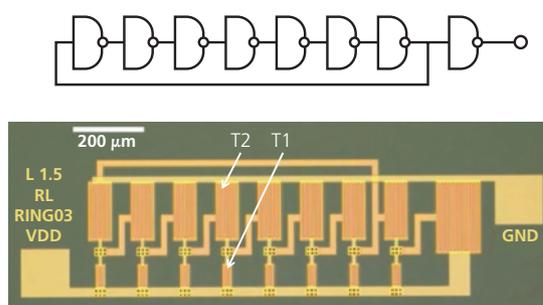

A *ring oscillator* circuit is another means to determine the transistor frequency response. A ring

**Figure 8.29** (a) Unipolar voltage inverting amplifier circuit consisting of a load (T1) and a drive transistor (T2). The logical symbol for the inverter is shown at the bottom. (b) Inverter voltage transfer characteristics comprising transistors similar to that in Fig. 8.23 shows a small hysteresis (arrows point in direction of the voltage sweep). The dashed line is the slope between the amplifier on and off states in the range  $-2\text{ V} < V_{IN} < -1.3\text{ V}$ . The voltage gain is  $A_v = \partial V_{OUT} / \partial V_{IN} = -2$ . After Klauk (2010).

oscillator comprises a series connection of an odd number of identical inverter circuits (Fig. 8.29a), with the output of the last inverter tied back to the input of the first inverter in the series. Each inverter input is out of phase by  $\pi$  from its output. Hence, the first inverter switches the second in the opposite sense, propagating through all the stages. The output of the last stage is “high” when the input of the first stage is “low.” The feedback loop thus flips the first stage back into its “low” state. Thus, the circuit oscillates (or *rings*) continuously at frequency  $2f_{osc} = 1/N\tau_{delay}$ , accumulating a delay per stage of  $\tau_{delay} = 1/2Nf_{osc}$ . The factor of 2 accounts for two transistor state changes per cycle. This number is not identical to  $f_T$  since each inverter output drives the input of the following stage. The interconnections between stages and their associated parasitic capacitances give  $f_{delay} = (2\tau_{delay})^{-1} < f_T$ , although the gate delay thus obtained is nevertheless useful for characterizing the transistor small signal response in an actual circuit.

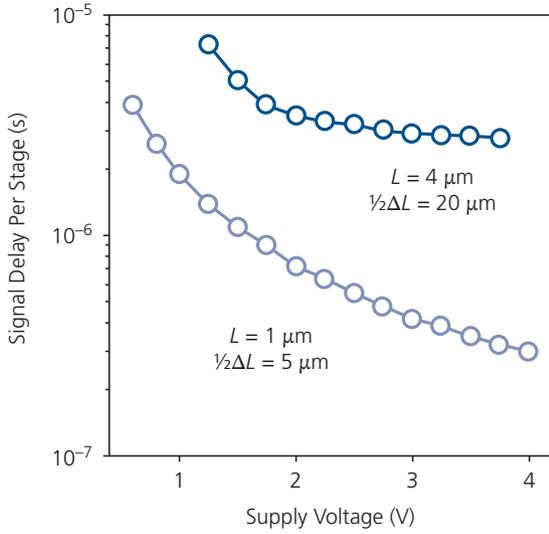

The logical circuit schematic and a micrograph of a 7-stage ring oscillator are shown in Fig. 8.30. The device has an output stage that buffers the oscillator from the subsequent load. The transistors use a small molecule/polymer blend for the channel, where the small molecule is a good hole conductor ( $\mu_{FEp} \sim 0.1\text{ cm}^2/\text{V s}$ ), and the polymer is used to provide a uniform film morphology. The gate lengths and widths for the BG/BC configuration are  $L = 1.5\text{ }\mu\text{m}$  for both T1 and T2, and  $W_1 = 0.2\text{ mm}$  and  $W_2 = 2\text{ mm}$  (giving  $A_v = -3.2$  per stage). The gate dielectric is PVP. A maximum  $f_{osc} = 100.2\text{ kHz}$  is measured, giving a stage delay of  $\tau_{delay} = 712\text{ ns}$  at  $V_{DD} = -120\text{ V}$  (Smith et al., 2008). This corresponds to a cutoff frequency that

**Figure 8.30** Logic diagram (top) and layout of a seven-stage ring oscillator comprising a blended small molecule/polymer channel. The feedback line from the 7th to the first stage is shown at the top of the micrograph. Note the asymmetry in sizes between the load (T1) and drive (T2) transistors in each stage. The last stage is used for driving an external load. White scale bar is  $200\text{ }\mu\text{m}$ . The output inverter driver is also shown in the logic diagram, top. After Smith et al. (2008).

is more than ten times smaller than the device in Fig. 8.28, as a result of the ten times lower mobility of the channel layer compared with  $C_{60}$ .

The oscillator in Fig. 8.30 has an exceptionally high  $V_{DD}$ . Increasing the supply voltage decreases the gate charging time, thus decreasing the gate delay. This is illustrated in Fig. 8.31 for the signal delay measured for 11-stage ring oscillators employing BG/TC transistors. The OTFTs comprised a 20 nm thick layer of the vacuum deposited small molecule,  $C_{10}$ -DNNTT, with  $\mu_{FEp} = 1.2\text{ cm}^2/\text{V s}$ . An  $\text{AlO}_x/\text{SAM}$  insulating layer is identical to that used in the devices in Fig. 8.23. The thin insulator layer and the substantial overlap between the gate and output electrodes of  $\Delta L = 5\text{--}40\text{ }\mu\text{m}$  ultimately limits  $f_{delay}$ . However, a benefit of the thin insulator is the low OTFT operating voltage used (Zschieschang et al., 2013). To minimize

**Figure 8.31** Gate delay time per stage for  $C_{10}$ -DNNT p-channel OTFTs with two different gate lengths. The circuit is an 11-stage ring oscillator (Zschieschang et al., 2013).

gate capacitance, the widths are only 72  $\mu\text{m}$  and 24  $\mu\text{m}$  for T1 and T2, respectively. As expected, the shorter gates have lower capacitance, and hence a smaller  $\tau_{\text{delay}}$ , which also decreases with increasing  $V_{DD}$ . The smallest delay time measured is 300 ns at  $V_{DD} = 4\text{V}$ . From the measured  $g_m = 1.2\text{ mS/mm}$  and  $C_G = 90\text{ pF/mm}$ , the cutoff frequency is  $f_T \approx 1/2\tau_{\text{delay}} = 2\text{ MHz}$ . This is reasonably close to the measured  $f_{\text{delay}} = 1.6\text{ MHz}$ , indicating that the effects of parasitic capacitance are small.

### 8.3.4 Transistor noise

The usefulness of a transistor in both analog and digital circuits is often determined by its noise characteristics. In an analog application such as a linear amplifier, the noise of the input transistor stage determines the smallest detectable signal by the subsequent circuitry. Hence, the input noise determines the amplifier dynamic range, which is the ratio of the largest signal that still results in a linear response, to the smallest signal set by the noise floor. In a digital circuit, the *noise margin* defines the maximum allowable noise output of one stage that still correctly triggers the logic state of the following stage (Hauser, 1993). Hence, lower gate noise results in a larger noise margin, and hence more error-free operation of the circuit.

Thin film transistors have several noise sources, each contributing a *mean square noise current spectral density* of  $S_{In} = \langle i_n^2 \rangle$ . The total noise spectral density,  $S_{\text{I}ot}$ , is that of all sources added in quadrature. Thus,

$$S_{\text{I}ot} = \sum_n \langle i_n^2 \rangle. \quad (8.51)$$

The determination of the separate noise sources in Eq. 8.51 follows an analysis developed for photo-detectors in Section 7.1.2.

When the voltage between drain and source is zero for a channel in accumulation, the channel performs as a resistor with conductance,  $g_0$ . The noise from a resistor in equilibrium is due to the random arrival of charge at an electrode. It is variously known as *thermal*, *Johnson*, or *Nyquist noise*, and has a spectral density of

$$S_{th} = \langle i_{th}^2 \rangle = 4k_B T g_0. \quad (8.52)$$

The frequency independence of  $i_{th}^2$  suggests that the noise current increases linearly with the bandwidth of the measurement window, and hence it is a *white noise* source. In saturation,  $V_{DS} \neq 0$ , and hence the OTFT channel is no longer a homogenous resistor, that is, the conductance varies along the channel. To good approximation, it can be shown that the thermal noise current in saturation is given by (Gray and Meyer, 1984)

$$S_{th} = \langle i_{th}^2 \rangle = \frac{8}{3} k_B T g_m, \quad (8.53)$$

which is commonly used to model Si MOSFETs. Now the channel current is coupled back to the gate via  $C_G$ . This, in turn generates a temporal gate potential resulting in a spectrally dependent current noise:

$$\langle i_G^2 \rangle = \frac{4}{5} k_B T g_m \left( \frac{f}{f_T} \right)^2. \quad (8.54)$$

Comparing this to Eq. 8.53,  $i_G^2 < i_{th}^2$  unless  $f > f_T$ , and hence the gate plays an insignificant role in the overall transistor noise.

We have shown in the previous section that OTFTs operate at relatively low frequencies, with  $f_T < 10\text{ MHz}$ . In this domain, the dominant noise source is known as  $1/f$ , or *flicker noise*. There are many potential sources for  $1/f$  noise described by as many models. Nevertheless, the noise behavior generally can be fit to Hooge's empirical formula (Hooge et al., 1981):

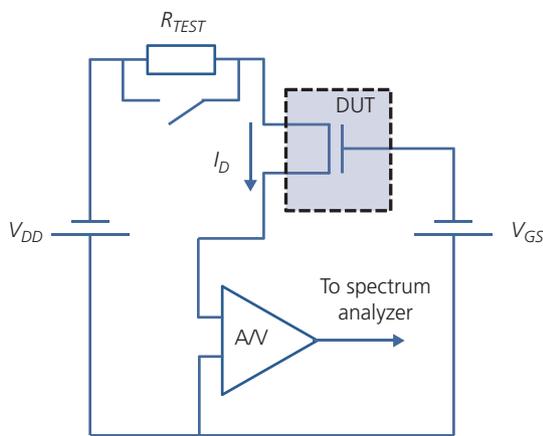

$$\frac{S_f}{I_D^2} = \frac{\langle i_f^2 \rangle}{I_D^2} = \frac{a}{N f^\gamma}, \quad (8.55)$$

where  $a$  is the *Hooge parameter*,  $N$  is the number of carriers in the channel, and  $\gamma \sim 1$ . Unlike the other white noise sources,  $1/f$  noise is frequency dependent. Flicker noise has variously been attributed to random fluctuations in the charge mobility as a function of

gate voltage, trapping and detrapping of charges from the insulator/channel interface and from within the bulk of the insulator into the channel, trapping within the channel itself, and parasitic resistances that shunt or lie in series with the channel. Indeed, the magnitude of  $S_f$  and even its slope,  $\gamma$ , depend on the choice of materials, physical dimensions of the OTFT, processes used in fabrication, and so on. The details of the various physical origins are largely contained in the Hooge parameter,  $\alpha$ , which is orders of magnitude higher in organics than in Si MOSFETs. To a much lesser extent, these processes also affect  $\gamma$  (Vandamme et al., 2002, Marinov and Deen, 2015).

An example noise measurement circuit schematic is shown in Fig. 8.32. The DUT is biased to its operating point. The drain current is input to a high gain transimpedance amplifier, whose output is connected to an electronic spectrum analyzer. The system should be calibrated with a known noise source. For example, a resistor is a thermal white noise source ( $S_{th}$ ) with mean square spectral density of  $4k_B T/R_{TEST}$  (cf. Eq. 8.52). A resistance value ( $R_{TEST}$ ) can be chosen that doubles the noise at the spectrum analyzer, in which case the test resistor noise is equal to that of the DUT.

The noise measurement for a diF-TESADT, p-channel OTFT operated in its linear regime is shown in Fig. 8.33. The device has a BG/TC configuration with a 200 nm thick SiO<sub>2</sub> insulating layer, yielding  $V_T = 5$  V. Analysis of the drain current characteristics gives  $\mu_{FEp} = 0.3$  cm<sup>2</sup>/V s (Jurcescu et al., 2008). The noise spectrum has an approximately

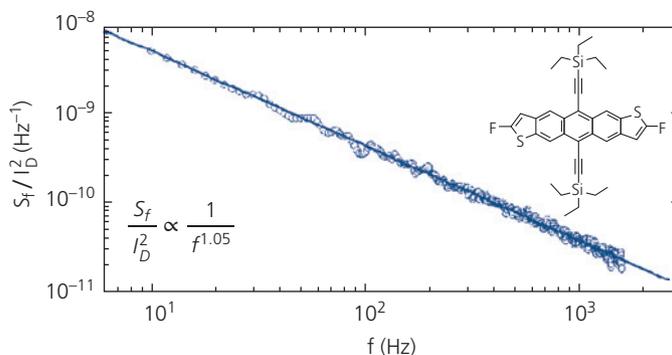

**Figure 8.32** Example test setup for measuring transistor channel noise current. The device under test (DUT) is biased at its operating point, and the noise current is amplified (after removal of the d.c. component of  $I_D$ ) by a low noise transimpedance amplifier (A/V). The output is connected to a spectrum analyzer. The test resistor,  $R_{TEST}$ , provides a noise source of known amplitude.

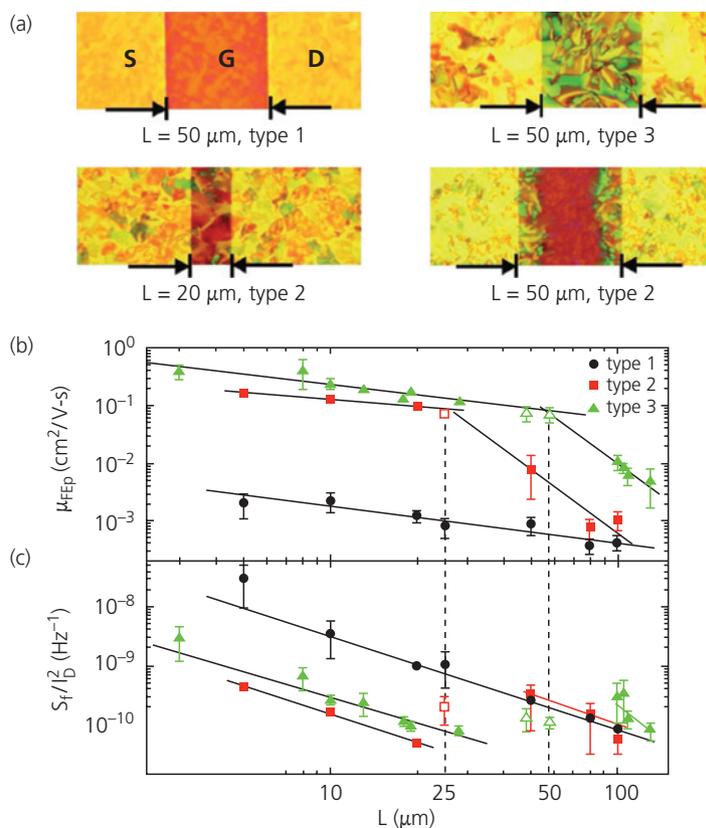

$1/f^\gamma$  dependence over more than two decades in frequency, with a slope of  $\gamma = 1.05$ .

The origins of the flicker noise in Fig. 8.33 were studied by measuring the hole mobility and noise spectral density as a function of the microcrystalline morphology of the semiconductor in the channel. The size and extent of crystallite formation is controlled by using different surface treatments of the Au S and D contacts, as well as by various treatments of the oxide. The type 1 device has no surface treatments resulting in a very high density of small crystallites. This poorly ordered region is apparent from the uniform coloration of the channel in Fig. 8.34a. For type 2 devices, the contacts are treated with a pentafluorobenzenethiol solution. This resulted in a more ordered, large grain polycrystalline zone extending approximately 10  $\mu\text{m}$  from each electrode into the channel. When the gate length exceeded 20  $\mu\text{m}$ , its central region reverted to the poorly ordered morphology of a type 1 device. Likewise, the type 3 device had type 2-treated contacts, but with an HMDS-functionalized oxide dielectric surface. This allowed for an extension of the large-scale crystallinity to distances of  $L \sim 50$   $\mu\text{m}$ .

Figure 8.34b shows that there is a continuous decrease in  $\mu_{FEp}$  with  $L$  for all three transistor types. The rate of decrease significantly increases when the morphology transitions from highly ordered, to a mixture, or ordered with disordered regions in type 2 and type 3 devices. Indeed, the more ordered channels have higher mobilities (0.13 and 0.24 cm<sup>2</sup>/V s for type 2 and 3, respectively) as  $L \rightarrow 10$   $\mu\text{m}$  than the more poorly ordered type 1 device (0.0022 cm<sup>2</sup>/V s). The noise,  $S_f$ , at short gate lengths decreases monotonically with increasing  $L$ , since the fluctuations decrease as the fraction of the ordered region to the total gate length increases (see Fig. 8.34c). Notably, the transitions to lower mobility at  $L \sim 25$   $\mu\text{m}$  for type 2, and 50  $\mu\text{m}$  for type 3 OTFTs are accompanied by abrupt increases in  $1/f$  noise. From the magnitude of  $S_f/I_D^2$ , Hooge parameters at  $L = 10$   $\mu\text{m}$  of  $\alpha = 50, 3$ , and 1.5 are obtained for type 1, 2, and 3 OTFTs, respectively. We infer, therefore, that changes in  $S_f$  follow changes in mobility, which in turn are related to the extent of the crystalline order. Hence,  $1/f$  noise appears to be due to scattering or charge trapping at grain boundaries. That is, while increased scattering at boundaries decreases mobility, the noise itself may result from random trapping and detrapping of charge at these same sites. Unfortunately, the data in Fig. 8.34 do not distinguish between these two scenarios, which may both be active.

**Figure 8.33** Noise spectrum of a diF-TESADT OTFT with channel dimensions of  $W = 270 \mu\text{m}$  and  $L = 10 \mu\text{m}$ . The bias conditions are  $V_{GS} - V_T = -20 \text{ V}$  and  $V_{DS} = -4 \text{ V}$ . Inset: Molecular structural formula of diF-TESADT (Jurcescu et al., 2008).

**Figure 8.34** (a) Microscope images of diF-TESADT channel OTFTs with different surface treatments of the source and drain electrodes for type 1, 2, and 3 structures. (b) Hole field effect mobility and (c)  $1/f$  noise spectrum vs. gate length ( $L$ ). Dashed lines indicate abrupt transitions in  $\mu_{FEp}$  (Jurcescu et al., 2008).

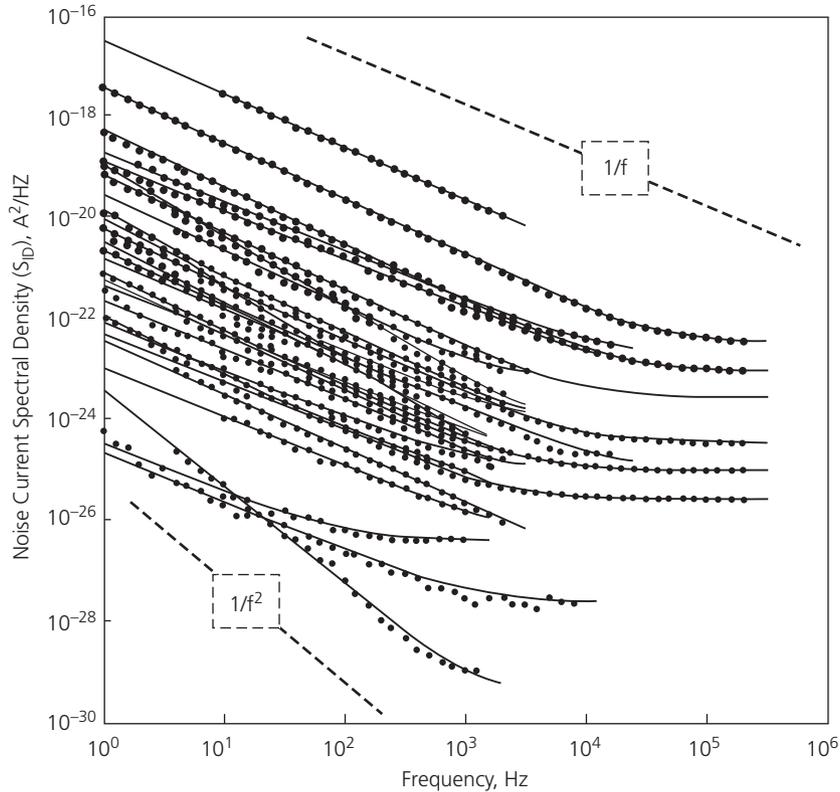

Typically,  $S_f$  is measured in the linear regime of OTFT operation. The charge density in the channel is thus:  $Q = \pm qN = WLC_i(V_{GS} - V_T)$ , such that

$$\frac{S_f}{I_D^2} = \frac{q\alpha}{WLC_i(V_{GS} - V_T)f^\gamma}. \quad (8.56)$$

Thus, the noise current scales inversely with gate area ( $WL$ ), and voltage,  $V_{GS}$ . Indeed, the relationship of

$S_f/I_D^2 \propto 1/L$  is apparent in Fig. 8.34c. A similar length-dependent scaling along with  $S_f/I_D^2 \propto 1/V_{GS}$  has been found for PTV, p-channel OTFTs (Vandamme et al., 2002).

The universality of the Hooge empirical relationship is shown by a compilation of the noise spectra measured from a large number of both small molecule and polymer OTFTs in Fig. 8.35. Regardless of

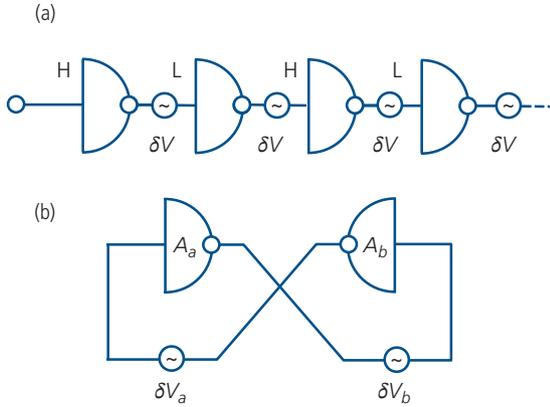

**Figure 8.35** Noise spectral densities for a variety of polymer and small molecule OTFTs (data points). Dashed lines show power laws for  $S_f \sim 1/f$  and  $1/f^2$ . Solid lines show fits to  $S_f(1\text{Hz})/f + S_{white}$  (Marinov and Deen, 2015).

the fabrication conditions, materials, device geometry, and other laboratory conditions used during measurement, with only one exception, the spectral density data (points in the figure) follow  $S_f(1\text{Hz})/f + S_{white}$  (solid lines). The white noise component ( $S_{white}$ ) provides an asymptotic value of  $S_f$  at high frequencies for many of the data sets. White noise has two possible origins: it represents either the noise floor of the measurement system, or it is due to channel noise given by Eq. 8.52. It is indeed remarkable that the dominant noise source in OTFTs is nearly independent of the details of the device or fabrication conditions. Statistical analyses of this population gives  $\gamma = 1.1 \pm 0.2$ , with a Hooge parameter that has a statistical spread with a standard deviation of  $\sigma \sim 9 \text{ dB}_{10}$ . This is no larger than that for inorganic CMOS and bipolar transistors. However, the magnitude of the flicker noise in OTFTs is  $\sim 3000$  times higher than for inorganic devices (Marinov and Deen, 2015).

In addition to random fluctuations in the noise current, variations in  $V_T$  due to small differences in the insulator/channel interface defect density or distribution, film morphology from process variations

during fabrication, unintentional doping or impurities in the channel, etc. determine whether or not a circuit consisting of a series of stages can consistently operate in a fault-free manner. The transistor noise margin provides a quantitative metric that characterizes the ability of a transistor to operate reliably (i.e. its “robustness” to variations from device to device) in a circuit. The noise margin is the maximum variation tolerated at the output of a logic gate that results in error-free switching at the input of the following gate in a circuit.

The noise margin can be understood in the context of an infinite chain of inverters in Fig. 8.36a. The challenge is to determine if the voltage noise at the input of an inverter rises to a level that inadvertently swings its output to a state (e.g. from high, H, to low, L) that is different from that required by the previous stage (e.g. H). Figure 8.36b shows the equivalent circuit of the logic chain that can be modeled as a cross-coupled inverter pair with noise sources  $\delta V_a$  and  $\delta V_b$ . In the equivalent, an H output from amplifier  $A_a$  drives the output of amplifier  $A_b$  to L. This is identical to each pair of gates in the infinite circuit in Fig. 8.36a.

**Figure 8.36** (a) An infinite chain of inverters with the high (H) and low (L) inputs at alternate stages. The noise voltage input at each stage contributed by the previous stage is  $\delta V$ . (b) Equivalent circuit of the infinite chain. Each stage has a voltage gain of  $A$ .

The transfer function of the cross-coupled pair is shown in Fig. 8.37. The curve corresponding to  $V_{out} = f(V_{in})$  is the transfer characteristic of an inverter (e.g. with its circuit shown schematically with its transfer function in Fig. 8.29). Its cross-coupled pair is shown as the mirror image,  $V_{in} = f^{-1}(V_{out})$ , where  $V_{out}$  is the stage output and  $V_{in}$  is its input voltage. The circles in the figure indicate the voltage at which the drive transistor transitions from the linear to the saturation regime ( $V_{in,a}$ ) with the load in saturation, or when the load transistor moves from the saturation to the linear regime ( $V_{in,b}$ ) with the drive transistor in saturation.

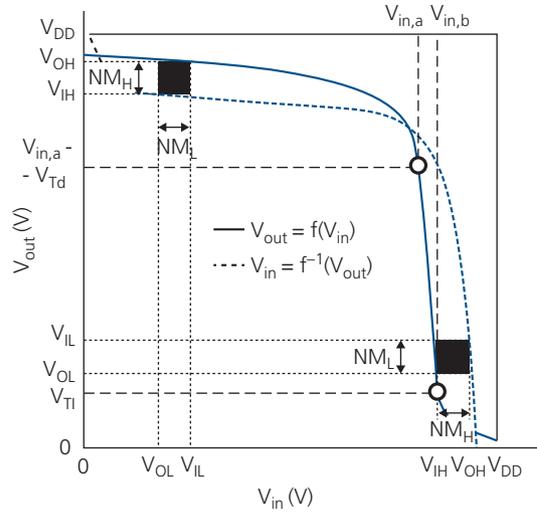

The inverter operates error free if the input voltage is greater than  $V_{IH}$ , which corresponds to the minimum voltage needed to assure the inverter will switch to its output low voltage,  $V_{OL}$ . Similarly, a low input voltage must be less than  $V_{IL}$  to drive the output into its high state at  $V_{OH}$  (Hauser, 1993). These operating conditions are summarized as follows:

$$\begin{aligned} V_{in} \leq V_{IL} &\Rightarrow V_{out} \geq V_{OH} \\ V_{in} \geq V_{IH} &\Rightarrow V_{out} \leq V_{OL} \\ &V_{IH} > V_{IL} \end{aligned} \quad (8.57)$$

We define the noise margins for the high and low states as

$$\begin{aligned} NM_H &= V_{OH} - V_{IH} \\ NM_L &= V_{IL} - V_{OL} \end{aligned} \quad (8.58)$$

The noise margins are shown graphically by the solid rectangles in Fig. 8.37 for a cross-coupled inverter. For the most robust operation, the area within the rectangles should be maximized. Comparison with Fig. 8.37 suggests there are two ways to increase

**Figure 8.37** Illustration of the noise margin ( $NM$ ) of a series of inverters as in Fig. 8.36 (De Vusser et al., 2006).

$NM$ : decreasing the stage gain, which decreases the slope of the transfer characteristics,  $A_{vI} = \partial V_{OUT} / \partial V_{IN}$ , and shifting the threshold voltage of the drive and load transistors to move the transfer characteristic in a direction that increases the separation between input and output states in Eq. 8.57.

### 8.4 Alternative thin film transistor architectures

Figure 8.2 illustrates various common OTFT configurations. However, several other transistor designs have been explored due to potential applications not served by the conventional, lateral architecture. These include dual gate OTFTs, depletion mode, and vertical channel transistors. In this section we describe several of these alternative designs and what they offer that differs from those already discussed.

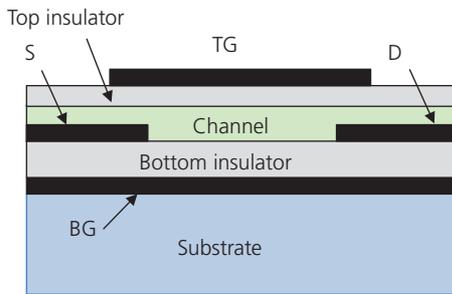

#### 8.4.1 Dual gate OTFTs

The dual gate OTFT shown in Fig. 8.38 consists of the channel sandwiched between two insulators with opposing gate contacts, called the bottom and top gates. Voltage applied to the bottom gate changes the potential across the channel, which in turn changes the operating point (i.e.  $V_T$ ) of the transistor. The device can be thought of as two parallel transistors sharing a common channel. For example, consider a p-channel OTFT operating in the accumulation-saturation regime. Then, the top gate potential is  $V_{GT} - V_{TT} < 0$ , where  $V_{GT}$  is the top gate-source voltage, and  $V_{TT}$  is

the top gate threshold voltage, both of which are  $< 0V$ . Application of a small positive potential to the bottom gate ( $V_{GB}$ ) partially depletes the channel. This reduces the charge at the top of the channel (the top channel) by the ratio of the bottom-to-top capacitances,  $C_B$  and  $C_T$ , respectively. The effect is a shift of the top channel threshold voltage by:

$$\Delta V_{TT} = \frac{C_B}{C_T} V_{GB}. \quad (8.59)$$

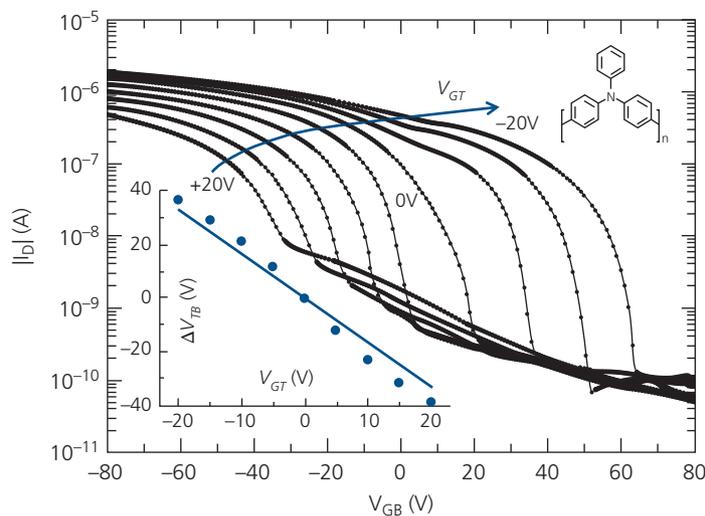

Conversely, if the bottom gate is negatively biased, the top gate threshold is shifted in the opposite direction. At some point,  $V_{GB} - V_{TB} < 0$ , where  $V_{TB}$  is the threshold voltage of the bottom gate, leading to accumulation at the bottom channel. Since the source and drain contacts of both the OTFTs are shared, this additional accumulation layer adds to the total drain current. Increasing  $|V_{GB}|$  higher than  $|V_{GT}|$  eventually leads to a shift of the accumulation layer to the bottom channel while completely depleting the top channel.

**Figure 8.38** Schematic cross-section of a dual gate OTFT.

The second gate can be used to control the threshold voltage over a substantial range, which increases the noise margin in large integrated circuits. Indeed, very large circuits including a 99-stage ring oscillator and a 64-bit radio frequency identification (RFID) transponder have been demonstrated using dual gate OTFT technology (Myny et al., 2011). The design is appealing due to its simplicity, and its compatibility with methods used in fabricating large and complex circuits. The top insulator can also serve as an encapsulation layer that can retard degradation in performance over time. Requiring a more complex biasing scheme consisting of four rather than three terminals to each transistor partially offsets benefits gained by its fabrication simplicity.

Dual gate transistors have been implemented using several different small molecule and polymer semiconductor channels (Cui and Liang, 2005, Gelinck et al., 2005, Morana et al., 2005, Maddalena et al., 2008, Brondijk et al., 2012). Example transfer characteristics of a dual gate PTAA, p-channel OTFT are shown in Fig. 8.39. The bottom gate-substrate/insulator combination is p-Si/ $1\ \mu\text{m}$   $\text{SiO}_2$  functionalized with HMDS before the 80 nm thick PTAA channel is deposited. The top gate/insulator comprises a Au contact on 400 nm thick PIBM. At  $V_{GT} = 0$ , the device behaves as a single gate transistor with  $V_{TB} = 0$  V. As the top gate is positively biased, the channel depletes, resulting in a threshold shift towards more negative  $V_{GB}$ . The additional potential is required to restore the charge under the bottom gate to its value at  $V_{GT} = 0$ . Conversely, as the top gate is negatively biased, the

**Figure 8.39** Drain current vs. bottom gate bias ( $V_{GB}$ ) characteristics for a PTAA dual gate transistor with  $W = 1$  cm by  $L = 10\ \mu\text{m}$ , operating in saturation. The curves correspond to various top gate biases ( $V_{GT}$ ) in 5V steps. Bottom inset: Threshold voltage shift of the bottom gate vs.  $V_{GT}$ . Top inset: Molecular structural formula of PTAA (Spijkmann et al., 2008).

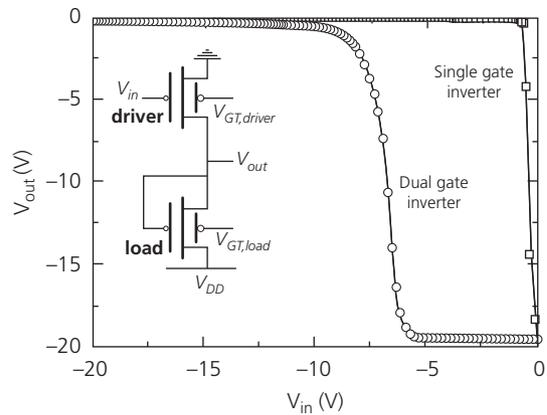

top channel enters the accumulation mode, and the transfer characteristics require more positive bias to maintain the same drain current (i.e. the charge in the bottom channel is reduced, thereby decreasing  $I_D$ ). The linear dependence of the threshold shift on  $V_{GT}$  predicted by Eq. 8.59 is shown in the lower inset. The threshold voltage is varied over approximately 80 V, with a 40 V swing in  $V_{GT}$  (Spijkmán et al., 2008).

The change in slope at  $V_{GT} < 0V$  and  $V_{GB} > 0$  is due to increasing depletion of the channel with  $V_{GB}$ , as the conducting region shifts toward the top gate. The charge density in the top accumulation region is much larger than the background concentration in the channel. Hence, once the channel is depleted all the way to the top accumulation region, an additional bottom gate voltage must be applied to completely turn off the drain current. Hence, sweeping charge from the undoped channel region takes less voltage than doing so in the accumulation region, resulting in the change in slope, indicated by the kink at bottom gate biases between 10 V and 20 V. The channel leakage current is also affected by changes in  $V_{GT}$ . When the channel is strongly depleted at  $V_{GT} > 0$ , the OTFT leakage is significant (see the rising current following the steep drop in drain current), and is equal to the top channel current.

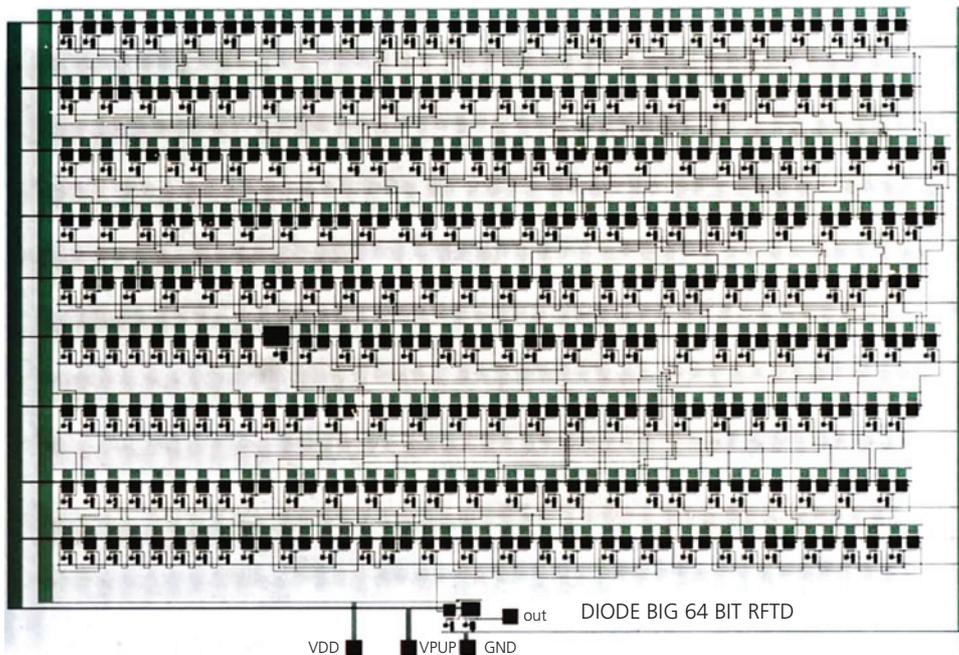

Increased noise margins are achieved using inverters comprising the dual gate OTFT in Fig. 8.39. The inverter circuit and its transfer characteristics are

shown in Fig. 8.40. Due to the ability to shift the threshold voltage, the noise margin of the inverter is dramatically improved from that obtained using a single gate inverter. The dual gate  $NM = 5.9$  V is achieved at  $V_{GT,driver} = 50$  V and  $V_{GT,load} = -10$  V, compared to the single gate inverter with  $NM = 0.5$  V (Spijkmán et al., 2008).

Increasing  $NM$  using the dual gate design leads to reduced errors in circuit operation compared to single gate devices. This was necessary for the realization of the RFID transponder shown in Fig. 8.41 (Myny

**Figure 8.40** Inverter transfer characteristics of the PTAA dual gate OTFTs in Fig. 8.39. Also shown are the characteristics for a comparable single gate inverter circuit. Inset: Inverter circuit schematic (Spijkmán et al., 2008).

**Figure 8.41** Photographic image of a 64-bit RFID transponder operating at 4.3 kb/s using dual gate inverter logic (Myny et al., 2011). Copyright 2011 IEEE. Reprinted, with permission, from IEEE Journal of Solid-State Circuits, 46, 1223–30.

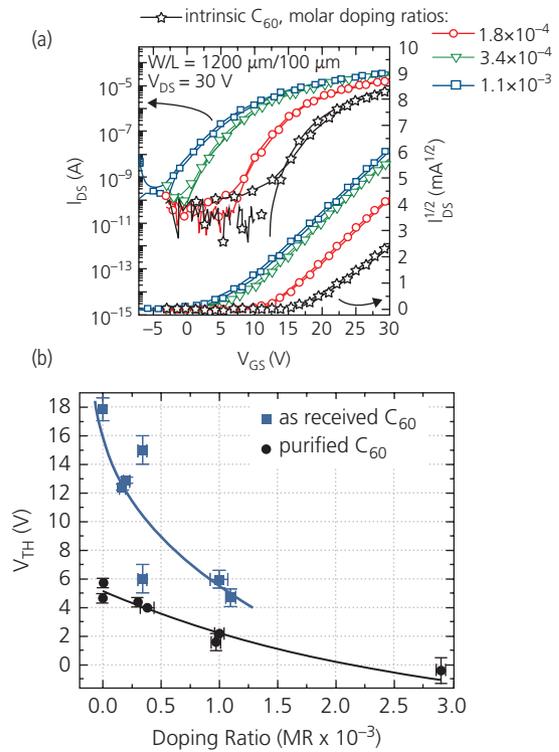

et al., 2011). The dual gate allows for flexibility in design of logic circuits that require both depletion and/or accumulation mode operation, level shifting, etc. The 4.3 kb/s circuit employs spin-cast pentacene dual gate transistors with a polyvinylphenol insulator for both top and bottom dielectrics (Gelinck et al., 2005). While dual gate transistors add some complexity that may not be necessary in simple analog circuits, they may well become indispensable in more sophisticated multistage digital circuits given their ability to precisely adjust the operating points of devices that otherwise may be subject to variations in materials properties and fabrication processes.

### 8.4.2 Doped channel OTFTs

We have noted that conventional OTFT channels are undoped. Nevertheless, unintentional doping can be a source of channel leakage that limits the on/off ratio, and also affects the threshold voltage. In contrast, intentional doping of the channel can compensate charges due to ionized impurities and defect states that lead to shifts in  $V_T$  (Abe et al., 2005, Lee and Chen, 2011, Hählen et al., 2012, Olthof et al., 2012, Hein et al., 2014, Lüssem et al., 2016), while it can significantly reduce channel contact resistance (Minari et al., 2007, Tiwari et al., 2010, Wakatsuki et al., 2011, Günther et al., 2016). It has been suggested that doping can lead to depletion and inversion mode operation (Lüssem et al., 2013), although convincing demonstrations of such OTFTs are absent.

The dependence of  $V_T$  on the purity of the channel semiconductor, and the impact of doping on the charge mobility has been investigated for BG/TC  $C_{60}$  n-channel OTFTs with dimensions  $W = 1.2$  mm,  $L = 100$   $\mu\text{m}$ , and a  $\text{SiO}_2$  dielectric with  $t_i = 200$  nm. The channel source material was either 99.9% pure  $C_{60}$  evaporated as-received from the supplier or after purification by vacuum thermal gradient sublimation (see Section 5.3.2). The channels were doped by co-evaporation with the n-type dimer dopant,  $[\text{RuCP}^*(\text{mes})]_2$ , at molar ratios ( $MR$ ) between  $1.8 \times 10^{-4}$  to  $1.1 \times 10^{-3}$ . The dopant molecules react to form two  $[\text{RuCP}^*(\text{mes})]^+$  cations that provide negative polarons to compensate positive charges from traps within the  $C_{60}$ .

The drain current transfer characteristics of the OTFTs employing as-received  $C_{60}$  with and without doping are shown in Fig. 8.42a. The threshold voltage is a sensitive function of  $MR$ , shifting from  $V_T = 17.9$  V for the undoped channel, to only 4.7 V for  $MR = 1.1 \times 10^{-3}$  (see Fig. 8.42b). The change of

**Figure 8.42** (a) Drain current transfer characteristics of n-channel OTFTs using as-received  $C_{60}$  channels that are undoped (labeled intrinsic), and with different molar ratios ( $MR$ ) of the acceptor,  $[\text{RuCP}^*(\text{mes})]^+$ . (b) Threshold voltages of as-received and purified  $C_{60}$  OTFTs vs. dopant  $MR$  (Olthof et al., 2012).

the threshold on doping concentration decreases as  $MR$  increases, setting an upper limit to the density of background charges. Similarly, the electron mobility increases from  $\sim 0.4$   $\text{cm}^2/\text{V s}$  for the undoped to 0.6  $\text{cm}^2/\text{V s}$  for the doped samples, also suggesting that the charge density in the channel increases with  $MR$ . In Section 4.3.2, we found that mobility increases with filling of the DOS, pushing the mobility edge closer to the LUMO. Hence, compensation of residual positive charge in the channel by doping increases the electron density, and hence  $\mu_{FEH}$ . Note also that the  $I_{on}/I_{off}$  is not strongly dependent on  $MR$ , increasing by only a factor of 10–30 over the entire range of  $MR$  studied.

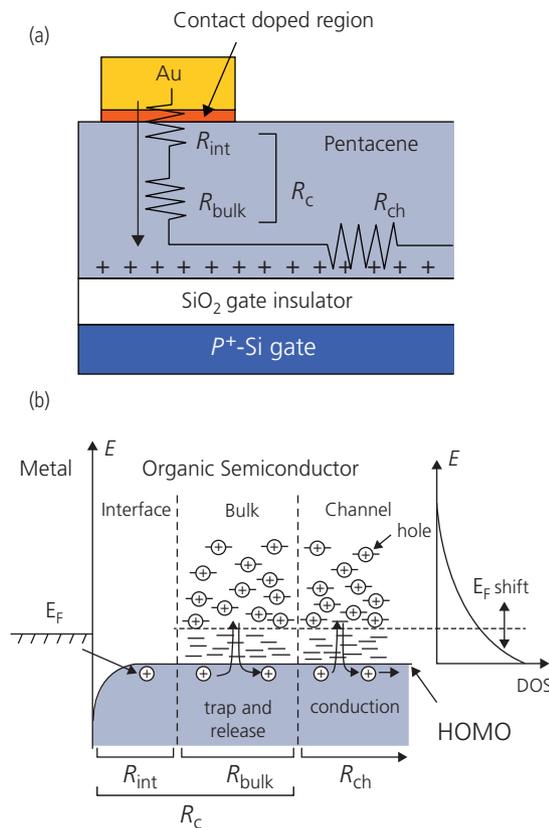

The effects on  $V_T$  are even more dramatic for channels employing pre-purified  $C_{60}$ . The  $V_T$  for the purified source material is 4.7 V, equivalent to that for the heavily compensated channel for the as-received  $C_{60}$ . Addition of the dopant is effective in neutralizing adventitious impurities in the as-received  $C_{60}$ . A second conclusion, also discussed in Section 5.2, is that material purification is essential to achieving high performance electronic and photonic devices (Bailey-Salzman et al., 2006). Additional doping

continues to reduce  $V_T$  to as low as  $\sim 0$  V at  $MR = 2.9 \times 10^{-3}$  (Fig. 8.42b). However, at this high doping concentration,  $I_{on}/I_{off}$  is reduced to 70 due to the high electron concentration in the channel. A second indication of the improved purity of the  $C_{60}$  is the relatively high mobility of  $\sim 1.6$ – $1.7$   $\text{cm}^2/\text{V s}$  for the intrinsic and doped OTFTs.

Transistor performance is influenced by the total output resistance, which is the series combination of the channel resistance,  $R_{ch} = 1/g'_D$  (cf. Eqs. 8.22 and 8.24), the depleted semiconductor under source and drain contacts,  $R_{bulk}$ , and the resistance of the contact itself to the channel layer,  $R_{int}$  (see Fig. 8.43a). Ignoring channel leakage, in the linear regime of operation, the total on-resistance of the OTFT above threshold is

$$R_{ON} = R_{bulk} + R_{int} + \frac{1}{g_D} = R_C + \frac{L}{\mu_{FE} W C_i (V_{GS} - V_T)}. \quad (8.60)$$

To separately determine  $R_C$  and  $R_{ch}$ , either the gate length or voltage is varied while measuring  $I_D$  vs.  $V_{DS}$ .

**Figure 8.43** (a) Detail of the source-channel contact and channel region of an OTFT. (b) Contact region showing the physical origins of the various resistances (Minari et al., 2007).

The slope gives  $R_{ch}$  and extrapolating the data to  $L \rightarrow 0$  gives  $R_C$ .

As the contact and other parasitic channel resistances increase, the measured output conductance decreases (see Eq. 8.24), which limits the gain in a common source inverting amplifier. Doping under the gate (Minari et al., 2007) or inducing damage from deposition of the metal contacts are means for reducing  $R_{int}$ . Doping, therefore, results in an output conductance that is limited by the depleted bulk resistance, and  $R_{ch}$ . The bulk resistance is found to follow the *Meyer-Neldel rule* (MNR) that asserts that conductivity is thermally activated:

$$\sigma = A \exp(-\Delta E_a/k_B T), \quad (8.61)$$

with a prefactor of

$$A = \sigma_0 \exp(\Delta E_a/k_B T_0). \quad (8.62)$$

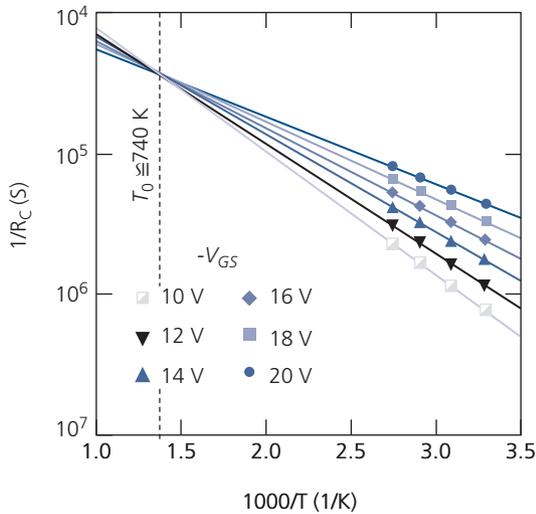

Here,  $\sigma_0$  is a constant and  $\Delta E_a$  is the activation energy. The MNR is found to be broadly applicable to disordered solids, and specifically to organic semiconductors (Kemeny and Rosenberg, 1970, Roberts, 1971, Gutmann et al., 1983, Metselaar and Oversluizen, 1984). There is no concise derivation of Eqs. 8.61 and 8.62, although the MNR has been attributed to thermal activation over the interface, a Schottky barrier between the metal and the semiconductor, thermally activated tunneling due to small polaron hopping between molecules (Kemeny and Rosenberg, 1970), or an exponentially decreasing DOS into the energy gap of the disordered semiconductor (Roberts, 1971). For this latter case,  $T_0$  is a characteristic temperature determined by the slope of the DOS, as illustrated in Fig. 8.43b. This is similar to  $T_0$  employed to model the current-voltage characteristics in disordered organic media discussed in Section 4.4.2.

Since  $R_{bulk} \propto 1/\sigma$ , we have from Eqs. 8.60 and 8.61:

$$R_{bulk} = R_{bulk0} \exp(-\Delta E_a/k_B T_0) \exp(\Delta E_a/k_B T), \quad (8.63)$$

where  $R_{bulk0}$  is a temperature-independent prefactor.

The validity of MNR has been explored in BG/TC pentacene OTFTs where the p-channel is doped with a 3 nm thick layer of the acceptor,  $F_4\text{TCNQ}$ , located immediately beneath the Au source and drain contacts; see Fig. 8.43a. With the doped layer, the interface resistance,  $R_{int}$  is three times less than in devices where it is absent. For doped contacts,  $R_{int} \ll R_{bulk}$ . The contact resistance vs.  $T$  at several gate voltages  $V_{GS} > V_T$  extracted from the OTFT in the linear regime ( $V_{DS}$  small) is shown in Fig. 8.44. A feature of Eq. 8.63 is that the resistance is thermally activated. The data taken at various  $V_{GS}$  intersect at a single point corresponding

**Figure 8.44** Contact resistance vs.  $1000/T$  for several gate voltages for the device in Fig. 8.43a with  $W \approx 1$  mm,  $L = 20$   $\mu\text{m}$ , and  $t_i = 200$  nm  $\text{SiO}_2$ . The resistances are thermally activated, crossing at  $T_0 = 740$  K, corresponding to an activation energy of  $\Delta E_a = 64$  meV. After Minari et al. (2007).

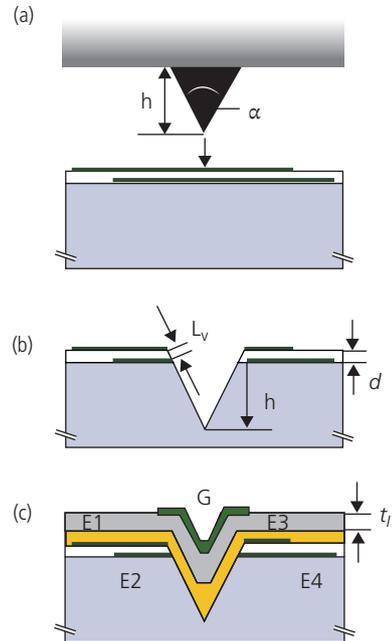

to  $T_0$ , indicating that the approximation of  $R_C \cong R_{bulk}$  is valid. The data yield an activation energy of  $\Delta E_a = k_B T_0 = 64$  meV (Minari et al., 2007). This is double that of the channel conductance, suggesting that hopping between molecules stacked end-to-end in the bulk, and parallel to the substrate plane requires less energy compared to that needed to overcome the contact barrier.

The thermal activation of  $R_{bulk}$  inferred from Fig. 8.44 indicates the bulk conductivity is ultimately limited by charge trapping in an exponential DOS. A similar situation results in an increase in channel conductivity with  $V_{GS}$  as the Fermi energy approaches the HOMO energy. The injection process is illustrated schematically in Fig. 8.43b.

While doping of the contacts and the bulk are both means for improving the output characteristics of an OTFT, it can also increase the channel conductance to the point that  $I_{on}/I_{off}$  is significantly reduced (Lim et al., 2007, Lee and Chen, 2011, Olthof et al., 2012).

### 8.4.3 Vertical organic field effect transistors

The current sourced by the OTFT and its frequency response are limited by the channel length,  $L$ . Large gate lengths require large  $V_{DS}$  for the device to achieve saturation. In many of the examples above,  $V_{DS}$  between 20 and 100 V are common. Orienting the gate along the vertical direction, perpendicular to the substrate plane, in principle, eliminates this

**Figure 8.45** Fabrication sequence for a vertical organic field effect transistor (VOFET). (a) Source and drain contacts (black) separated by a polymer insulator (gray) of thickness  $d$  are deposited onto a plastic substrate. (b) It is cut by a wedge-shaped punch, leaving a "V"-shaped notch in the layers and substrate. (c) The polymer channel layer (orange) is deposited, followed by the gate insulator and the top gate contact (Stutzmann et al., 2003).

shortcoming. In the *vertical organic field effect transistor* (VOFET), the gate length is determined by the channel layer thickness (a few hundred nanometers), which in principle should lead to high frequency operation. In this geometry the current is determined by the device diameter, which can be considerably higher than in lateral OTFTs with a similar device footprint. An example VOFET and its fabrication process is illustrated in Fig. 8.45. The source and drain contacts are deposited on a PET substrate, and are separated from each other by a 700 nm thick insulating layer of PVP. This trilayer structure is embossed using a V-shaped metal wedge of height  $h = 10$   $\mu\text{m}$ , and with angle  $\alpha = 70^\circ$ . The wedge cuts a channel through the metal contacts and the substrate. The  $p$ -channel material, F8T2, is deposited from solution. The gate insulator is a second PVP layer, followed by the gate contact electrode.

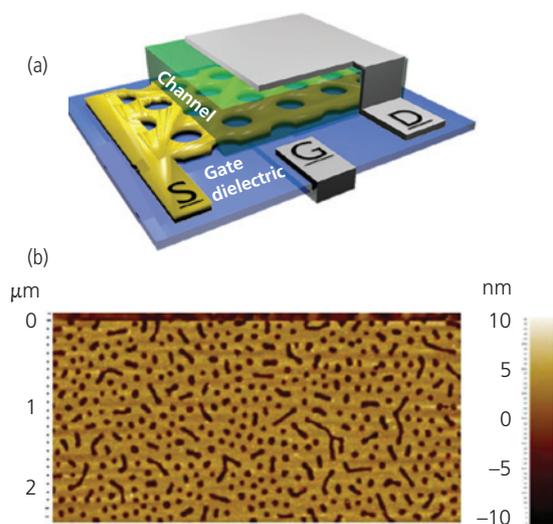

The VOFET can be operated employing two geometries. By using electrodes E1 and E3 as source and drain, a conventional planar OTFT is accessed with  $L = 12$ – $17$   $\mu\text{m}$  as defined by the depth of the embossed pattern. In the second geometry, E1 and E2 or E3 and E4 are the source and drain electrodes, and in this case the gate length is only  $L_v \approx 900$  nm.

The  $\mu_{FE}$  measured for both device geometries is in the range  $2\text{--}3 \times 10^{-3} \text{ cm}^2/\text{V s}$ , consistent with conventional F8T2 OTFTs. The devices did not turn off entirely at  $V_{GS} = 0$ , which limited the on/off ratio to only  $\sim 10^3$ . Also, the VOFET (E1–E2) did not exhibit saturated characteristics: apparently it only operated in the linear regime. While no high frequency characteristics were provided, it is expected that the frequency response is limited by the parasitic drain-source capacitance that results from substantial overlap of the contacts separated by only a thin layer of insulating PVP. The drain current of  $I_D = 6 \mu\text{A}$  is 20 times larger than that for the planar OTFT, although the operating voltages ( $V_{GS} = V_{DS} = -20 \text{ V}$ ) are approximately the same for both geometries. Hence, while this architecture has attributes of high drain current, low voltage and potentially high frequency operation, these have not been demonstrated by the devices in Fig. 8.45 (Stutzmann et al., 2003).

A second approach to the VOFET uses a *permeable source electrode* illustrated in Fig. 8.46a (Ben-Sasson et al., 2009). The gate electrode is positioned beneath the gate dielectric, while the source and drain electrodes are vertically stacked with the channel layer sandwiched between them. A Schottky barrier between the source electrode and the channel or a thin oxide coating prevents leakage when  $V_{GS} = V_{DS} = 0$ . As gate bias is applied, the barrier is lowered, and current is injected into the channel, creating a conductive path from source to drain.

The permeable source contact pores are approximately equal to the organic channel thickness. This is done by depositing a rough and very thin metal layer onto the gate dielectric (Ma and Yang, 2004) that is almost certainly discontinuous, containing a distribution of fissure sizes and spacings. Alternatively, the permeable source is fabricated by depositing a copolymer where one component is dissolved away with a material-selective solvent, leaving behind the remaining copolymer that forms micropillars of the desired height and spacing. The micropillars are coated with a thin gate metal. The pillars are subsequently removed by immersing in a second solvent, only leaving metal between the pillars. An image of a permeable, 10-nm-thick Au source electrode is shown in Fig. 8.46b.

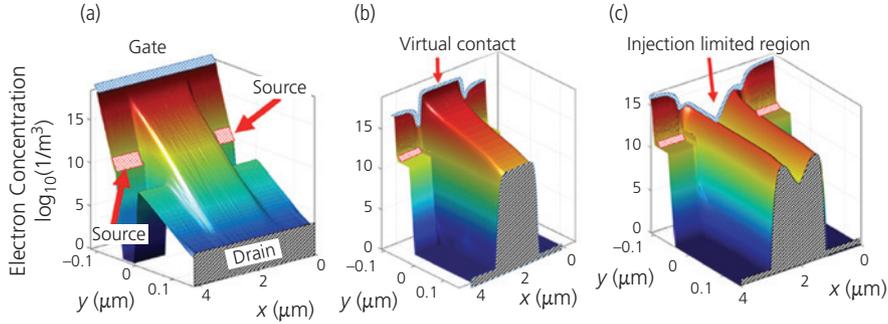

The operating principle of the n-channel permeable source transistor is understood from the simulated charge densities at several  $V_{DS}$  (with  $V_{GS} = 5 \text{ V}$ ) shown in Fig. 8.47. At  $V_{DS} = 0$ , no charge flows from source to drain due to the Schottky barrier or oxide layer between permeable source layer and the semiconductor channel (Fig. 8.47a). A charge

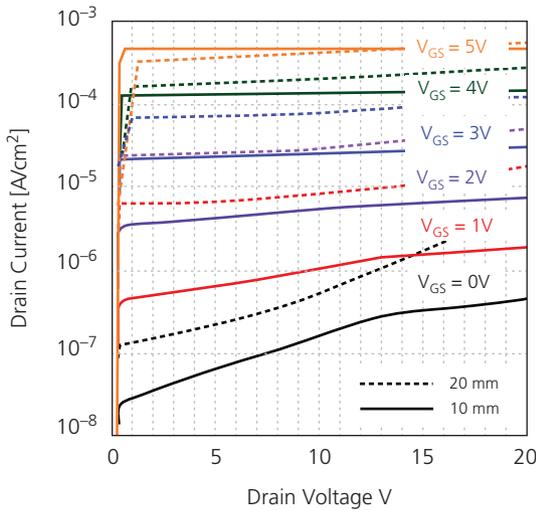

**Figure 8.46** (a) Schematic of a permeable source VOFET (Ben-Sasson et al., 2012). (b) Atomic force microscope image of a 10 nm thick Au grid patterned via lift-off used as the source electrode (Ben-Sasson et al., 2009).

accumulation layer forms at the gate dielectric interface within the pores due to the positive gate potential. As the drain potential is made positive ( $V_{DS} = 5 \text{ V}$ , Fig. 8.47b), electrons are drawn into the channel due to field lowering of the source contact energy barrier. Current between source and drain increases linearly with voltage, and the transistor enters the linear regime. As the drain voltage is increased, the demand for charge at the drain exceeds the supply from the source. The current is limited by space charge injection, and hence is no longer linearly dependent on voltage. The current is higher near the edges of the source electrode, that is, at the point of injection, and lower toward the center, as shown in Fig. 8.47c. The output current henceforward increases only slowly with  $V_{DS}$  as the transistor characteristics become saturated.

The drain current can be increased by depositing a layer of semiconductor onto the gate insulator prior to deposition of the permeable S contact. This effectively increases the area of the contact by allowing charge extraction from the entire pore area rather than only from its periphery. Increasing the layer thickness beneath S increases the area of this “virtual contact.” Calculated output characteristics for a PTCDI- $C_8$  channel transistor assuming  $\mu_n = 0.1 \text{ cm}^2/\text{V-s}$  for 10 nm and 20 nm thick buried source layers are shown in Fig. 8.48. There are several features of note from these simulations. The first is the very narrow linear region, that gives way to saturation at  $V_{DS} \ll V_{GS}$ . Also, the current is high compared to a conventional OTFT due to the very short channel length,

**Figure 8.47** Calculated charge density in an n-channel permeable source transistor at operating points of  $V_{GS} = 5$  V and  $V_{DS}$  of (a) 0 V, (b) 5 V, and (c) 8 V. The barrier height at the source/channel contact is 0.7 eV (Sheleg et al., 2017).

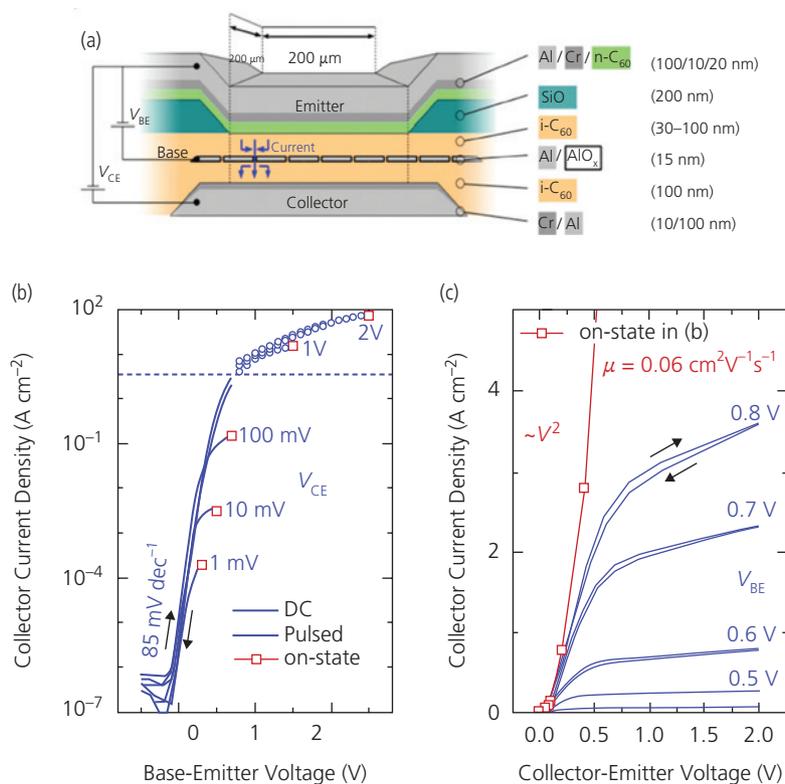

**Figure 8.48** Calculated characteristics of a PTCDI- $C_8$  VOFET with a 10 nm or 20 nm thick buried source contact semiconductor layer. The channel layer thickness is 150 nm, and the  $SiO_2$  gate insulator is 40 nm thick (Sheleg et al., 2017).

which is equal to the device thickness of 150 nm. For example, drain currents of up to  $4 \text{ A/cm}^2$  are more than sufficient to drive an OLED (Ma and Yang, 2004), although the cutoff frequencies are limited by the high gate-source and drain-source capacitances due to complete overlap of the S and D contacts with the gate. As expected, the current is increased with the thickness of the buried source film, since this increases the cross-sectional area effective in charge injection. Finally, the output conductance of vertical transistors tends to be high due to thermionic emission across the source/channel barrier (Ma and Yang, 2004, Ben-Sasson et al., 2009, 2012). This limits the amount of gain that can be achieved, and hence the noise margin of circuits employing the VOFET may be small. High  $g_D$  also reduces the on/off ratio, although  $I_{on}/I_{off} > 10^6$  has been achieved.

A permeable base transistor is an alternative vertical geometry that provides high current gain (Fujimoto et al., 2005, Fischer et al., 2012, Klinger et al., 2017). Its operating principle is similar to a vacuum tube triode or a bipolar junction transistor as opposed to a gate-voltage-controlled FET. An illustration of a permeable base transistor is shown in Fig. 8.49a. The device consists of an organic semiconductor sandwiched between ohmic emitter and collector electrodes. The current is controlled by interposing a very thin, permeable metal sheet (in this case, Al) near the center of the organic thin film. The base contact metal is oxidized in air for several minutes at elevated temperatures. This creates an insulating barrier around the electrode to prevent the flow of base current. It also may create pinholes due to crystallization of the organic that protrudes through fissures in the metal layer. The penetration of the organic permits unimpeded charge transport from emitter to collector (Fischer et al., 2012). An alternative explanation for the base current is hot electron transport across the base metal, that is, high energy electrons are emitted from the  $C_{60}$  into the base whose thickness is on the order of or less than their mean free path of  $\sim 50$  nm. Hence, electrons can penetrate the base without loss until the thickness exceeds this limit (Fujimoto et al., 2005).

The common emitter current gain is  $h_{FE} = \partial I_C / \partial I_B$ , where  $I_C$  is the collector and  $I_B$  is the base current. The device in Fig. 8.49 shows a maximum of  $h_{FE} = 10^5$  at a base-emitter voltage of  $V_{BE} = 1$  V; a value that is comparable to high performance inorganic heterojunction (HJ) bipolar transistors (Streetman and Banerjee, 2006). Furthermore, the base transport factor is given by:  $\alpha_{CE} = \partial I_C / \partial I_E$ , where  $I_E$  is the emitter current. Hence,  $\alpha_{CE}$  is a measure of the loss of current as it transits the base electrode. Since  $I_E = I_C + I_B$ , then

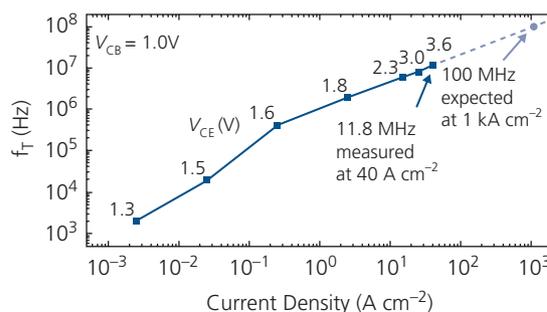

$$h_{FE} = \frac{\alpha_{CE}}{1 - \alpha_{CE}}. \quad (8.64)$$

**Figure 8.49** (a) Schematic view of a permeable base transistor based on undoped (intrinsic)  $i\text{-C}_{60}$ , and an oxidized Al base layer. (b) Transfer and (c) output characteristics of the transistor. The squares in (b) indicate the transition from the linear to saturation regime. High current density data are taken in pulsed mode to minimize Joule heating. In (c) the linear regime is dominated by space charge limited transport, yielding an electron mobility of  $0.06 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  (Klinger et al., 2017).

Thus, for the transistor in Fig. 8.49, we obtain  $\alpha_{CE} = 99.999\%$ , indicating near lossless transport through the permeable base.

From the transfer characteristics in Fig. 8.49b, the device delivers a current density of  $75 \text{ A/cm}^2$  at  $V_{CE} = 2 \text{ V}$ , and  $V_{BE} = 2.5 \text{ V}$  under pulsed operation. This is increased to  $>1 \text{ kA/cm}^2$  by increasing the emitter area, thus reducing limitations due to current injection. This is orders of magnitude higher than the current that is sourced by conventional, lateral geometry OTFTs. Other characteristics of the permeable base transistor are  $I_{on}/I_{off} = 10^8$  and  $S = 85 \text{ mV/decade}$ ; the latter parameter nearly equal to the theoretical minimum of  $60 \text{ mV/decade}$  (cf. Eq. 8.34). The output characteristics in Fig. 8.49c indicate that the linear regime is dominated by space-charge-limited injection from the emitter, following its characteristic  $I_C \sim V_{CE}^2$  behavior (see Section 4.4.2). From these data, the electron mobility in the vacuum-deposited  $i\text{-C}_{60}$  layers is  $\mu_n = 0.06 \text{ cm}^2/\text{V s}$ . Note that this is bulk and not a field effect mobility measured in the lateral OTFT configuration. As is the case for all triode

**Figure 8.50** Cutoff frequency vs.  $I_{CE}$  and  $V_{CE}$  of the transistor in Fig. 8.49 (Klinger et al., 2017).

architectures, the output conductance is comparatively high, leading to a potentially low voltage gain when used in common-emitter circuits.

Given the short emitter-collector distance, we expect that the transit time across the transistor bulk will be short, even though the mobility is low. Indeed, this is found to be the case from the data for the transfer frequency vs.  $I_C$  in Fig. 8.50. A  $f_T = 11.8 \text{ MHz}$  is

obtained at  $40 \text{ A/cm}^2$ , which is approximately half of that obtained in a  $C_{60}$  OTFT with  $L = 2 \text{ }\mu\text{m}$  (Fig. 8.26). The projected frequency response is 100 MHz at  $I_C = 1 \text{ kA/cm}^2$ . However, this projection does not account for contact resistance effects that become increasingly dominant at high currents and frequency.

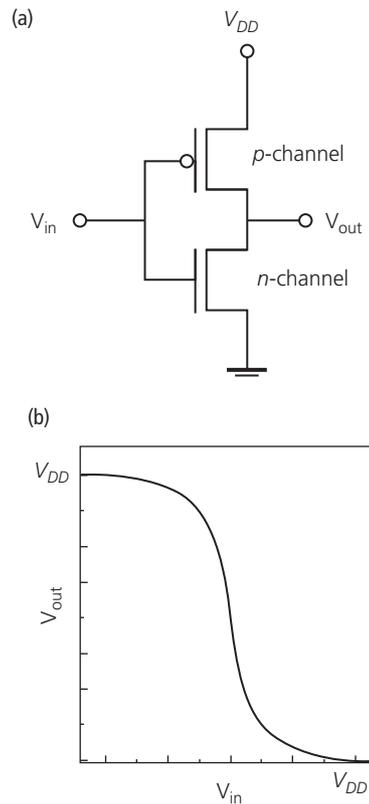

There are several variants to vertical transistors beyond those discussed here, including static induction transistors (Kudo et al., 1998) and devices employing a variety of other permeable base and source concepts. A common attribute of these alternative structures is that their output currents fail to enter saturation, they require very precise control of fabrication parameters, and have high output capacitance, and hence presumably low cutoff frequencies. Countering these disadvantages is their ability to source high currents at low voltages. Nevertheless, conventional single and dual gate OTFTs dominate applications comprising integrated circuits from simple inverters to ring oscillators, shift registers and other digital and analog circuits.

#### 8.4.4 Complementary logic and ambipolar transistors

Unipolar conduction in the channel is limited by several factors, including the contact work functions or metal/insulator barriers that preferentially inject one carrier type, or asymmetries in mobilities between holes and electrons that leads to low resistance transport for one or the other, but not both carriers. However, some channels can have balanced hole and electron mobilities, and contacts can be engineered to inject electrons and holes with equal efficiency. In such cases, reversing the polarities of  $V_{DS}$  and  $V_{GS}$  can result in the conduction of either charge, but in opposite directions. *Ambipolar transistors*, or integrated combinations of *n*- and *p*-channel transistors, enable *complementary logic* circuits that form the foundation of all modern electronics (known as complementary MOS, or CMOS). A complementary logic inverter circuit is shown in Fig. 8.51a. An *n*-channel and *p*-channel FET are connected in series, or for ambipolar devices, a single OTFT type is used in both positions. When  $V_{in}$  is in the logical "high," or H state (i.e.  $V_{in} = V_{DD}$ ), the *p*-channel OTFT is off, and the *n*-OTFT is on (i.e. conducting), and hence  $V_{out} = 0$ , that is, in the "low" or L state. When  $V_{in} = 0$ , the *p*-channel OTFT turns on with the *n*-channel off, and  $V_{out} = V_{DD}$ . Thus, the circuit output switches its logical state to H. The transfer characteristic of this inverter is shown in Fig. 8.51b. The advantage of this circuit compared to the unipolar inverter in Fig. 8.29,

and the reasons for its widespread adoption in electronic logic circuits, is its low static power dissipation. Since one of the transistors is always off, the circuit is non-conducting (i.e.  $I_D = 0$ ) except during the brief time that it switches its logic state. Furthermore, given the very low  $I_{off}$  of enhancement mode transistors, the circuit has a high noise margin that leads to robust, error-free operation in integrated circuits.

An integrated combination of *n*- and *p*-channel OTFTs with nearly balanced electronic properties is illustrated in Fig. 8.52. The fabrication of this circuit on a flexible PEN substrate involves five vacuum depositions through a series of shadow masks to pattern (i) the Al gate contacts, (ii) the gate interconnection vias followed by deposition of the gate insulator consisting of  $\sim 3 \text{ nm}$  thick  $\text{Al}_2\text{O}_3$  whose surface is functionalized by a 25%/75% mixture of an alkyl/fluoroalkyl phosphonic acid SAM, resulting in a total insulator thickness of 5.7 nm. The SAM lowers the threshold voltage (see Section 8.6.1), (iii) the 12 nm thick *p*-channel semiconductor comprising DPh-BTBT, (iv) the 15 nm thick *n*-channel semiconductor, N1100, and finally (v) the

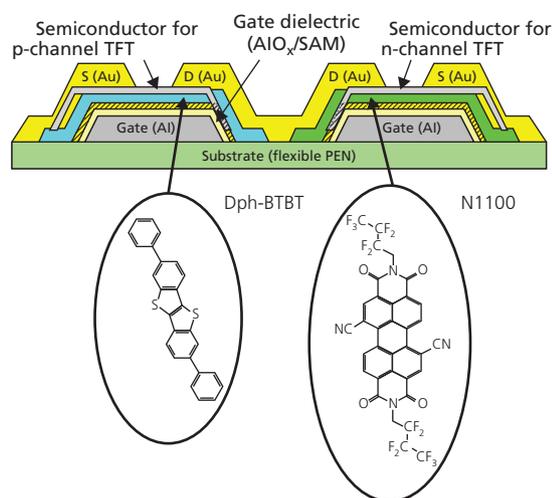

**Figure 8.51** (a) Complementary inverter circuit comprising series-connected *p*- and *n*-channel OTFTs. Note the different symbols used for the complementary transistors. (b) Transfer characteristic of the inverter circuit.

Au source and drain contacts. The need to align the several masks results in a relaxed gate dimension of  $L=40\ \mu\text{m}$  with gate-to-source and gate-to-drain overlaps of  $80\ \mu\text{m}$  each (Zschieschang et al., 2017).

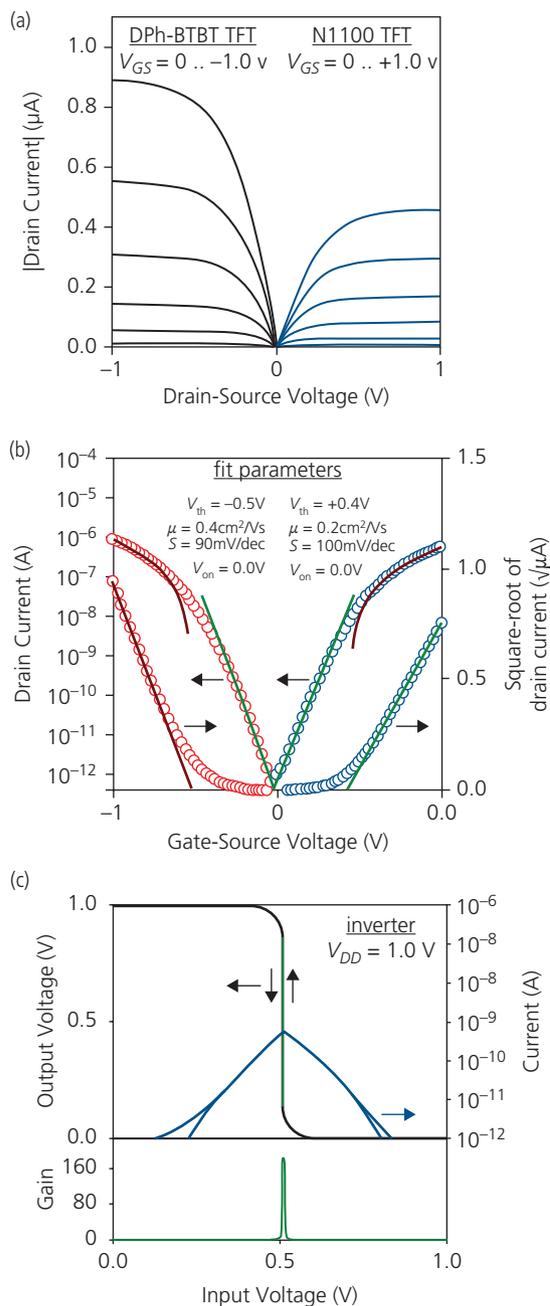

The characteristics of the  $n$ - and  $p$ -channel OTFTs with  $W = 1\ \text{mm}$  are nearly balanced, as shown in Fig. 8.53a and b. Fits to the drain current transfer characteristics in the saturation region show  $|V_T| < 0.5\ \text{V}$ , and nearly equal mobilities and sub-threshold slopes for the complementary pair. The transfer characteristics of the circuit in Fig. 8.53c show logic state switching at  $V_{in} = 0.5\ \text{V}$ , and a maximum switching current of  $1\ \text{nA}$ . The static power dissipation of the circuit is  $< 1\ \text{pW}$ . This is in marked contrast to the unipolar inverter that draws significant current even in the quiescent mode, and points to the low-power advantage of complementary logic. Furthermore, this circuit shows a maximum voltage gain of  $A_v = 160$ . One disadvantage of very low voltage, and hence low power, is that the gate takes longer to charge during switching. Hence, the cutoff frequency obtained from a five-stage ring oscillator with a  $\tau_{delay} = 20\ \text{ms}$  is only  $f_T = 1/(2\tau_{delay}) = 25\ \text{Hz}$ . As the supply voltage is increased along with the static and switching powers, the cutoff frequency also increases.

While the performance of the complementary circuit can be modified for a particular application, circuit fabrication can be complex and lead to compromises in design (e.g. large alignment tolerances are required for positioning multiple shadow masks without error). An alternative approach is to use dual ambipolar OTFTs in place of separate  $n$ - and  $p$ -channel transistors. This eliminates the need for

**Figure 8.52** Integrated complementary p- and n-channel OTFTs employing the vapor deposited small molecules shown (Zschieschang et al., 2017).

separate deposition steps for electron and hole conducting channels. There are three different architectures for achieving ambipolar OTFT operation. (i) Use a bilayer channel, with one layer having a high electron mobility and the other a high hole mobility (Kang et al., 2005, Kuwahara et al., 2005, Wang et al.,

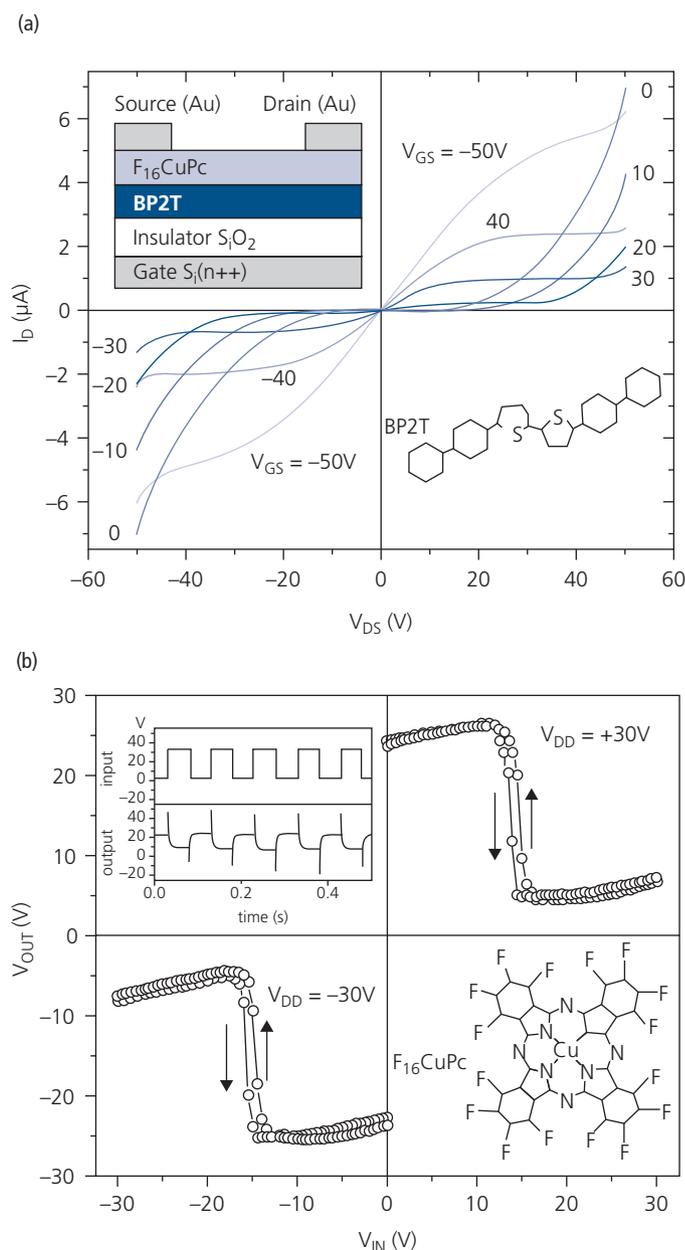

**Figure 8.53** (a) Drain current and (b) transfer characteristics of the  $n$ - and  $p$ -channel OTFTs in Fig. 8.52. Lines are fits to the data (points) using the theory in Section 8.3. (c) Transfer characteristics of the integrated complementary inverter showing the gain (lower panel) and drain current during switching (Zschieschang et al., 2017).

2006). Since two different layers are deposited sequentially, this design preferentially employs vacuum deposited small molecules, where dissolution of pre-deposited, thin layers is not a concern. (ii) Use a single layer whose source and drain contacts have small barriers to electron and hole injection. It is preferable to use different metals for source and drain (one with large work function for hole injection, and the other with a small work function for electron injection) (Schmechel et al., 2005). Alternatively, a narrow energy gap channel semiconductor can be used with a small injection barrier to either carrier. This

promotes ambipolar charge injection at the cost of increased channel leakage due to thermal generation (see Chapter 4). (iii) Use a blend of a hole and electron conducting organic semiconductor channel material (Meijer et al., 2003). Given the ease with which materials can be blended in solution, polymers are well suited for this purpose. In the following we provide examples of each of these architectures, with a further discussion of potential materials combinations that support ambipolar conduction in Section 8.6.

In Fig. 8.54a we show the bipolar output characteristics of a bilayer of the electron conducting  $F_{16}CuPc$ ,

**Figure 8.54** (a) Ambipolar drain current characteristics of the bilayer OTFT with  $L = 180 \mu\text{m}$ ,  $W = 1350 \mu\text{m}$  and  $t_f = 150 \text{nm}$  shown in the inset, upper left. (b) Transfer characteristics of a complementary inverter circuit. Inset: Pulse response of the inverter. Insets, 4th quadrants: Molecular structural formulae of the molecules used in the channel (Wang et al., 2006).

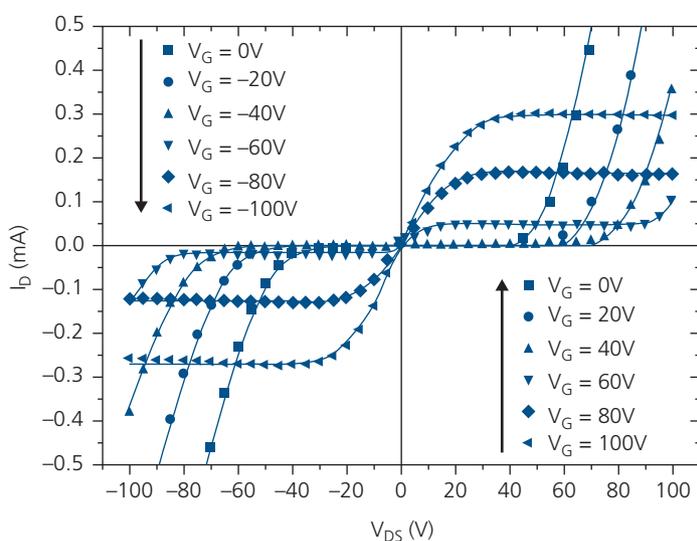

and hole conducting BP2T whose molecular structural formulae are shown in the inset. The LUMO energy of 4.61 eV for F<sub>16</sub>CuPc and the HOMO energy of 5.24 eV for BP2T allow for reasonably efficient and symmetrical injection of electrons and holes from the Au source and drain contacts (the Au work function is 5.1 eV), respectively. The BP2T and F<sub>16</sub>CuPc layers are sequentially deposited to thicknesses of 3 nm and 20 nm on a thermally grown SiO<sub>2</sub> gate insulator, respectively, and then Au for the S and D contacts is deposited, all by vacuum thermal evaporation.

The drain current characteristics in Fig. 8.54a are remarkably symmetrical at  $\pm V_{DS}$  due to the near equal electron and hole mobilities of 0.036 and 0.04 cm<sup>2</sup>/V s, and threshold voltages of  $V_{Tn} = 13$  V and  $V_{Tp} = -10$  V. The characteristics are similar to those determined using the analysis in Section 8.3.2, and illustrated in Fig. 8.19. The drain current shows  $I_D \propto V_{DS}^2$  ambipolar behavior for small  $V_{GS}$ , reverting to the unipolar saturation regime as the gate voltage is increased. Implementation in a complementary OTFT inverter shows abrupt switching at  $V_{in} = \pm 15$  V for  $V_{DD} = \pm 30$  V (Fig. 8.54b), with a voltage gain of 13. Switching response to a square  $V_{in}$  pulse stream is shown in the inset.

A second architecture for ambipolar operation uses a single channel material but with different S and D contacts; one with a large work function for hole injection, and the second with a smaller work function for electron injection. One example uses a pentacene channel that can transport both carriers, albeit with

different mobilities of  $\mu_{FEp} \approx 0.2$  cm<sup>2</sup>/V s and  $\mu_{FEh} \approx 0.1$  cm<sup>2</sup>/V s. A BG/TC ambipolar pentacene OTFT using a thermally grown SiO<sub>2</sub> gate dielectric has bipolar drain current characteristics shown in Fig. 8.55. The electron and hole injecting channel contacts are Ca and Au, respectively. The fits to Eqs. 8.19 and 8.27 assume the mobilities and threshold voltages are dependent on gate voltage. In addition to differences in mobilities, the threshold voltages vary from  $V_{Tn} \approx 18$  V to  $V_{Tp} \approx -35$  V. The observed asymmetry may be due to differences in injection efficiencies from the Ca and Au contacts.

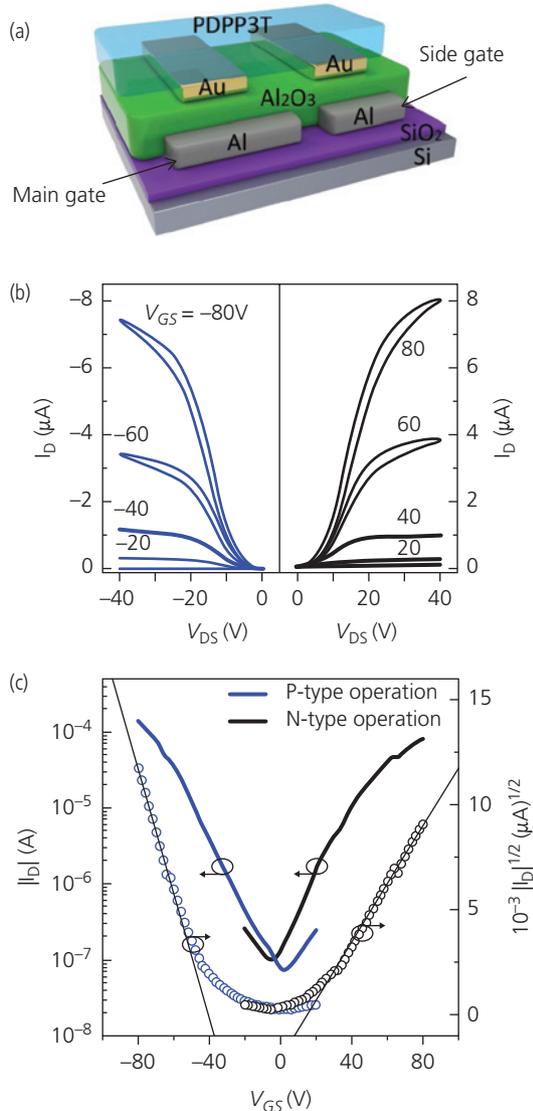

Finally, ambipolar transistors using blends of the electron conducting PC<sub>61</sub>BM and the hole conducting OC<sub>1</sub>C<sub>10</sub>-PPV have been demonstrated (Meijer et al., 2003). A challenge with blended channels is efficient injection into the constituents from the source and drain contacts. In this particular example, energy barriers exceeding 0.8 V are overcome, in part, by varying the gate potential. Significant hysteresis is observed in the drain current characteristics when sweeping the drain voltage in the positive and negative directions, which is reflected in hysteresis in a complementary inverter circuit incorporating these devices. The hysteresis may arise from charge trapping and detrapping within the blend network, at the contacts, etc. In general, the blended channel ambipolar OTFTs appear to have inferior performance to bilayer and single component ambipolar conducting, small molecule and polymer channel devices.

**Figure 8.55** Drain current characteristics of an ambipolar pentacene OTFT with electron and hole injecting channel contacts. The transistor dimensions are  $L = 70$   $\mu\text{m}$ ,  $W = 8$  mm, and  $t_i = 200$  nm. Lines are fits to theory in Section 8.3 (Schmechel et al., 2005).

### 8.4.5 Split gate transistors

Ambipolar transistors have a disadvantage of a low  $I_{on}/I_{off}$  since there is no bias condition whereby the channel is completely free of conduction from electrons or holes. This results in a high off-state power dissipation and a low noise margin. A means of limiting leakage is to use a split gate electrode (Hsu et al., 2010), as shown in Fig. 8.56a (Yoo et al., 2017). This

**Figure 8.56** (a) Schematic view of a split gate OTFT. (b) Unipolar drain current characteristics for both p- and n-channel conduction (left and right panels, respectively) accomplished by control of the side gate bias. The OTFT dimensions are  $L = 6 \mu\text{m}$ ,  $W = 810 \mu\text{m}$ , with a gate electrode gap of  $1 \mu\text{m}$ .  $V_{GS} = 0$  for the lowest curves in both panels. (c) Transfer characteristics of the split gate OTFT. Solid lines are fits to the  $\sqrt{I_D}$  vs.  $V_{GS}$  characteristics (Yoo et al., 2017).

BG/BC device consists of a main and a side (or control) gate beneath the drain contact separated by a small gap, allowing for their independent bias. When the gates are shorted, the device behaves as an ambipolar OTFT providing that an ambipolar conducting channel is used. When the side and main gates are independently biased, the side gate raises or lowers the potential barrier beneath the source electrode. When the control voltage  $V_{CS} < 0$ , holes are drawn into the channel at the exclusion of electrons, and then the transistor behaves as a p-channel OTFT. Conversely, when  $V_{CS} > 0$ , n-channel operation is induced. Hence, adjustment of the side gate voltage for different transistors within a circuit enables complementary transistor operation without compromising  $I_{on}/I_{off}$ .

The drain current characteristics exhibiting complementary unipolar operation of a split gate OTFT employing the ambipolar conducting channel material, PDPPP3T, is shown in Fig. 8.56b. The transistor features a  $t_i = 200 \text{ nm}$  thick  $\text{Al}_2\text{O}_3$  gate insulator deposited by ALD, along with a spin-coated PDPPP3T channel vacuum annealed at  $180^\circ\text{C}$ .

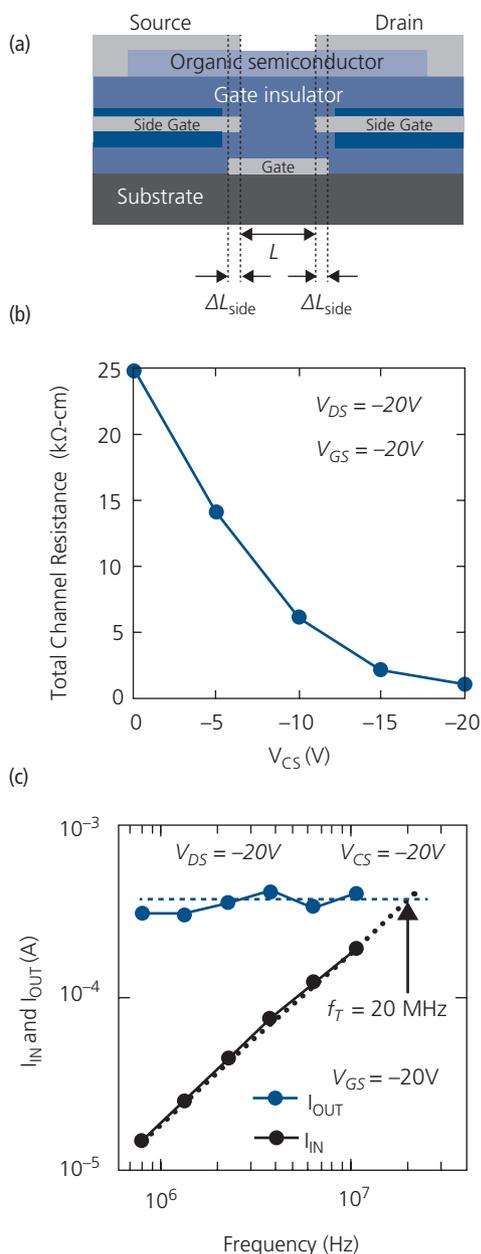

The magnitude of the hysteresis in the drain current induced by changing the  $V_{DS}$  sweep direction once it has reached its maximum value ( $\pm 40 \text{ V}$ ), depends on how fast the voltage is scanned. Hysteresis is a common feature of many OTFTs, and results from trapping and detrapping of charge from the semiconductor/insulator interface, or from within the semiconductor bulk. Changing the occupancy of traps shifts the surface potential,  $\psi_s$ , which has an effect similar to changing the gate bias,  $V_{GS}$ . The change in  $I_D$  at a fixed  $V_{DS}$  is known as *drain current drift*. Its presence can significantly reduce the noise margin of digital circuits over time, and can also adversely affect the operating point of analog circuits.

Nearly symmetrical characteristics are achieved for both p- and n-channel operation (left and right panels, respectively, in Fig. 8.56c), with  $I_{on}/I_{off} = 10^3$ . While this is not particularly high, it is an improvement of between 10 and 100 over conventional ambipolar OTFTs. Indeed,  $I_{on}/I_{off} = 10^7$  has been achieved for OTFTs with two split gates (a trigate architecture), where charge injection is controlled by side gates under both the source and the drain (Uemura et al., 2014; Torricelli et al., 2016).

The transfer characteristics in Fig. 8.56c show nearly ideal symmetrical behavior when used in either the p- or n-channel modes of operation. The threshold voltages in both cases are  $V_{Tp} \approx V_{Tn} \approx 0$ , which is optimal for complementary transistor operation. The hole an electron mobilities are also

comparable, with  $\mu_{FEp} = 0.026 \text{ cm}^2/\text{V s}$  and  $\mu_{FEn} = 0.012 \text{ cm}^2/\text{V s}$ .

The cutoff frequencies of split gate OTFTs are higher than for conventional, single gate designs due to their reduced contact resistance and higher charge concentration at the insulator interface at low gate voltages. This can be understood as follows: The main gate is placed between two split side

**Figure 8.57** (a) Schematic illustration of a trigate OTFT with a buried split gate. (b) Channel resistance vs. side gate control voltage,  $V_{CS}$  for a  $C_{10}$ -DNTT/ $F_6$ TNAP OTFT with  $W = 3 \text{ mm}$ ,  $L = 2.5 \text{ }\mu\text{m}$ , and  $\Delta L_{side} = 500 \text{ nm}$ . (c) Frequency response of the trigate OTFT (Uemura et al., 2014).

gates buried within the insulator, as in Fig. 8.57a, eliminating the gap between the channel contacts and the gate that often exists in a conventional device. Thus, the charge density at  $V_{CS} \neq 0$  can be high even at  $V_{GS} = 0$ . In Section 8.3.2, we found that the total channel resistance is given by:  $R_{tot} = 1/g_D + r_S + r_D = R_{ch} + R_C$ , where  $R_{ch} = 1/g_D$  and  $R_C$  is the sum of the contact resistances (cf. Fig. 8.25). The split gate draws charge into the channel even at  $V_{GS} = 0$ , thereby greatly decreasing the contact barriers that contribute to  $R_C$ .

The reduction in channel resistance with  $V_{DS}$  is shown for a buried split gate OTFT in Fig. 8.57b. This device comprises the hole conducting semiconductor,  $C_{10}$ -DNTT, doped with the acceptor,  $F_6$ TNAP, beneath the S and D contacts to reduce  $R_{contact}$  (Uemura et al., 2014). To create the buried split gate configuration, the  $Al_2O_3$  insulator is deposited by ALD at  $150^\circ\text{C}$  in two steps: 200 nm followed by deposition of the split gate contacts, and capped with 100 nm that is in contact with the vacuum-deposited channel layer. The second insulator surface is functionalized with an  $n$ -tetradecylphosphonic acid SAM prior to  $C_{10}$ -DNTT deposition to result in  $\mu_{FEp} = 0.4 \text{ cm}^2/\text{V s}$ .

The contact resistance in the saturation regime decreases from 20 k $\Omega$  cm at  $V_{CS} = 0$  corresponding to that of a conventional OTFT, to 1.2 k $\Omega$  cm at  $V_{CS} = -20$  V. This dramatic reduction in  $R_{tot}$  results in a considerably enhanced frequency response, which is inversely proportional to the time to charge the gate capacitance,  $\tau = R_{tot}C_{tot}$ . This device exhibits  $f_T = 20$  MHz (Fig. 8.57c); a significant improvement over conventional OTFTs.

The foregoing results suggest that split gate OTFTs can have a high frequency response and improved ambipolar conducting properties compared with single gate structures. The question remains whether the higher fabrication complexity counters the benefits of the multiple gate design. High gain, high frequency complementary logic circuits would appear to benefit from the split gate architecture, and indeed in some cases they are enabled by it.

## 8.5 Phototransistors

An organic phototransistor (OPT) is a thin film transistor with light incident on the organic semiconductor channel. Since the potential at the organic/insulator interface is a sensitive function of the gate voltage, optically generated charges shift the Fermi energy at that interface, causing a concomitant and potentially large change in the drain current. Thus,

the phototransistor is a device that can have a high optoelectronic gain, albeit at a reduced bandwidth due to limitations set by their gain-bandwidth product (see Section 7.1.1). In this section, we consider the principal modes of operation of the phototransistor, and provide a few example OPTs. Since an OPT is a hybrid between a photodetector and a transistor, a complete understanding of its operation requires a knowledge of conventional organic photodiode and photoconductor behavior. A few of the important expressions derived in Chapter 7 for OPDs will be reproduced here for convenience, with more complete discussions of their origins found in that chapter.

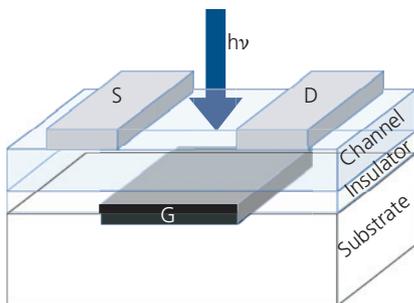

An illustration of a top illuminated, BG/TC OPT is shown in Fig. 8.58. The light is incident on the channel between source and drain contacts. If a transparent gate contact is used, illumination can be incident via the substrate. Using a metal contact in the TG configuration is also possible. Indeed, all the various iterations of OTFT architectures in Section 8.1 have also been applied to OPTs.

The phototransistor can operate in either the photovoltaic or the photoconductive mode. In the photovoltaic mode, the charge concentration at the insulator/channel interface is increased under illumination due to an optically-induced change in the gate voltage. This change, called the *photovoltage*,  $V_{ph}$  is determined using

$$\Delta C_{GS} = \frac{\partial Q}{\partial V_{GS}} = q^2 \frac{\partial n_s}{\partial E_F}, \quad (8.65)$$

where  $\Delta C_{GS}$  is the change in gate capacitance due to a change in surface charge concentration  $\Delta Q = \Delta n_s$ . The photovoltage,  $V_{ph}$  is simply equal to the change in the Fermi energy at the interface, viz. (Romero et al., 1996)

$$qV_{ph} = \Delta E_F. \quad (8.66)$$

**Figure 8.58** Schematic illustration of a BG/TC, top illuminated organic phototransistor.

The total interface charge density in the presence of illumination,  $n_T$ , is related to that in the dark,  $n_0$ , by the energy level bending,  $\Delta E_F$ , via Boltzmann statistics:

$$n_T = n_0 \exp(q\Delta E_F/k_B T). \quad (8.67)$$

The charge density is related to the total channel current via:

$$n_T = n_{ph} + n_0 = \frac{(j_{ph} + j_D)}{q\mu F}, \quad (8.68)$$

where  $j_{ph}$  and  $j_D$  are the induced photocurrent and the drain current in the dark, respectively. We assume for simplicity that the mobility is field independent, which is valid if the photocurrent does not significantly exceed the dark current. Then, combining Eqs. 8.66–8.68, we obtain

$$V_{ph} = \frac{nk_B T}{q} \ln\left(\frac{j_{DT}}{j_D}\right) = \frac{nk_B T}{q} \ln\left(1 + \frac{j_{ph}}{j_D}\right), \quad (8.69)$$

where the total drain current is  $j_{DT} = j_{ph} + j_D$ . Also, the factor  $n \leq 1$  accounts for the decrease in energy level bending as the photocurrent is increased (Chen, 1981). That is, at low power, we expect  $n = 1$ . However, at high power the bending becomes sublinear with  $j_{ph}$  as  $\Delta E_F$  approaches the nearest frontier orbital energy.

From Section 7.1, the photocurrent is related to the incident optical power per area,  $P_{inc}$ , via  $j_{ph} = \eta_{ext} q \lambda P_{inc} / hc$ , leading to

$$V_{ph} = \frac{nk_B T}{q} \ln\left(1 + \frac{q\eta_{ext}\lambda P_{inc}}{j_D hc}\right), \quad (8.70)$$

where  $h$  is Planck's constant and  $\eta_{ext}$  is the external quantum efficiency for charge generation (see Section 7.1). The external efficiency is given by

$$\eta_{ext} = \frac{hc}{q\lambda P_{opt}} (I_{DT} - I_D), \quad (8.71)$$

where the total optical power is  $P_{opt} = WLP_{inc}$  and  $I_{DT} = WLj_{DT}$  is the total drain current under illumination.

The relationship in Eq. 8.70 was originally derived in the context of high mobility, modulation doped inorganic transistors (Chen, 1981, Takanashi et al., 1998, 1999). However, the derivation does not specifically apply to a particular device geometry; rather it relies only on the presence of a sheet density of charge confined to a surface by surrounding energy barriers where Boltzmann statistics apply. Hence, it should also be valid for organic OPTs where a large sheet charge exists in the accumulation layer at the organic/gate insulator interface.

Finally, the photocurrent in the photovoltaic mode is related to the photovoltage by the transconductance, viz.

$$I_{ph} = g_m V_{ph} = \frac{g_m n k_B T}{q} \ln \left( 1 + \frac{q \eta_{ext} \lambda P_{inc}}{j_D h c} \right). \quad (8.72)$$

The photocurrent, therefore, is linear in  $P_{inc}$  at low power, and saturates once the incident power generates a photocurrent larger than the background drain current, that is, when  $\eta_{ext} P_{inc} > \frac{j_D h c}{q \lambda}$ .

In the photoconductive mode, illumination generates electrons and holes within the accumulation region. The lack of a junction in the channel results in an increase in its photoconductivity, and hence an increase in the drain current. From Eq. 7.4, we obtain

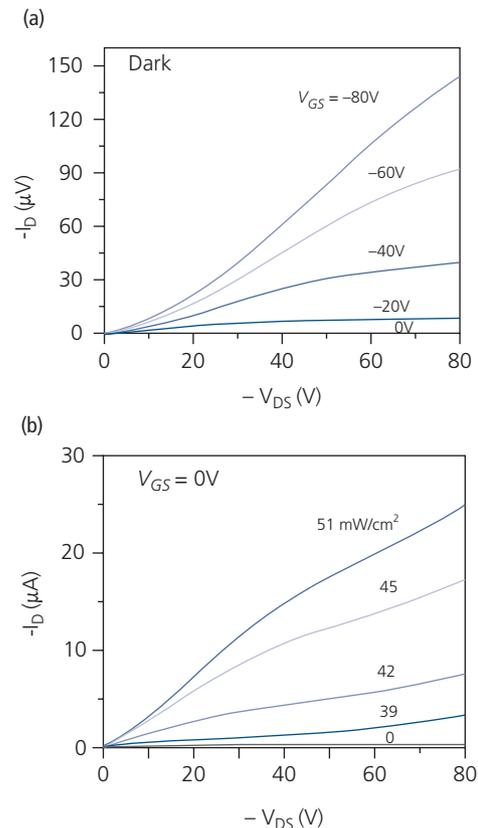

$$I_{ph} = q \eta_{ext} \mu_{FE} d \frac{(P_{inc} \lambda / h c)}{k_D} \frac{V_a}{L}, \quad (8.73)$$

where  $d$  is the thickness of the channel, which in this approximation is less than the exciton diffusion length,  $L_D$ . As in Chapter 7,  $k_D$  is the lifetime of the exciton. Generally, the photoconductive current is considerably less than the photovoltaic current since the latter is amplified by the transconductance. That is, the photoconductive current is  $I_{ph} \sim P_{inc}$ , whereas the photovoltaic current follows  $I_{ph} \sim g_m P_{inc}$  at small incident powers. Photoconductivity is generally only observed near  $V_{GS} = 0$  where  $g_m \rightarrow 0$ , and the photovoltaic effect vanishes.

Charge generation in the unipolar channel suggests that photocurrent effects are small, given the absence of an exciton-dissociating donor-acceptor HJ. Yet, this contradicts the observation of a very large responsivity of  $>10^4$  A/W that has been observed (Guo et al., 2010). While the photogeneration mechanism is not well understood, several hypotheses for the large photocurrent have been proposed. For example, exciton dissociation may occur via field ionization at the insulator-semiconductor interface (Guo et al., 2009). However, the electric field strengths rarely exceed  $5 \times 10^5$  V/cm at this junction. We have seen in Section 4.7.2, Fig. 4.104 that Onsager-Braun theory predicts a probability for dissociation of  $\sim 10^{-4}$  for a 0.7 nm exciton radius at this field, which is too small to account for the very large photocurrents observed. An alternative mechanism is that excitons may be quenched by defect states at the interface, trapping one carrier type and releasing the other charge into the channel. The change in trapped surface charge induces a change in threshold voltage, thus increasing

the current according to Eq. 8.72 (Wang et al., 2010). The change in threshold voltage is expected to have a far greater effect on the drain current than field ionization.

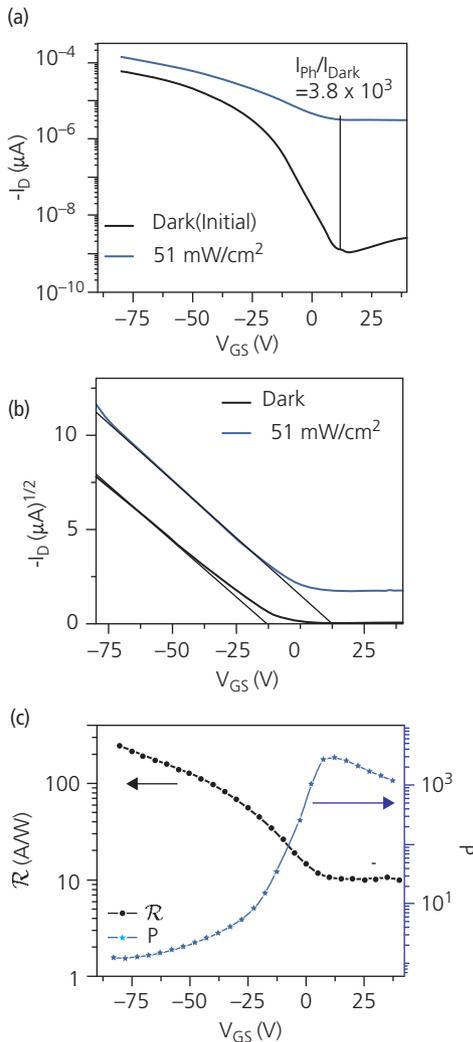

Representative drain current characteristics in the dark and under white light illumination for a P3HT/SiO<sub>2</sub> BG/TC OPT are shown in Fig. 8.59. The saturated dark characteristics in Fig. 8.59a yield a mobility of  $\mu_{FEp} = 0.07$  cm<sup>2</sup>/V s. There is a small curvature in the linear regime due to source contact resistance. Under white light illumination and  $V_{GS} = 0$  V in Fig. 8.59b, the photocurrent overwhelms the  $< 1$   $\mu$ A dark drain current, and increases with illumination intensity. The photocurrent also increases with drain current. In the saturation regime, at  $V_{GS} = -40$  V, the drain current is  $\sim 100$   $\mu$ A at  $V_{DS} = -60$  V, compared to 20  $\mu$ A at  $V_{GS} = 0$  V (Pal et al., 2010). The polymer absorption extends from 2.0 eV to  $>3.5$  eV, thus resulting in photocurrent generation across much of the visible spectrum. Often, OPTs are characterized using unspecified white illumination making it

**Figure 8.59** Transfer characteristics of a P3HT/SiO<sub>2</sub> with  $L/W = 200$   $\mu\text{m}/3$   $\mu\text{m}$  OPT (a) in the dark and (b) under white light illumination at  $V_{GS} = 0$  V (Pal et al., 2010).

difficult to compare characteristics taken in different laboratories. As a rule, it is more useful to use monochromatic light sources that coincide with the peak absorption of the semiconductor.

The characteristics in the dark and under illumination for this OPT are shown in Fig. 8.60a for  $V_{DS} = -60$  V. The photoresponse ratio of  $P = I_{ph}/I_D$ , has a peak of 3800 at  $V_{GS} = -12$  V. Note that under illumination, the channel current does not switch off, but rather saturates at a photocurrent of  $I_{ph} = 4$   $\mu$ A. A plot of  $\sqrt{|I_D|}$  vs.  $V_{GS}$  in Fig. 8.60b shows that slopes in the dark and under illumination are approximately equal, indicating that the field effect is independent of illumination. This eliminates the possibility that photogenerated minority carriers (electrons) or light-

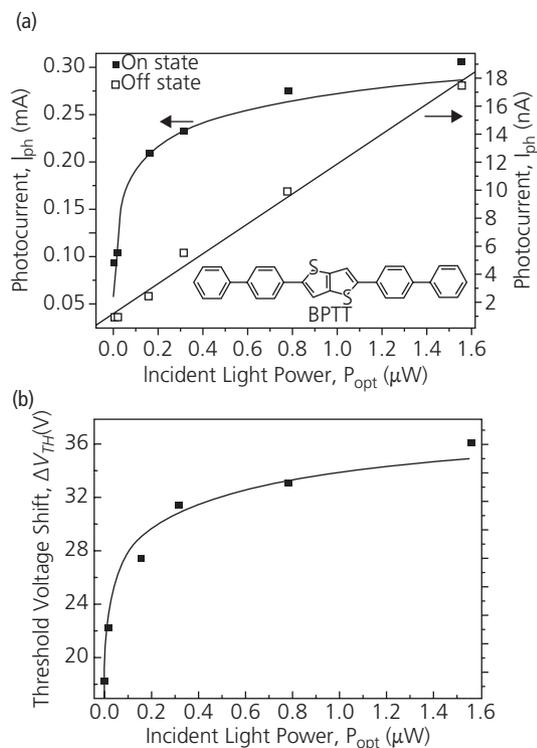

**Figure 8.60** (a, b) Transfer characteristics of the P3HT/SiO<sub>2</sub> OPT in Fig. 8.59 in the dark and under illumination for  $V_{DS} = -60$  V. (c) Responsivity and photoresponse ratio,  $P = I_{ph}/I_D$  vs.  $V_{GS}$ , at  $V_{DS} = -60$  V (Pal et al., 2010).

assisted trapping or detrapping at the interface affect the hole mobility (Wang et al., 2010). As in Fig. 8.60a, illumination induces a photocurrent offset that prevents the transistor from fully switching off, even for  $V_{GS} > 0$ . Further, the illuminated characteristics indicate a threshold voltage shift to +12 V, compared to -13 V in the dark. This  $\Delta V_T$  is equal to the photovoltage given in Eq. 8.70. An increase in the sub-threshold slope for the illuminated device is also apparent from the increased linearity of the data near  $V_{GS} = 0$  V.

Finally, the responsivity and photoresponse are provided in Fig. 8.60c. A maximum responsivity of  $\mathcal{R} = 250$  A/W is observed in saturation at  $V_{GS} = -75$  V and  $V_{DS} = -60$  V. Due to the large  $I_D$  at this voltage, the photoresponse is relatively small. Nevertheless, as we have seen in Section 7.2, this is  $\sim 100$  times the responsivity of a photodiode. Hence, we expect that the bandwidth of the OPT will be at most, 100 times lower than an OPD of comparable dimensions. It is uncommon to find OPTs whose bandwidths exceed a few kilohertz (Baeg et al., 2013).

The photocurrent and photovoltaic regimes of operation have been explored for small molecule-based BPTT/SiO<sub>2</sub> BG/TC OPTs, with results shown in Fig. 8.61 (Noh et al., 2005). The device exhibited  $\mu_{FEp} = 0.082$  cm<sup>2</sup>/V s and a threshold voltage of  $V_T = -29$  V. The maximum responsivity of the OPTs is 82 A/W at an intensity of 1.55 mW/cm<sup>2</sup> at  $\lambda = 340$  nm, with a photoresponse of  $2 \times 10^5$ . Fits to Eqs. 8.70 and 8.73 (lines, Fig. 8.61a) are obtained in the transistor on and off states, corresponding to  $V_{GS} = -50$  V and the  $V_{GS}$  at the minimum  $I_D$ , respectively. Fits affirm that the photoconductive current dominates when the OPT is in the off state, whereas it follows a logarithmic dependence on optical power when the device is in the on state. Also, the change in the threshold voltage,  $\Delta V_T = V_{ph}$ , also follows the theoretical trend predicted by Eq. 8.72, as shown in Fig. 8.61b.

Ambipolar OPTs that consist of either bilayer or blended channels can increase the charge generation efficiency by combining materials that form a type II, exciton dissociating interface (Marjanović et al., 2006, Anthopoulos, 2007, Labram et al., 2010). An example of a bilayer OPT is shown schematically in Fig. 8.62a, inset. The device comprises a bottom Al gate contact deposited on a glass substrate. The Al is exposed to an O<sub>2</sub> plasma to enable growth of a 5–10 nm thick AlO<sub>x</sub> insulator, which is then capped by dipping in an octadecylphosphonic acid solution to deposit a 2.3 nm thick SAM. Next, a 100 nm thick pentacene donor channel is deposited by VTE, followed by Au S and

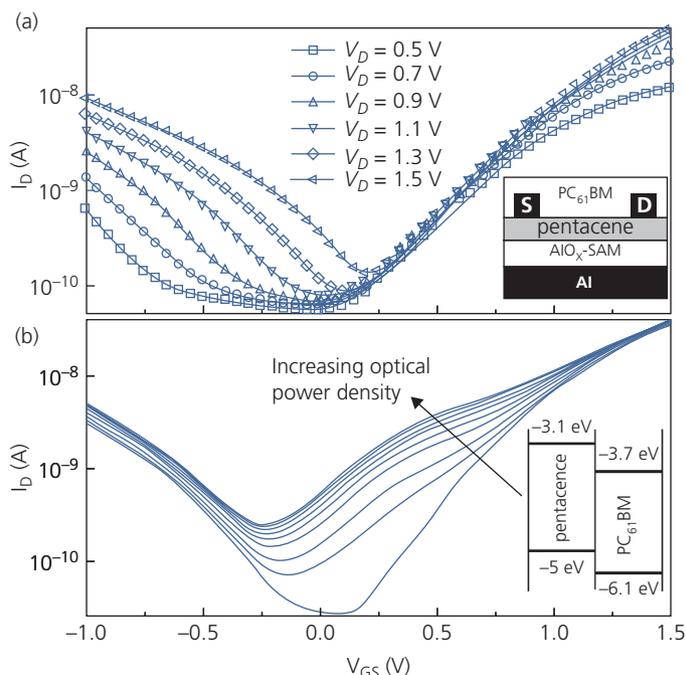

**Figure 8.61** (a) Photocurrent vs. total incident optical power  $P_{opt} = WLP_{inc}$  at  $V_{GS} = -50$  V and  $\lambda = 340$  nm (closed squares, on state) and at the minimum  $I_D$  (open squares, off state) at  $V_{DS} = -50$  V for a BPTT OPT with  $WL = 5$  mm/20  $\mu$ m. Inset: Molecular structural formula of BPTT used as the channel semiconductor. (b) Threshold voltage shift in the on state. Lines are fits to Eqs. 8.70–8.73 (Noh et al., 2005).

D contacts, and then capped with drop-cast PC<sub>61</sub>BM in CB, see inset, Fig. 8.62b. Exposing the pentacene to the PC<sub>61</sub>BM solution roughens its surface, reducing its mobility to  $\mu_{FEp} = 7 \times 10^{-4}$  cm<sup>2</sup>/V s (compared to 0.1–1 cm<sup>2</sup>/V s typically observed). The electron mobility of the PC<sub>61</sub>BM layer is  $\mu_{FEn} = 0.2$  cm<sup>2</sup>/V s. This difference results in asymmetric transfer characteristics shown in Fig. 8.62a. The threshold voltages are  $V_{Tn} = 0.7$  V and  $V_{Tp} = -1.4$  V.

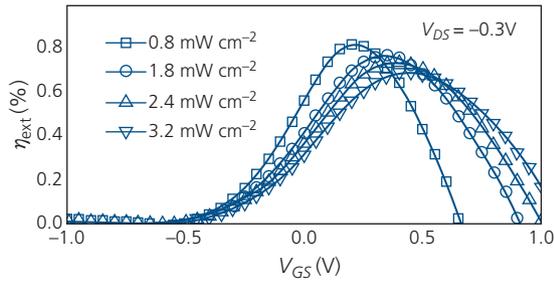

The donor–acceptor HJ gives a significant ambipolar photoresponse when illuminated at  $\lambda = 469$  nm (2.64 eV), as shown in Fig. 8.62b. Light of this wavelength is absorbed in both layers, although it is primarily absorbed in the top PC<sub>61</sub>BM layer on which it is incident. The n-channel threshold voltage shifts by  $\Delta V_{Tn} = -0.2$  V for an illumination intensity of 3.2 mW/cm<sup>2</sup>, while  $\Delta V_{Tp} = 0$  V. This difference is possibly due to charge trapping at the roughened pentacene/PC<sub>61</sub>BM interface. Importantly,  $I_{off}$  also increases with illumination intensity due to the large density of photogenerated charges at the D–A junction.

The photocurrent efficiency vs. illumination intensity at  $V_{DS} = -0.3$  V is shown in Fig. 8.63. The maximum external efficiency is only 0.8% obtained at the lowest power. As the input power increases, the efficiency decreases. This is a common feature of OPTs, and is due to a saturation in  $\Delta V_T = V_{ph}$  as the density of photogenerated charges increases (see Eq. 8.72). That is, recombination of photogenerated charges

**Figure 8.62** (a) Dark ambipolar transfer characteristics of the pentacene/PC<sub>61</sub>BM transistor shown in the inset. (b) Characteristics at  $V_{DS} = -1$  V under  $\lambda = 469$  nm illumination from a blue LED. Inset: Energy level diagram showing the exciton separating HJ (Labram et al., 2010).

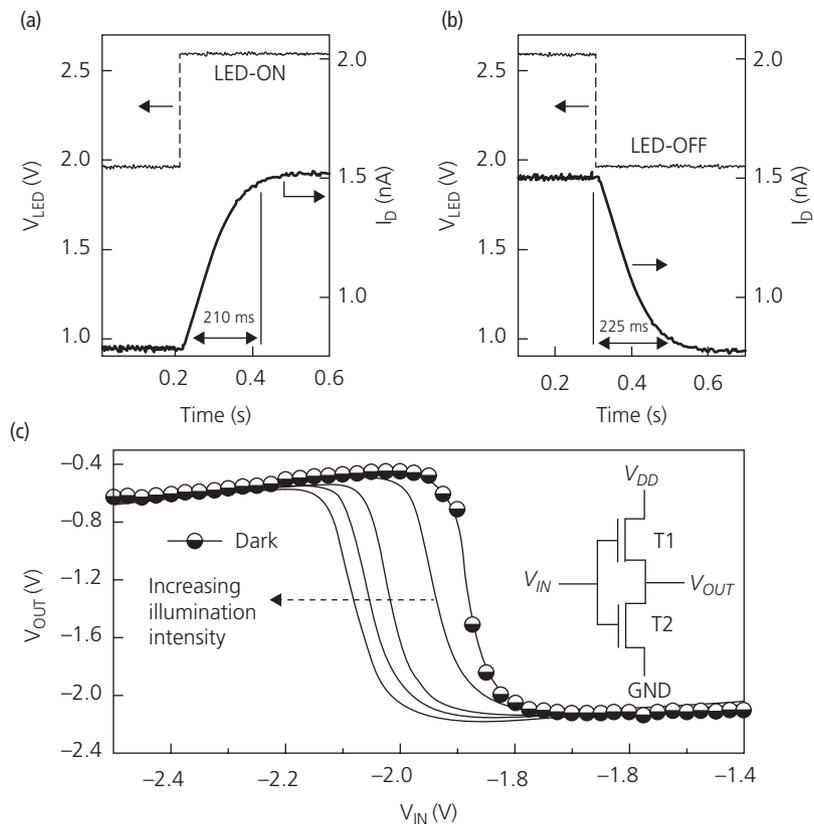

increases with the number of electron-hole pairs, thus decreasing their ability to increase the channel current at high illumination intensities (Wasapinyokul et al., 2009). This imposes a limit to the linear dynamic range of OPTs, which may be increased somewhat by increasing  $V_{DS}$  to more efficiently sweep out photogenerated charges.

**Figure 8.63** External quantum efficiency vs.  $V_{GS}$  of the device in Fig. 8.62 for various input optical powers and  $V_{DS} = -0.3$  V (Labram et al., 2010).

We have shown that the bandwidth of OPTs is also limited by their gain. This is in addition to other factors that limit response such as gate and drain capacitances, charge mobility, etc., see Section 8.3.3. The rise and fall time transient response to a pulsed LED source of the OPT in Fig. 8.62 with  $W/L = 1$  mm/50  $\mu$ m are shown in Fig. 8.64a. The total rise and fall time is  $t_r + t_f = 435$  ms, corresponding to a bandwidth of  $\Delta f = 1/2(t_r + t_f) \approx 1$  Hz. This is quite slow compared to most OPTs, and is most probably due to charge trapping at the highly disrupted pentacene/PC<sub>61</sub>BM interface.

Finally, low voltage ambipolar OPTs have also been used as complementary transistors in the inverter circuit shown in Fig. 8.64b, inset. In the dark, the circuit shows a maximum gain of  $A_v = 35$  at a supply voltage of  $V_{DD} = 2.5$  V, and an input voltage of  $V_{IN} = 0.7$  V. The gain decreases with increasing channel illumination intensity, accompanied by a voltage shift of approximately  $-0.2$  V at a power of  $1.2$  mW/cm<sup>2</sup>. The operating point shift is due to a

**Figure 8.64** (a) Rise and (b) fall times of the OPT in Fig. 8.62 to a fast optical pulse whose waveforms are shown in the upper halves of the panels.  $V_{LED}$  is the voltage applied to the InGaN LED source. (c) Transfer characteristic of a complementary ambipolar OPT pair in the dark and under illumination up to  $1.2$  mW/cm<sup>2</sup>. Inset: Schematic of the complementary inverter circuit (Labram et al., 2010).

D., Low-voltage ambipolar phototransistors based on a pentacene/PC<sub>61</sub>BM heterostructure and a self-assembled nano-dielectric. 1250-1254. Copyright 2010 with permission from Elsevier.

similar shift observed for the threshold voltage seen in Fig. 8.62b. Presumably, the channels of both transistors, T1 and T2 are illuminated simultaneously and at the same power. Differential illumination of the transistors can provide optical logic functionality, where the circuit output voltage,  $V_{OUT}$ , depends on whether one or both transistors are illuminated, and whether or not the intensity during illumination is the same (Anthopoulos, 2007).

In summary, an OPT is capable of very high photosensitivity (and hence responsivity) due to the strong dependence of the gate photovoltage on illumination intensity. However, this advantage is counterbalanced by its slow response to changes in optical signals, confining them to applications where bandwidths less than a few kilohertz are acceptable. Also, the devices are more complex than organic photodiodes discussed in Chapter 7. Nevertheless, their integration into complex circuits may provide advantages in specialized applications where optical signal processing is combined with detection.

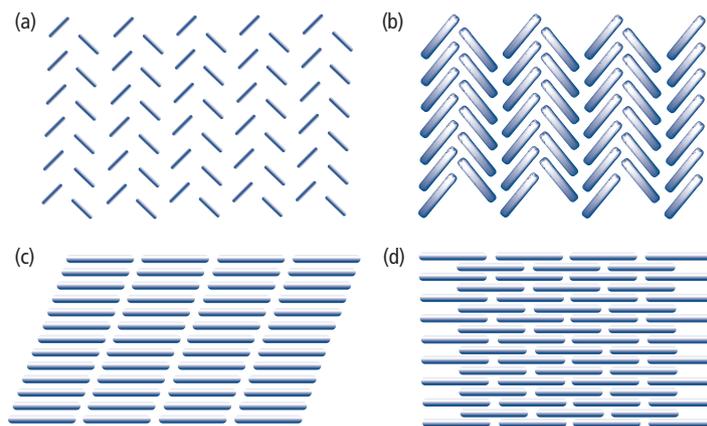

## 8.6 OTFT materials

The performance of an OTFT is determined by several factors, including the organic semiconductor used for the channel and the dielectric, the deposition conditions for the channel layer that leads to a particular morphology, the quality of the contacts to the source and drain, and the gate and channel geometries. Both small molecules and polymers have been successfully used in OTFTs, and considerable effort has been directed toward morphology control to achieve high mobilities. These methods include deposition of large crystalline domains from the vapor or solution phases, applying strain to the as-deposited films to

assist in driving their orientation into a preferred configuration, and orientation of single crystals. One of the most attractive features of organics is that they lend themselves to a nearly limitless modification of properties through variations in their composition and structure.

Figure 8.7 gives an example of how transistor performance is linked to film morphology. Unlike OLEDs that require amorphous emission regions, or blended OPVs requiring nanocrystalline domains distributed throughout the active region, OTFTs benefit from ordered crystal morphologies with polycrystalline grains extending across the entire channel. Single crystals exhibit the highest mobilities since charges are neither scattered nor trapped at grain boundaries, or in disordered regions (Reese and Bao, 2007, Liu et al., 2009a). Indeed, field effect mobilities can be several orders of magnitude higher for single crystals than for disordered films (Sundar et al., 2004, Stingelin-Stutzmann et al., 2005, Seo et al., 2006). Unfortunately, there has been no convincing demonstration that single crystals can be reproducibly deposited over large areas, and with mobilities that exceed those of thin films deposited from the vapor or solution phases. In addition to achieving crystalline growth, in Chapter 4 we found that organic crystals are characterized by highly anisotropic conductivities. Hence, the crystals need to align with their high mobility axes parallel to the S-D conducting direction. For these reasons, effort has been directed to finding materials and scalable process conditions that lead to thin film morphologies beneficial to high mobilities and on/off ratios.

Small molecule organics can take on crystal habits ranging from herringbone to lamellar  $\pi$ - $\pi$  stacking arrangements that depend on the molecular

**Figure 8.65** Common small molecular crystal stacking habits found in transistor thin films. (a) Face-to-edge herringbone structure lacking strong  $\pi$ - $\pi$  stacking. (b) Closely packed, co-facial herringbone structure with strong  $\pi$ - $\pi$  stacking. (c) Slip-stack co-facial  $\pi$ - $\pi$  stacking. (d) Lamellar, brick-like  $\pi$ - $\pi$  stacking.

structure and growth process; several possible stacking habits are illustrated in Fig. 8.65 (also see Chapters 2 and 5). Unlike vertical device architectures found in OLEDs and OPVs, OTFTs require the high conductivity direction parallel to the substrate along the S-D direction. Often, the organic crystal forms the herringbone motif in Fig. 8.65a and b. While these structures do not have the most advantageous  $\pi$ -orbital overlap between molecules within the plane, they have the advantage of a reasonably isotropic conductivity, and hence the in plane orientation relative to the S-D axis becomes less important. The open, face-to-edge structure in Fig. 8.65a results in the lowest conductivity due to the relative absence of intermolecular orbital overlap.

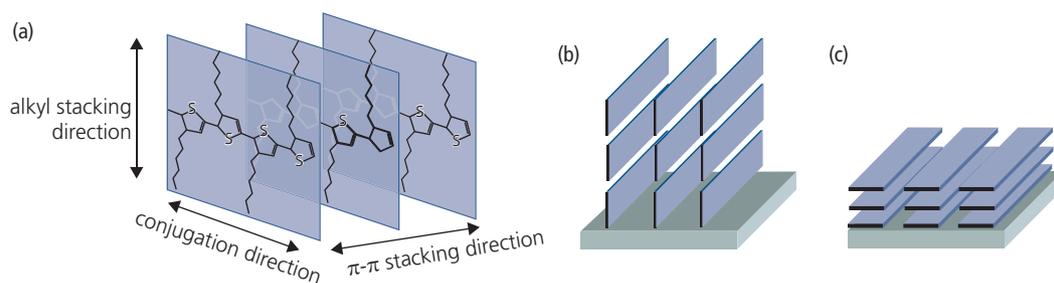

All else being equal, the planar, or flat-lying habits of Fig. 8.65c and d should have a higher conductivity perpendicular to the molecular plane than the herringbone structures. Both the slip-stack and lamellar configurations can have tight intermolecular spacing and a low hopping energy barrier between adjacent molecules. The two different structures are driven by intermolecular van der Waals forces that determine the lowest energy configuration. These motifs are often found in polyaromatic hydrocarbon molecules such as naphthalene, anthracene or tetracene. Unfortunately, often the same forces that lead to lamellar stacking may also cause the molecules to lie flat on the substrate (e.g. PTCDA). Then the high conductivity direction lies perpendicular, and not parallel to the substrate as required in OTFTs. The high mobility that arises from parallel stacking is of no use in this configuration.

The orientation relative to the substrate plane is due to a balance of forces between the molecule and substrate, and between the molecules themselves. Hence, pentacene molecular stacks orient with their molecular axes perpendicular to an SiO<sub>2</sub> gate insulator, allowing the lamella to  $\pi$ -stack along the S-D direction giving a high in-plane mobility. In the following

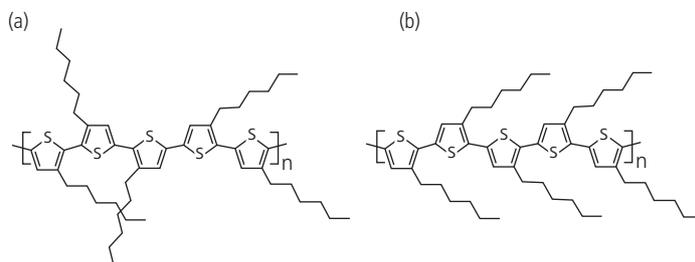

sections we will find that planar molecules are often functionalized using alkane “tails” to force them into the appropriate orientation relative to the substrate. Also, as noted in Section 8.3, a pre-deposited SAM can functionalize the surface to drive the orientation of subsequently deposited molecules. These strategies reinforce the conclusion that realization of high performance OTFTs requires exploitation and control of the interplay between the molecular structure, the insulator-organic interface morphology and surface energies, and the deposition and post-deposition process conditions. As a consequence, seeking high channel mobilities, low contact resistances and large  $I_{on}/I_{off}$  has become a very rich subject for investigation.

The situation for polymer films is analogous to that of small molecular weight materials. That is, achieving high in-plane mobility depends on the ability of the polymers to form crystals with the optimal interchain  $\pi$ -coupling direction positioned in the channel plane. The situation with a common p-channel polymer, P3HT, is shown in Fig. 8.66a. The extended polymer chain creates even larger anisotropies in electronic properties than do many small molecules. The highest conductivity direction is along the length of the chain, where each segment is attached to the next with a conjugated, covalent bond (Venkateshvaran et al., 2014). Interchain  $\pi$ - $\pi$  stacking also promotes conduction. In the case of P3HT, close packing along this second dimension is promoted by the unhybridized *p*-orbitals of the thienylene groups. The least conductive direction is along the alkyl chains (the vertical direction in Fig. 8.66a).

The most advantageous orientation is for the molecular lamella to couple with the  $\pi$ -stacking direction along the channel, as shown in Fig. 8.66b. Clearly, the out-of-plane stacking arrangement in Fig. 8.66c requires conduction edge-wise between molecules. The insulating nature of alkanes and lack of intermolecular  $\pi$ -orbital overlap prohibits a high mobility in this case.

**Figure 8.66** (a) P3HT molecular structure, showing the anisotropic orientation of the  $\pi$ - $\pi$  stacking, conjugation and alkyl stacking directions. Molecular planes are  $\pi$ -stacked (b) parallel and (c) perpendicular to the substrate plane. The former orientation is most useful for OTFT applications (Salleo, 2007).

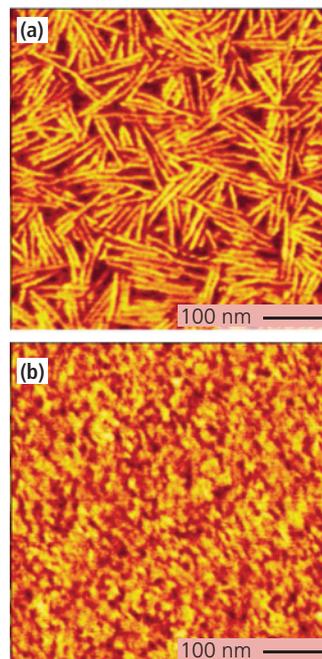

**Figure 8.67** (a) Regiorandom and (b) regioregular P3HT molecules.

The charge mobility and the ability for polymers to crystallize into ordered structures is complicated by several factors that are not present in small molecule systems. These include regioregularity, molecular weight, rapidity with which the polymers are deposited, and post deposition annealing used to establish equilibrium crystalline morphologies. *Regioregularity* is the property whereby the alkyl moieties on each thiophene unit are attached at the same location. This is understood by inspection of Fig. 8.67. The irregular structure in Fig. 8.67a shows a random attachment of the alkyl groups on the both sides of the conjugated backbone. Due to steric interference between alkyls, the thiophenes along the backbone are twisted out of the molecular plane. This prevents strong  $\pi$ - $\pi$  interactions, and at the same time breaks the conjugation along the backbone, such that the mobility in the two most favorable directions is substantially reduced. When the alkyl groups are on the same side, they are known as head-to-head or tail-to-tail arrangements (Fig. 8.67b). The uniform head-to-tail attachment maintains the planarity of the thiophene cores, as required to achieve the ordered structures in Fig. 8.66.

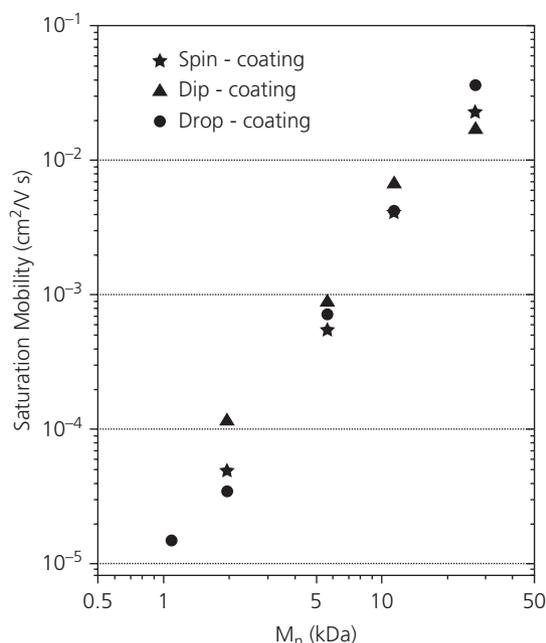

The molecular weight ( $M_n$ ) and processing conditions of the polymer films determine the degree of order as well as the relative orientation to the substrate plane. For example, low molecular weight films prepared by slow casting from a dilute solution result in the high mobility configuration of Fig. 8.66b, whereas high molecular weight films prefer the flat-lying and low mobility arrangement in Fig. 8.66c, even though the conjugation length increases with  $M_n$  (Sirringhaus et al., 1999).

The dramatic dependence of morphology on  $M_n$  is shown by the atomic force microscope (AFM) images in Fig. 8.68 of regioregular P3HT thin films spin-cast on an HMDS-functionalized  $\text{SiO}_2$  surface on Si. A rod-like morphology is observed for  $M_n = 3.2$  kDa, whereas the  $M_n = 31.1$  kDa film exhibits nanoparticle (NP) clusters. The lower molecular weight film is found to have a higher degree of crystalline order than that

**Figure 8.68** AFM images of regioregular P3HT films on HMDS coated  $\text{SiO}_2$ . (a)  $M_n = 3.2$  kDa, (b) 31.1 kDa (Kline et al., 2003).

with larger molecular weights (Kline et al., 2003, Verilhac et al., 2006). Further, the rods form into extended bunches if the low  $M_n$  regioregular P3HT is slowly deposited by dip coating vs. rapid spin-cast deposition (Verilhac et al., 2006). Slow crystallization allows the films to approach their equilibrium morphologies with lamella oriented with their intermolecular  $\pi$ -stacks in the plane, although the morphological dependence on  $M_n$  is stronger than it is on the rate of deposition. The rate is slowest for dip coating, less slow for drop-casting, and fastest for spin-coating. Thus, shorter chains are more likely to form ordered domains separated by grain boundaries between segments, independent of the rate of casting. Indeed, both a low molecular weight and slow crystallization lead to a lower mobility, as reflected in the data in

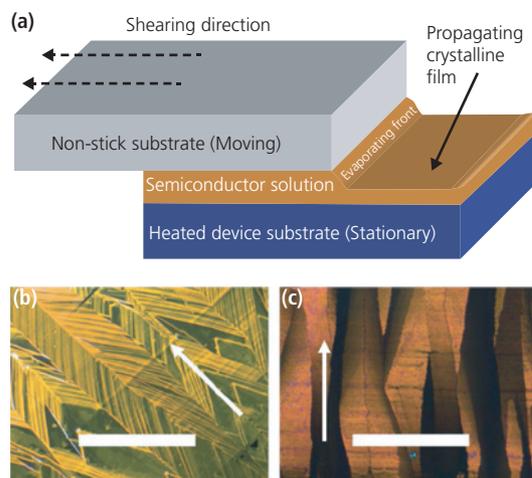

**Figure 8.69** Dependence of regioregular P3HT  $\mu_{FEP}$  on  $M_n$  and film coating method on OTFTs with an  $\text{SiO}_2$  gate insulator (Verilhac et al., 2006).

Fig. 8.69. The extended chains formed as  $M_n$  increases are likely to have many points of contact with adjacent chains, leading to efficient charge hopping with a reduced probability for trapping at grain boundaries or at macroscopic boundaries between the chains (Kline et al., 2003).

Another means for imposing order along the channel is via *solution shearing* (Becerril et al., 2008). This process, illustrated in Fig. 8.70, is similar to preparing films using a *doctor blade*. A dilute solution of the semiconductor is deposited onto the target substrate. A second planar slab with a non-wettable surface is placed onto the surface of the solution, and is drawn parallel to the substrate while the entire system is gently heated. The solvent at the liquid front evaporates as the moving slab is translated, leaving behind crystalline precipitates that orient along the drawing direction. These crystallites are nucleation sites for additional material deposition, resulting in a preferred polycrystalline orientation also parallel to the drawing direction. Polarization microscope images of solution sheared films of the small molecules trimethylsilyl-substituted quarterthiophene (TMS-4T) and dbo-P2TP are shown in Fig. 8.70b and c, respectively.

**Figure 8.70** (a) Solution shearing employs two planar slabs translated relative to each other, with a solution of the semiconductor sandwiched between them. Oriented films of the small molecules (b) TMS-4T and (c) dbo-P2TP prepared by solution shearing along the directions of the arrows. The films are shown using polarization optical microscopy. The scale bars are 1 mm (Liu et al., 2009a).

There is a clear morphological dependence on the shearing direction (indicated by the arrows), resulting in large-scale orientation of molecules and high conductivity along the channel. Dip coating can also result in directional crystallite formation, which may be in part responsible for improved performance using that technique.

Molecular structure is another factor that determines molecular arrangement. For example, inter-chain van der Waals forces in the planar conjugated F8BT copolymer has a preference for the flat-lying (tile) morphology of Fig. 8.66c (Donley et al., 2005). As a consequence, electron field effect mobilities of  $\sim 10^{-3} \text{ cm}^2/\text{V s}$  are observed, in comparison to up-standing molecular structures such as P3HT, whose mobilities are a factor of 100 or more larger.

Below, we describe approaches to surface functionalization using SAMs, and then present several small molecules and polymers used in p-channel, n-channel, and ambipolar OTFTs. Many p- and n-channel materials often show ambipolar conductivity, depending on the contacts employed. If the hole and electron mobilities of a material are significantly different, it is discussed in the sections focused on unipolar transport.

In the same spirit that we discussed OLED and OPV materials in Chapters 6 and 7, the example materials should provide an appreciation of the challenges that are faced by the materials scientist and chemist in developing high performance compounds for

transistor applications. Given the necessarily cursory nature of our treatment, the reader is referred to extensive literature from which our examples are drawn (Newman et al., 2004, Facchetti, 2007, Murphy and Fréchet, 2007, Zaumseil and Sirringhaus, 2007, Klauk, 2010, Wang et al., 2011, Zhao et al., 2013).

We will also include some further techniques used to achieve morphologies that yield the best transistor results. In contrast, single crystal OTFTs and their associated materials will not be discussed. While these devices hold scientific interest, the value of the OTFTs is in their use in integrated circuits. Single crystal transistors often exhibit high mobilities, yet they do not lend themselves to fabrication beyond one or only a very few transistors on a substrate due to the special, and non-scalable handling necessitated in their fabrication (Reese and Bao, 2007).

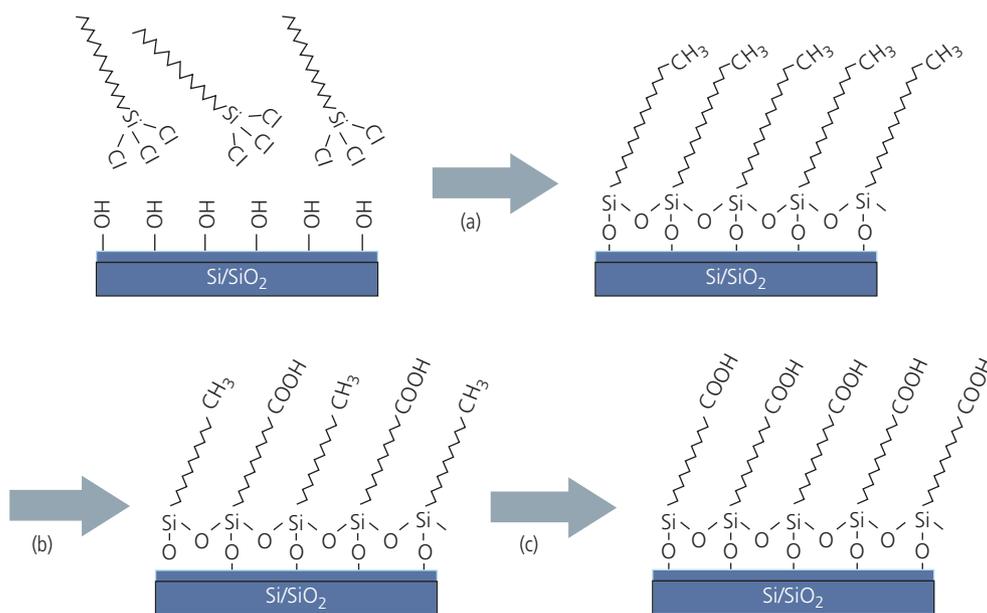

### 8.6.1 Self-assembled monolayers

A SAM is a space-filling layer of surface molecules that serve two primary purposes. The most common is to functionalize the insulator surface to increase the mobility and decrease  $V_T$ . The application of SAMs can also result in improvements in sub-threshold slope and on-off ratio. Their second use is in bottom contact OTFTs, where the channel semiconductor is deposited onto the source and drain contacts. SAMs have been developed to increase adhesion that decreases contact resistances, decrease the metal/

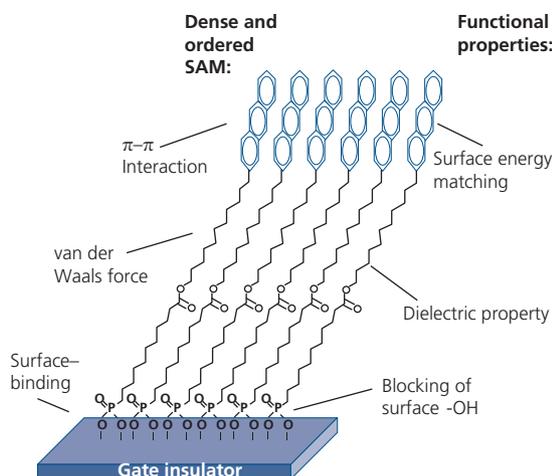

semiconductor barrier height, and nucleates crystalline growth that can spread into the channel, thus increasing mobility.

An example SAM is OTS, which is a precursor to functionalizing  $\text{SiO}_2$  gate insulators. Packing into a space-filling monolayer begins by hydroxylating the insulator surface by exposure to UV-ozone, as in Fig. 8.71a. This creates a hydrophilic surface, which is transformed to hydrophobic by subsequent adsorption of the OTS. Next, the Cl atoms are washed away and are replaced with Si–O bonds to the  $\text{SiO}_2$  surface. In Fig. 8.71b and c, the distal end of the alkane chain can be oxidized by further exposure to UV-ozone to controllably adjust the hydrophobicity of the surface. Alternatively, the end of the alkane chains can be functionalized to create nucleation sites for subsequently deposited channel molecules, including attachment of hydroxyl, anthryl, or other groups, depending on the desired morphological outcome (DiBenedetto et al., 2009).

Chlorosilanes such as ODTs and HMDS are members of a large class of SAM precursors. Another class of stable SAMs useful for modifying  $\text{Al}_2\text{O}_3$  and other metal oxide surfaces are the anthryl-terminated phosphonic acids (PAs) in Fig. 8.72 (Ma et al., 2012). We show how the several molecular elements in the SAM are designed to perform different functions, leading to the desired structure/property relationships in the channel layer. The precursor molecule is the anthryl-terminated phosphonic acid containing a

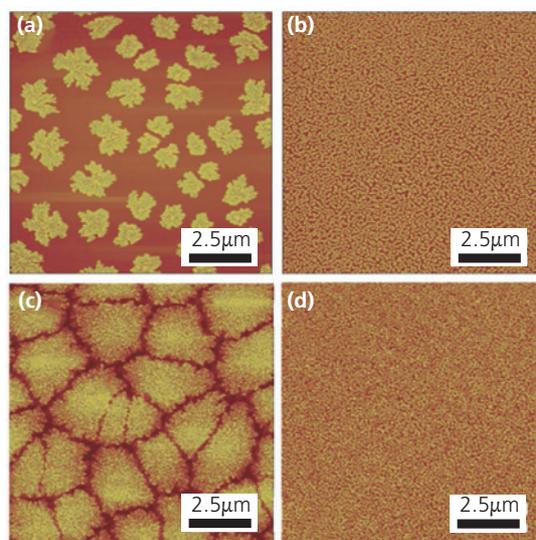

**Figure 8.71** (a) Attachment of OTS onto a  $\text{SiO}_2$  surface forming a close-packed, space filling monolayer. (b) Partial and (c) full oxidation of the distal end of the alkane chain to functionalize it for subsequent deposition of the channel molecules (Son et al., 2008).

**Figure 8.72** Surface functionalization using a  $\pi$ - $\sigma$ -phosphonic acid SAM employing an anthryl end group, with the function of each component shown (Ma et al., 2012).

combination of  $\pi$  and  $\sigma$  bonds. The molecule (or its analogs) can be applied by either vacuum or solution deposition. It attaches to the oxide via a reaction that replaces the surface hydroxyl group with an insulator P–O bond to the oxide (e.g.  $\text{Al}_2\text{O}_3$  or  $\text{HfO}_2$ ). The attachment of this space-filling monolayer blocks the surface states, while the aliphatic and anthryl groups close pack. The ensemble is stabilized by strong intermolecular  $\pi$ – $\pi$  interactions between anthracene terminations. The anthracene groups tailor the surface energy and morphology such that the subsequently deposited channel molecules (typically a linear polyacene such as tetracene or pentacene) adhere in an orientation that promotes conductivity in the in-plane direction. Close packing of the SAM promotes alignment of the channel molecules in a layer that is largely free of defects, and that templates the surface to subsequently promote nearly commensurate or quasiepitaxial growth (Section 2.6). The alkane chains themselves are insulating and dipolar, which can have a significant impact on the surface potential,  $\psi_S$ , and hence  $V_T$  and  $\mu_{FE}$ . As with the chlorosilanes, different functionalizing end groups can be tailored for the purpose of modifying different insulator surfaces and channel morphologies.

The modification of the morphology of  $\text{C}_{60}$  films on a  $\text{HfO}_2$  surface in the absence or presence of the  $\pi$ - $\sigma$ -PA, octadecylphosphonic acid (ODPA), is shown in the AFM images in Fig. 8.73. To prepare the surface, the  $\text{HfO}_2$ -coated substrates are immersed in a solution of 0.1 mM ODPA mixed in a 1:1 solution of THF and ethanol at  $70^\circ\text{C}$  where they remain for 12 h, followed by rinsing in solvents and then dried. The addition of

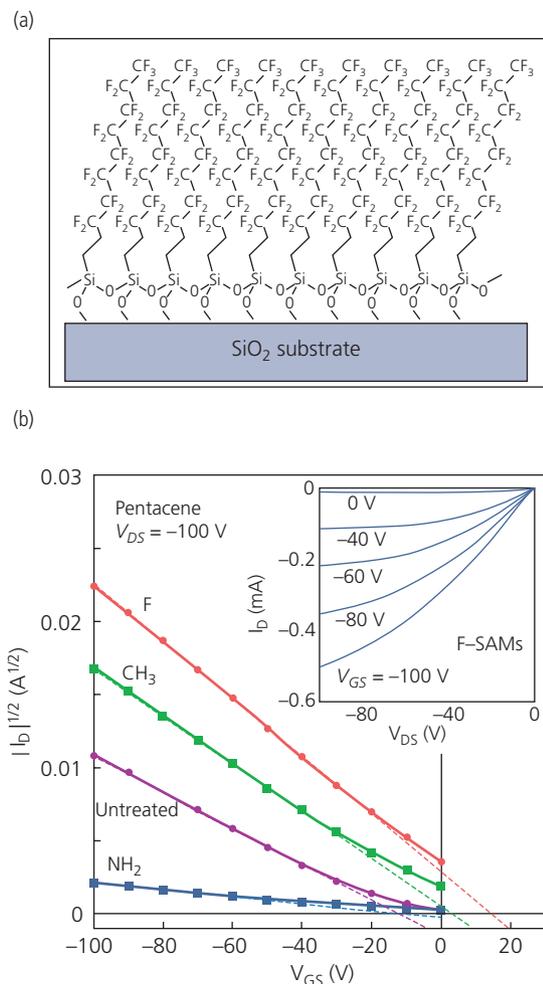

**Figure 8.73** AFM images of ultrathin films of  $\text{C}_{60}$  on (a) ODPA on  $\text{HfO}_2$ , (b) bare  $\text{HfO}_2$ . (c) 50 nm thick  $\text{C}_{60}$  on ODPA/ $\text{HfO}_2$  and (d) on bare  $\text{HfO}_2$  (Acton et al., 2008).

the SAM has a profound effect on the subsequently vacuum deposited  $\text{C}_{60}$  film morphology. That is, from the nucleation (Figs. 8.73a and d) to the bulk film (Figs. 8.73c and d) stages, the presence of ODPA results in larger grain sizes ( $\sim 2.3 \mu\text{m}$ , average vs.  $0.1 \mu\text{m}$  on the SAM and on bare  $\text{HfO}_2$  surfaces, respectively). This is attributed to more efficient diffusion of  $\text{C}_{60}$  during film deposition on the SAM. The larger grain size results in a higher mobility compared to the unfunctionalized oxide surface. Thus,  $\mu_{FE} = 0.28$  vs.  $0.097$ , and  $I_{on}/I_{off} = 10^5$  vs.  $10^3$ , respectively (Acton et al., 2008).

Various explanations have been advanced to explain how SAMs on the gate insulator modify transistor characteristics, including the control of morphology by influencing the surface energy, and hence the surface wettability (Janssen et al., 2006). Close-packing can create a template for ordering the deposited film. And the interface potential itself can be influenced by passivation (i.e. neutralizing) of traps at the insulator surface, or it can introduce a dipole that shifts the energy levels (see Section 8.3).

Surface dipoles introduced by a series of organosilane SAMs with different molecular dipole moments on an  $\text{SiO}_2$  gate insulator alters the charge mobilities of both pentacene and  $\text{C}_{60}$  OTFTs (Kobayashi et al., 2004). The molecules used are based on fluoroalkyl-, alkyl-, and aminoalkylsilane (denoted F,  $\text{CH}_3$ , and  $\text{NH}_2$ , respectively). The molecular formula and packing of the F-SAM is shown in Fig. 8.74a. The drain current transfer characteristics for BG/TC pentacene OTFTs employing these SAMs, as well as an

untreated SiO<sub>2</sub> insulator are shown in Fig. 8.74b. The most dipolar species, the F-SAM, results in the largest shift in  $V_T$  to +17 V, with  $V_T$  monotonically decreasing with dipole moment to a minimum of  $V_T = -11$  V

**Figure 8.74** (a) Schematic of a closely packed F-SAM comprising (CF<sub>3</sub>)(CF<sub>2</sub>)<sub>7</sub>(CH<sub>2</sub>)<sub>2</sub>Si(OC<sub>2</sub>H<sub>5</sub>)<sub>3</sub> on a SiO<sub>2</sub> surface. for both the untreated and NH<sub>2</sub>-SAM (with molecular dipole moments of  $p = 0$  and 0.60 D, respectively) functionalized surfaces.

The relative surface energies of the SAM surfaces are determined by the water contact angles ( $\theta$ ) listed in Table 8.1. In Section 5.6.5, we showed that the surface energy between the solid and the ambient is given by the Young equation (Israelachvili, 2011):

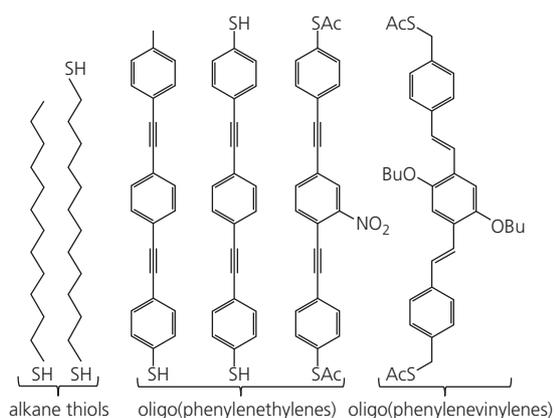

$$\sigma_{sg} = \sigma_{sl} + \sigma_{lg} \cos \theta, \quad (8.74)$$

where the interfacial surface energy between the liquid and the solid is  $\sigma_{sl}$ , and between the liquid and the ambient is  $\sigma_{lg}$ . Larger contact angles (i.e. for F-SAM and CH<sub>3</sub>-SAM) correspond to a greater hydrophobicity, and hence a higher liquid–solid surface energy. The pronounced dependence of mobility and  $V_T$  on SAM composition for both pentacene p-channel OTFTs in Fig. 8.74, and C<sub>60</sub> n-channel OTFTs (not shown) indicate that the SAM dipole moment controls the semiconductor/insulator interface potential. This, in turn, determines the charge type in the channel at  $V_{GS} = 0$  V. The majority carriers at the interface in equilibrium are electrons, with  $V_T > 0$  for F-SAM and CH<sub>3</sub>-SAM devices, whereas holes populate the untreated OTFT interface. It is not a simple matter to isolate the origin of the dependence of the OTFT on a single factor such as molecular dipole moment due to the complex interrelationships between chemistry, morphology and trap structure.

Earlier in this section, we noted that SAMs have been applied to BC OTFTs to seed ordered growth, or to increase the adhesion of the channel layer to the source and drain contacts. As in the case of insulator/semiconductor junctions, the dipole moment at metal/semiconductor contacts also influences the injection barrier height (see Section 4.6). All of these factors suggest that SAM functionalization of the S and D surfaces can affect both the contact and channel resistances. Evaporated Au electrodes are favored for S and D contacts since the films are uniformly flat and continuous. A thin layer of Cr or Ti

deposited prior to the thick Au contact improves adhesion to an underlying oxide since both of these refractory metals form strong metal-oxygen bonds. The top surface of the Au is functionalized using one of any number of thiols that can form a SAM that attaches to the Au via the Au-S bond (Hu et al., 2005, Marmont et al., 2008). Examples of a few thiolated molecules used in SAMs are provided in Fig. 8.75. The most commonly used species are the alkane-thiols, although the alkane chain is non-conducting. It can be replaced with conducting analogs exemplified by the oligo(phenyleneethynylene) thiols or the oligo(phenylenevinylene) thiols (DiBenedetto et al., 2009).

The efficacy of using thiols on Au contacts is illustrated in Fig. 8.76a. The OTFT is a BG/BC architecture employing an OTS-treated SiO<sub>2</sub> on Si gate insulator and contact. The channel comprising PQT-12 is shown in the inset of Fig. 8.76a. Due to the bottom contact arrangement, application of PQT-12 on the untreated Au surfaces leads to a large channel series resistance as evidenced by the nonlinear rise in  $I_D$  at low  $V_{DS}$  (highlighted by the oval). When the Au contacts are immersed in a solution of 1-octanethiol (C<sub>8</sub>H<sub>17</sub>SH) in ethanol for 24 h, and then rinsed in solvents prior to spin-coating with PQT-12, the resistance decreases, and the low voltage drain current characteristics become linear, as shown in Fig. 8.76b. The SAM initiates polycrystalline growth in an otherwise amorphous film (see AFM images in Fig. 8.76c and d). This not only reduces series resistance, but also results in a nearly ten-fold increase in mobility, from  $\mu_{FEp} = 0.015 \text{ cm}^2/\text{V s}$  for the untreated, vs.  $0.09 \text{ cm}^2/\text{V s}$  for the SAM-functionalized S and D contact surfaces. The increase in mobility may be a function of increased film conductivity or decreased contact resistance (cf.

**Figure 8.75** Example thiols used as SAMs for functionalizing Au contact surfaces.

Eq. 8.23) due to improved wetting of the Au surface. This, in turn, reduces the injection barrier to the polythiophene channel layer (Cai et al., 2008).

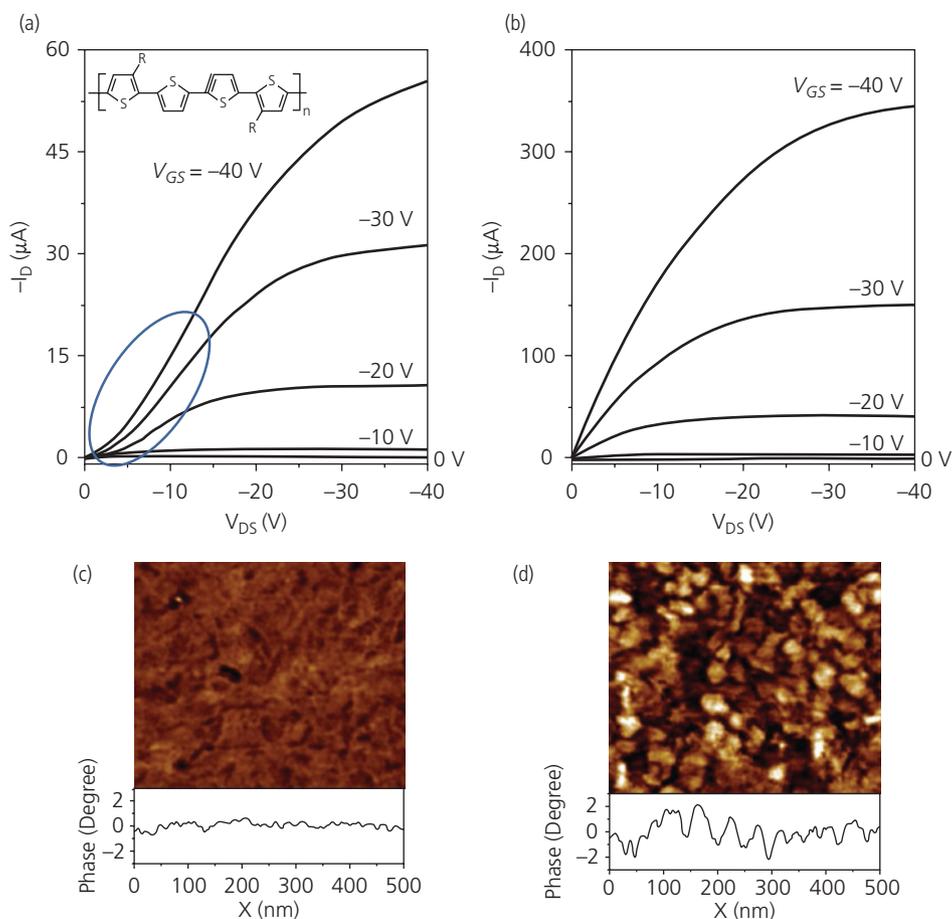

## 8.6.2 Small molecules for p-channel transistors

We now introduce several important small molecules developed for p-channel OTFTs. As discussed in Chapter 4, there is no intrinsic reason why hole mobilities are higher than that for electrons. The family of p-channel materials is, nevertheless, more extensive than for other conductivity types. The molecules selected typically have field effect mobilities  $> 0.5 \text{ cm}^2/\text{V s}$  which is the nominal minimum value for practical applications. In a few instances, lower mobility materials are discussed to illustrate a point or introduce a family of structures that are of more general interest as OTFT channel materials. The potential of a transistor, however, is not simply a function of mobility. As shown in previous sections, the threshold voltage should be close to zero, the contact resistance low, and the sub-threshold slope should approach the theoretical minimum of  $60 \text{ meV/decade}$ . Transistors with all of these qualities ensure high bandwidth, low voltage operation and a high noise margin when employed in circuits. The materials cited fulfill one but generally not all of these criteria.

The molecular structural formulae for several p-channel materials are shown in Figs. 8.77 and 8.78. In Table 8.2 we summarize the properties of OTFTs made with the species in both figures, along with relevant aspects of device architecture and process conditions. Channel layers deposited by either vapor or solution phase deposition are represented.

Compounds 1–3 are representative fused ring aromatics. The molecules tend to form lamellar stacks in either a brick- or slipped-stack configuration due to interactions between their extended  $\pi$ -orbital systems. The molecules are insoluble in organic or aqueous solvents, requiring VTE deposition onto OTS-treated substrates to achieve the highest performance. They tend to form polycrystalline morphologies that lead to mobilities as high as  $5 \text{ cm}^2/\text{V s}$  in the case of pentacene (2). That result was taken from a statistical study of a large sample of devices that underscored the importance of materials purity (as achieved by thermal gradient sublimation and deposition in high vacuum), and process control as a cornerstone of high performance OTFTs (Kelley et al., 2003b).

It is tempting to assume that increasing the number of fused rings in the linear polyacenes will result in more ordered  $\pi$ -stacking. However, as we found in Chapter 3, extending the molecule increases its

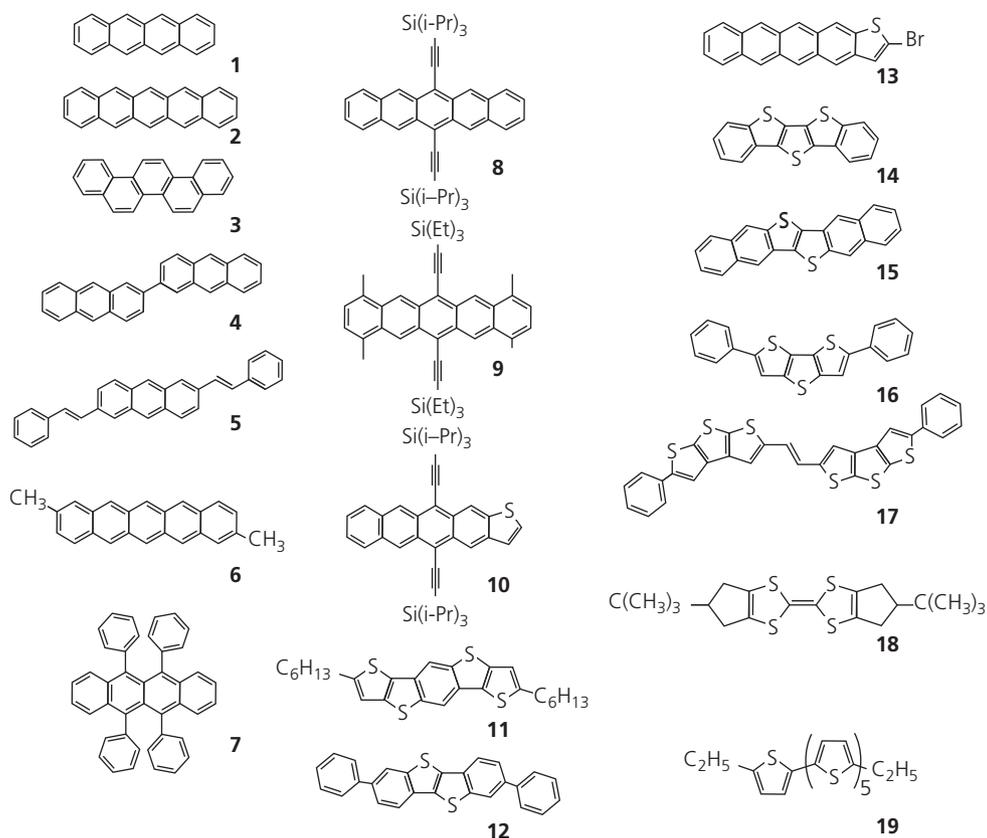

**Figure 8.76** (a) Drain current characteristics of a BG/TBC p-channel OTFT with  $L = 20 \mu\text{m}$  and  $W = 9 \text{ nm}$  employing the polythiophene, PQT-12 ( $R = \text{C}_{12}\text{H}_{25}$  in inset) with untreated Au S and D contacts. The oval highlights the nonlinear characteristics at low  $V_{DS}$ . (b) An analogous device to (a) but with the S and D contacts pre-treated with a 1-octanethiol SAM. (c) AFM image of the untreated substrate (lower panel is the AFM image phase indicating relative surface roughness). (d) Image of the SAM-treated substrate (Cai et al., 2008).

conjugation length. This, in turn, results in a reduced energy gap, which can increase the off current (and hence decrease  $I_{on}/I_{off}$ ), as well as decrease device stability. Indeed, the longer molecules may not necessarily form deep, ordered stacks compared with molecules with five or fewer rings. Hence, few investigations of linear polycyclic aromatics have gone beyond pentacene. However, bianthracene (**4**) and other anthracene and pentacene derivatives (**5**, **6**) have shown good stacking behavior along with concomitantly high  $\mu_{FEp}$  and  $I_{on}/I_{off}$ . These molecules can be grown in an up-standing orientation when deposited on SAM-modified insulator surfaces, leading to enhanced  $\pi$ -stacking and higher stabilities than their un-modified core moieties.

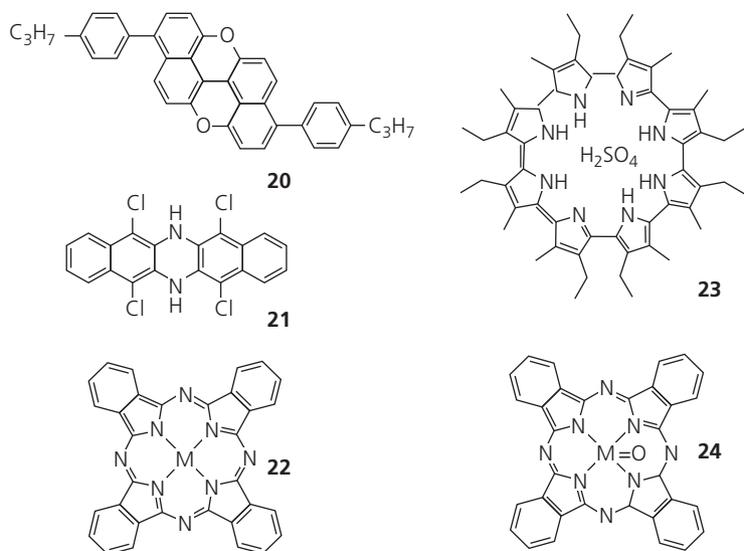

Chapter 5.4.2 discussed OTFTs employing rubrene (**7**). Single crystals of this molecule form a co-facial herringbone structure (Fig. 8.65b), although films are most often amorphous with very low mobilities. To

achieve mobilities approaching  $1 \text{ cm}^2/\text{Vs}$ , the molecules were crystallized by dissolving in the glassy vitrifying species, 5,12-diphenylanthracene. This creates a hypereutectic that grows into extended crystallites rather than in a completely disordered film. The vitrifying mixture is blended into an ultrahigh molecular weight polystyrene matrix to provide mechanical stability and flexibility needed for use in circuits on bendable substrates. The polycrystallinity of the films containing all three components is apparent in the polarized optical micrograph in Fig. 8.79 (Stingelin-Stutzmann et al., 2005).

The series of compounds **8–10** are solution-processable variants of pentacene or tetracene, some with propyl (Pr) and others with ethyl (Et) groups appended to the perimeter (peri) groups surrounding the molecular core to improve solubility. The most fully studied molecule in this series is TIPS-pentacene, **8**. It forms lamellar structures with mobilities of

**Figure 8.77** Example small molecules used in p-channel OTFTs and listed in Table 8.2.

**Figure 8.78** Additional small molecules used in p-channel OTFTs and listed in Table 8.2.

$\mu_{FEp} = 1.8 \text{ cm}^2/\text{V s}$  when cast from solution. The solubility and crystal-forming ability is increased further with the tetramethylated variation, **9**.

Strong S-S interactions between adjacent molecules have made various thiophene derivatives a focus of

considerable attention for use in OTFTs, several of which **10–19** are shown in Fig. 8.77. Attaching alkyl chains (e.g. **11**) leads to good film forming characteristics via dip or spin coating, and improved intermolecular  $\pi$ - $\pi$  stacking is made possible by

end-capping the molecules with planar phenyl groups, as in the case of DPh-BTBT, **12**, where high mobilities (1.5–3.9 cm<sup>2</sup>/V s) along with very high  $I_{on}/I_{off} = 10^8$  are achieved. Indeed, this compound, along with **15** (DNNT, see Fig. 8.23) have shown  $V_T \sim 0$  V, making them suitable for low power circuit applications (Zschieschang et al., 2017). Indeed, nearly all of the fused thienoacenes shown have high mobilities, and in most cases suitably low  $V_T$  due to their ability to form ordered stacks. Many of these moieties (e.g. **15**–**18**) can be vacuum deposited.

The oligothiophenes ( $\alpha$ -6T, **19**, being an example) have attracted considerable attention due to the ease of functionalization, especially when compared to phenyl-based compounds, or to the ability to controllably adjust the number of thiophene units. As the

number of links in the oligomer increase, the molecular solubility decreases. Unfortunately, the stability of these molecules is not high, nor is their mobility. For **19**, attaching alkyl chains at the end positions increases the oligomer solubility. Finally, the rigid (HMTTF) molecule readily forms crystallites with hole mobilities as high as  $3.6 \text{ cm}^2/\text{V s}$ , albeit with a low ( $\sim 10^3$ ) on-off current ratio (Kanno et al., 2009). Hence, the best combination of characteristics is for device using **18** in Table 8.2.

An advantage of many of the compounds in Fig. 8.78 is their stabilities. The *peri*-xanthoxanthene, **20**, has shown exceptional stability to air exposure, even at temperatures as high as  $150^\circ\text{C}$ . The molecule has been adapted for vacuum and solution processing (with and without the alkane moiety). It features a nanocrystalline structure necessary for high mobility. The thin film mobilities obtained via vacuum and solution processing on a PVP gate dielectric are  $\mu_{FEp} = 0.8$  and  $0.4 \text{ cm}^2/\text{V s}$ , and the threshold voltages are  $V_T = 0 \text{ V}$  and  $4 \text{ V}$ , respectively (Kobayashi et al., 2009). Hence, as is often the case, improved performance is achieved by vacuum deposition as a result of its ability to produce a more highly ordered film. The halogen-substituted azaacene, **21**, also leads to advantageous  $\pi$ -stacking, and hence high mobility due to intermolecular Cl–Cl interactions.

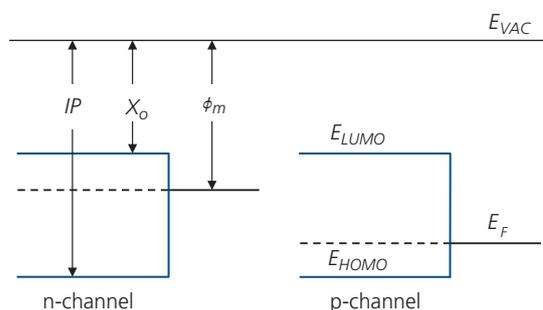

Lastly, we turn to the phthalocyanines (Pcs) and porphyrins (**22–24**). Phthalocyanines are particularly stable compounds that have found ubiquitous applications as dyes. Their stability naturally leads to interest in their suitability for electronic devices. Most metallated phthalocyanines (MPc, **22**), including CuPc, form into a range of stacking habits, depending on deposition conditions, although the slip-stack is the most common (Fig. 8.65c). To be useful in OTFTs, the stacks must tilt edge-on relative to the substrate, which depends on the relative energies between molecules and substrate, and among the molecules themselves (Yook et al., 2011). Unfortunately, the MPcs have not shown high mobilities, and hence are not often employed in OTFTs. An exception is the metal oxide Pcs (**24**) such as TiOPc. Unlike the MPcs, MOPcs are non-planar, forming a pyramidal structure leading to very tightly spaced molecules ( $\sim 3.15 \text{ \AA}$ ) with significant  $\pi$ - $\pi$  overlaps (Li et al., 2007). The result is higher mobilities than the MPcs and that are, in a few cases (including VOPc, Li et al., 2008) competitive with many of the thiophene and acene-based compounds. An analogous cyclic molecular family to the Pcs is the porphyrins (**23**, for example). Langmuir–Blodgett techniques (Section 5.4.2) have been used to

deposit 30 monolayers of the acid-based cyclo[8]pyrrole to achieve a modest mobility and  $V_T = 0 \text{ V}$  (Xu et al., 2005).

### 8.6.3 Small molecules for n-channel transistors

The selection of high performance n-channel materials is more limited than for p-channel semiconductors, possibly due to their reduced air stability, and also due in part to the shorter time in their development. In Section 8.2 we showed that the early OTFT demonstrations were almost entirely focused on p-channel devices due to the immediate availability of established, high hole mobility materials such as the thiophenes and the linear polyacenes. The n-channel materials generally are based on molecules with strong electron withdrawing groups via attachment of amino, cyano, or halogen moieties, or molecular cores with large HOMO energies such as the naphthalene- or perylenetetracarboxylic diimide families. The deep energy levels create low electron injection barriers from the source contact.

Many materials used for n-channel transistors have nearly comparable hole and electron mobilities. In that case, they can be employed in ambipolar OTFTs whose characteristics are primarily determined by the S and D contact barriers, see Fig. 8.80. That is, a high work function ( $\phi_m$ ) metal results in a low HOMO energy ( $E_{HOMO}$ )/work function offset allowing for efficient hole injection into the channel. This combination is preferable for p-channel contacts. Likewise, a low work function metal is employed for n-channel operation. As seen in Chapter 4, the Fermi energy of the organic is often determined by the injected, rather than the intrinsic charge, which justifies the relative position of the metal and semiconductor energies in

**Figure 8.80** Channel contact energies favorable for n- and p-channel OTFTs.  $IP$  = ionization potential,  $\chi_o$  = electron affinity of the organic, and  $\phi_m$  = contact metal work function. Energy level bending on the organic side of the contact is omitted for clarity.

Fig. 8.80 for ambipolar conducting organics. Reducing the energy gap of the organic is an alternative means to reducing the injection barrier, although this can lead to higher output conductance and a lower  $I_{on}/I_{off}$ .

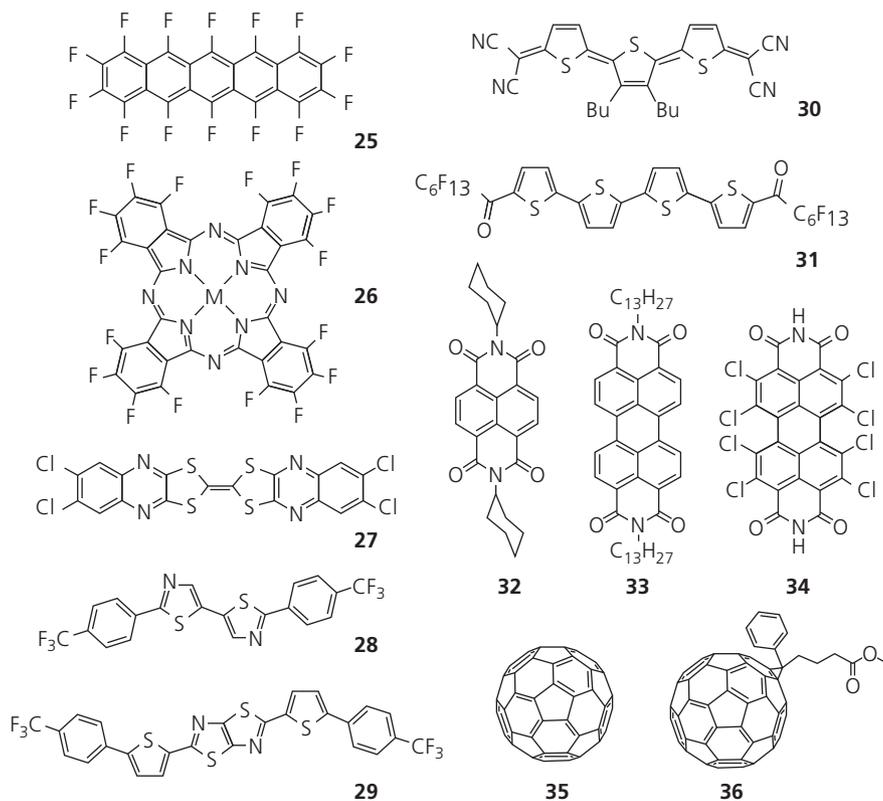

Example materials primarily employed in n-channel devices are shown in Fig. 8.81, with detailed OTFT characteristics listed in Table 8.3. Perfluoropentacene (**25**) is an example of a halogen-containing linear polyacene, where the electron-withdrawing F atoms replace H at the pentacene *peri* positions. The electron mobility of  $\mu_{FE n} = 0.11 \text{ cm}^2/\text{V s}$  is considerably less than the core, hole-conducting pentacene (**2**) with  $\mu_{FE p} = 5.1 \text{ cm}^2/\text{V s}$ . Fluorination has also been employed to improve electron conduction in the phthalocyanines, with the example of  $\text{SnCl}_2\text{F}_{16}\text{Pc}$  (**26**) yielding  $\mu_{FE n} = 0.3 \text{ cm}^2/\text{V s}$ , compared with the best *p*-channel TiOPc, (**24**) of  $\mu_{FE p} = 3.3 \text{ cm}^2/\text{V s}$ . Compound **26** forms a tightly packed co-facial, polycrystalline herringbone structure (Fig. 8.65b) with grain sizes  $\sim 1 \mu\text{m}$ . Like most of the Pcs, this compound is reasonably air stable.

Several halogenated analogs of *p*-channel materials shown are **27**–**29**. Notably, the tetrahalogenated TTF derivative, **27**, is analogous to the *p*-conducting

compound **18**. Both are planar, lending themselves to compact and ordered  $\pi$ -stacking arrangements. One of the highest electron mobilities is achieved with **28** (and its analogous thiophene derivative, **29**), with  $\mu_{FE n} = 1.83 \text{ cm}^2/\text{V s}$ . This molecule, too, forms a nearly planar motif leading to tight  $\pi$ - $\pi$  stacking. Unfortunately,  $V_T$  approaches 78 V, leading to an excessive voltage swing that makes it unusable for circuit applications.

An example non-halogenated molecular structure is DCMT, **30**, where the four cyanomethylenes are electron-withdrawing. Interestingly, low work function Mg contacts were used in place of the conventional Au contacts to achieve improved electron injection, leading to a mobility of  $0.2 \text{ cm}^2/\text{V s}$ . Oligothiophenes are also good hole conductors, but when halogenated (**31**), they result in electron-conducting semiconductors useful in n-channel transistors.

Naphthalene- and perylenetetracarboxylic diimides (compounds **32**–**34**) have comparatively large  $E_{HOMO}$ , making them excellent building blocks for n-channel devices. Their stability and the ease with which they can be synthetically modified has led to their extensive use in OTFTs. The central aromatic

<sup>a</sup> p6P is a 3.5 nm thick SAM deposited from solution.

<sup>b</sup> PS is 24 nm thick with  $M_w = 280\text{k}$ .

<sup>c</sup> Tested under an Ar atmosphere, showing large hysteresis in the forward and backward sweep directions. In air,  $\mu_{FE}$  was reduced to 0.41 cm<sup>2</sup>/V s.

cores are functionalized with carbon rings (**32**) or alkane groups (**33**) to increase their solubility, and to encourage  $\pi$ -stacking of the conjugated planar perylene or naphthalene cores along the in-plane direction. Indeed, one of the advantages of these structures is their large and extended conjugated  $\pi$ -systems that lead to the formation of very deep, ordered stacks. The cyclohexyl substituted naphthalene compound (**32**) shows a remarkably high electron mobility of 6.2 cm<sup>2</sup>/V s in an Ar atmosphere. Unfortunately, this particular compound is unstable, showing vastly different (and lower) performance in oxygen and air. Even in Ar, the device drain current characteristics showed significant hysteresis, depending on whether  $V_{DS}$  is swept from 0 to  $+V_{DS}$  or vice versa. The tridecyl-functionalized perylenetetracarboxylic diimide (**33**), on the other hand, is quite stable in air, and has  $\mu_{FE_n} = 2.1$  cm<sup>2</sup>/V s. When the alkane is replaced with C<sub>3</sub>F<sub>7</sub>, very high mobility ( $\mu_{FE_n} = 1.42$  cm<sup>2</sup>/V s) was observed for air-stable BG/TC OTFTs, comprising a solution-deposited OTS SAM on SiO<sub>2</sub> gate insulator. This mobility is double that achieved via vacuum deposition of the SAM (Schmidt et al., 2009). Solution processing via substrate immersion in an OTS solvent solution results in improved order, leading to larger crystallite formation within the transistor plane. The most stable compound, albeit with the lowest mobility of these three planar compounds is 1,2,5,6,7,8,11,12-octachloroperylene-3,4,9,10-tetracarboxylic diimide (**34**). The OTFTs have a stable  $\mu_{FE_n}$  and  $I_{on}/I_{off}$  after exposure to air for

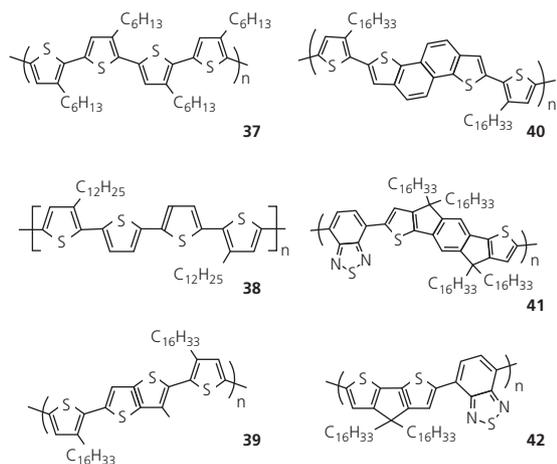

20 months. This is attributed to their deep  $E_{LUMO}$  (and hence low probability for reduction), and the exceptionally close intermolecular packing promoted by Cl-Cl interactions at distances as small as 3.25 Å (Gsänger et al., 2010).

The last two  $n$ -channel materials are the vacuum-deposited fullerene, C<sub>60</sub>, (**35**) and its solution deposited analog, PC<sub>61</sub>BM (**36**) that are extensively used in organic detectors (see Chapter 7). The spherical symmetry of C<sub>60</sub> promotes intimate close-packed arrangements when deposited on almost any surface, and in all three orthogonal directions. The resulting strong  $\pi$ -coupling between adjacent molecules has made this material desirable for  $n$ -channel FETs, with mobilities in excess of 3 cm<sup>2</sup>/V s and with relatively low threshold voltages of  $V_T \sim 10$  V. In contrast, the butyric acid methyl ester functionalization of PC<sub>61</sub>BM that leads to its solubility, also lends steric bulk to the molecules that prohibits its close packing and structural ordering. Hence, solution-processed fullerene-based OTFTs have characteristics that are inferior to those of their vacuum-deposited analogs. Unlike the perylene and naphthalene-based compounds, fullerenes are not easily functionalized. The higher order fullerenes such as C<sub>70</sub> that lack the symmetry of C<sub>60</sub>, exhibit field effect mobilities approximately three orders of magnitude smaller than the latter molecule (Haddon, 1996). An additional disadvantage of fullerene-based OTFTs is that their operating characteristics are not as stable as the perylene- and naphthalene-based compounds.

### 8.6.4 Polymers for p-channel transistors

Example polymers developed for *p*-channel OTFTs are shown in Fig. 8.82. Properties of OTFTs using these molecules are provided in Table 8.4. The molecules fall into two general families; those based on the regioregular polythiophenes (37–40), and thiophene copolymers with rigid, fused molecular backbones (41, 42). Molecular design entails the incorporation of high performance monomers, such as those listed in Table 8.2, into a high molecular weight, soluble chain that can be crystallized into a structure with favorable intermolecular  $\pi$ - $\pi$  coupling such as in Fig. 8.66b.

Oligothiophenes and their derivatives are often employed in small molecule TFTs (19), and indeed are among the first materials to demonstrate organic transistor behavior (see Section 8.2). The thiophene core is easily functionalized to achieve a desired transistor property. Likewise, the thiophene core is employed in numerous *p*-channel polymers in Fig. 8.82. Typically, the performance of polymeric materials is inferior to that of small molecules due to the usual difficulties in achieving high purity, a monodisperse molecular weight distribution, and the needed level of crystalline order over long channels. This is the case in comparing 37, which is P3HT in Section 8.6.1, and PQT-12 (compound 38) that have mobilities approximately five times lower than small molecule oligothiophenes (19). Annealing polymer films can result in improved crystallinity, and hence improved charge transport. For example, polythiophenes with crystalline nano-domains form after annealing at elevated temperatures, resulting in significant improvements in  $\mu_{FEp}$  (Ong et al., 2005).

**Figure 8.82** Example polymers used in *p*-channel OTFTs, with characteristics in Table 8.4.

High thiophene mobilities have been achieved with the PB16TTT block copolymer (39), whose fused rings promote planar stacking, particularly when deposited on SiO<sub>2</sub> surfaces functionalized with fluoroalkyl-based SAMs that induce ordered  $\pi$ - $\pi$  coupling along the in-plane direction. The fused rings localize the electron density, preventing it from spreading along the chain. Field effect hole mobilities of 1 cm<sup>2</sup>/V s along with a low  $V_T = -8$  V and  $I_{on}/I_{off} = 10^6$  have been achieved. The extended fused rings of 40, lead to a performance similar to PB16TTT.

The rigid conjugated backbones of polythiophene copolymers, 41 and 42, show exceptionally high mobilities that are comparable to several high performance small molecule materials in Table 8.2. Compound 41 (IDT-BT) is a fused ladder indaceno-dithiophene (IDT) alternating copolymer with benzothiadiazole (BT). Its molecular structure encourages ordered crystal formation, avoiding the twists that occur in the other polythiophene molecules shown in Fig. 8.82. Similarly, the copolymer, 42, is found to order on PTES-treated SiO<sub>2</sub> gate insulators with their long axes parallel to the substrate, which is perpendicular to the dip coating direction. Both materials have mobilities >1 cm<sup>2</sup>/V s, albeit with somewhat low on-off current ratios.

### 8.6.5 Polymers for n-channel transistors

There have been only a handful of demonstrations of high electron mobility polymers useful in unipolar *n*-channel OTFTs. Many *n*-channel polymer devices have unstable characteristics, with reports providing only incomplete information about the details of fabrication, or other important transistor operating characteristics. Several of the highest performance materials useful in *n*-channel devices are ambipolar conductors: these compounds will be discussed in Section 8.6.6.

Examples of *n*-channel polymers are provided in Fig. 8.83 with device characteristics summarized in Table 8.5. Of these materials, thorough device characterization of a population of devices using a variety of dielectric layers and substrates has only been provided for 44 (Yan et al., 2009).

The intermolecular hydrogen bonding of the electron-deficient diketopyrrolopyrrole-diketopyrrolopyrrole copolymer (DPP-DPP, 43) leads to close  $\pi$ - $\pi$  stacking, and the alkyl chains provide for molecular solubility. For these reasons, DPP-DPP has a high mobility coupled to a low  $V_T$  compared with other *n*-channel polymers listed in Table 8.5. The  $\mu_{FE n} = 3$  cm<sup>2</sup>/V s is the best result obtained among the devices tested (Kanimozhi et al., 2012).

<sup>a</sup> D2200 is a polyolefin-polyacrylate from ActivInk, with  $\epsilon_r = 3.2$ .

The next two compounds (**44** and **45**) use the high ionization energy conjugated naphthalene molecule as their core moiety, largely due to its electronegativity and its ability to form intermolecular  $\pi$ -stacks. The alkyl chains in **44** also lead to good

solubility, and align the molecules in a configuration similar to P3HT in Fig. 8.66a. OTFTs based on this molecule were fabricated into TG/BC devices on glass, PEN and PET substrates using a number of polymer dielectrics (only D2200 is listed but other

**Figure 8.84** Example molecules used in ambipolar channel OTFTs, with characteristics in Table 8.6.

insulators including CYTOP, polystyrene, polymethyl methacrylate, etc. were tested). The device properties are reproducible and stable when exposed to humid air environments. Furthermore, inverter circuits with  $A_v = 26\text{--}29$  were fabricated by gravure printing of an  $n$ -channel device with **44** paired with a P3HT (**37**)  $p$ -channel OTFT.

The poly(pyridinium phenylene) compound, **46**, is interesting in that it is water soluble. Electron-deficient pyridinium rings lower the LUMO energy. The planar close-stacking motif leads to an exceptionally high mobility of  $\mu_{FEH} = 3.4 \text{ cm}^2/\text{V s}$ , although

the drain current characteristics were irregular and unstable. Also,  $I_{on}/I_{off} = 20$ , indicating substantial channel leakage. Hence, while some of these characteristics are intriguing, it is not of practical use at this time.

### 8.6.6 Materials for ambipolar transistors

Several representative materials with nearly balanced electron and hole conducting properties for ambipolar transistor applications are shown in Fig. 8.84, with the corresponding OTFT characteristics summarized in Table 8.6. The example materials

<sup>b</sup> Solution sheared to align molecules.

are selected due to their nearly equal electron and hole mobilities (necessary for high noise margin, low power dissipation complementary logic, see Section 8.4.4), and their beneficial properties for use in OTFTs.

A key attribute of an ambipolar material is a narrow energy gap that reduces the barrier for either hole or electron injection from the source contact. This, unfortunately, also leads to increased off current. In Table 8.6,  $I_{on}/I_{off}$  of most ambipolar OTFTs is  $\leq 10^3$ , which is  $10^3$ - $10^4$  times smaller than for unipolar OTFTs. A contact that is equally efficient for injecting electrons and holes is required. In all of the examples provided, Au is used due to its good film forming properties and a work function that approximately centers its Fermi energy within the ambipolar material energy gap.

Only two small molecule examples (47, 48) are provided; both are analogs of TIPS-pentacene. The molecules contain halogens (Cl and F, respectively) that lower the LUMO energies due to their electron-withdrawing natures. The lower LUMO also results in improved air stability, and their planar cores promote  $\pi$ -stacking. While these molecules provide reasonably balanced electron and hole mobilities, their mobilities are  $<0.5 \text{ cm}^2/\text{V s}$ , which is considerably less than almost all the ambipolar polymers (49-55). And as is the case for the polymers, the threshold

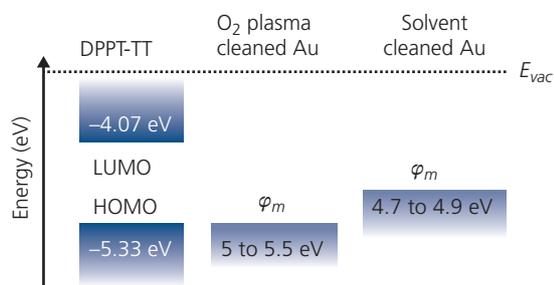

voltages are large, particularly for n-channel conduction.

The next four polymers (49-52) feature an electron-deficient DPP moiety that promotes  $\pi$ -stacking. The alkyl groups result in a high solubility. Hence, when assembled in a copolymer with an electron donating group (such as DPPT-TT, which comprises a thieno[3,2-*b*]thiophene along with two thiophene repeat units in 50), the resulting donor-acceptor motif reduces the energy gap. Compounds 50 and 52 are of particular note due to mobilities that reach to  $>1.5 \text{ cm}^2/\text{V s}$ . Indeed, 50 also has an unusually low  $V_{Tn}$  and  $V_{Tp}$  along with high on-off current ratios characteristic of unipolar compounds.

The energetics of DPPT-TT in Fig. 8.85 is instructive for understanding n-channel and ambipolar OTFTs. The energy gap of the molecule is  $E_G = 1.26 \text{ eV}$ , which results in a comparatively lower energy barrier for both electron and hole injection from Au. The preparation of the contacts also impacts the injection barrier. The contacts were prepared by solvent cleaning and exposure to an O<sub>2</sub> plasma. For the device in Table 8.6, the solvent-cleaned contacts give nearly equal hole and electron injection barriers of approximately 0.6 to 0.7 eV, respectively. When the somewhat weaker benzothiadiazole acceptor in benzobisthiadiazole bithiophene-thienothiophene replaces DPP (PBBTTT, 53), the LUMO and HOMO

energies are  $-3.80$  eV and  $-4.36$  eV, respectively, leading to an energy gap of only  $0.56$  eV. This produces a large  $I_{off}$ , and hence an unacceptably low  $I_{on}/I_{off} \sim 10\text{--}100$ .

The DPP-based copolymers that replace one of the thiophene units with a selenophene (**54**, **55**), and the alkyl group with a solubilizing siloxane, results in the highest mobilities of  $8.84$  and  $4.34$   $\text{cm}^2/\text{V s}$  for holes and electrons in **55**, respectively. The three-

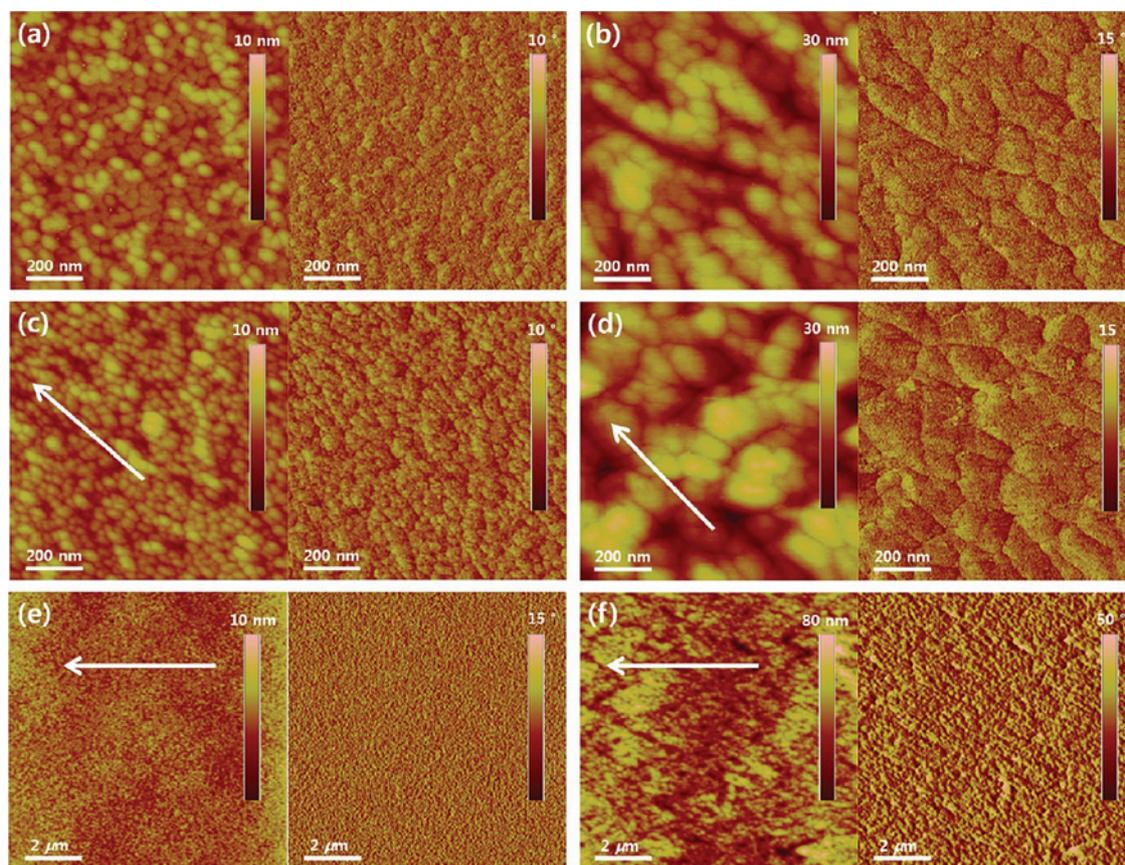

**Figure 8.85** Energetics of DPPT-TT and the work functions of Au contacts prepared by  $\text{O}_2$  plasma, or solvent cleaning (Chen et al., 2012).

dimensional (3D) conductivity was enhanced by limiting the length of the solubilizing side chains. This resulted in dense packing when the hexyl was replaced by a pentyl unit (Lee et al., 2013).

We have noted that the nanocrystalline morphology of solution-processed molecules depends on the rate and method with which the materials are deposited on the gate insulator. For example, a slower rate of deposition via dip coating, vs. drop or spin casting, can result in higher crystalline order, as observed for compounds **54** and **55**.

Solution shearing is one method that produces the unusually high mobilities observed for both the dithienyl-diketopyrrolopyrrole-selenophene copolymer, PTDPPSe with the long, branched 2-octyldodecyl side chain, (**54**) and a hexyl substituted PTDPPSe-Si analogous to (**55**). Atomic force micrographs of the surfaces of these films are shown in Fig. 8.86 (Lee et al., 2012a). While the morphological distinction between drop-cast and solution-sheared films is not as dramatic as implied by the optical micrographs in Fig. 8.70, the differences are nevertheless

**Figure 8.86** AFM images of (a, c, e) PTDPPSe and (b, d, f) PTDPPSe-Si thin films. (a, b) Drop cast and (c–f) solution sheared films. Arrows indicate the shear direction (Lee et al., 2012a).

apparent. Directionality is visible for the sheared films in Fig. 8.86c and f. It is noteworthy that the hole mobilities are more than twice that for similarly annealed (at 220°C) spin and drop-cast films of 55, and the electron mobilities are larger by a factor of nearly three. Even higher mobilities ( $>8 \text{ cm}^2/\text{V s}$ ) have been obtained for solution-sheared TIPS-pentacene that results in millimeter wide by centimeter long crystallites (Diao et al., 2013). These results suggest that entrainment of the crystallites along the in-plane S–D direction can significantly improve performance.

## 8.7 Material deposition and transistor patterning

Section 8.6 emphasized the need for achieving long range order in the in-plane direction. In this context, several different deposition and post-deposition techniques for achieving these desired morphologies were described. A slow deposition process such as drop-casting results in a morphology close to an equilibrium structure. Rapid solvent evaporation in spin-casting leads to a disordered thin film. We also showed that solution shearing induces crystallization along the shear direction via the controlled, slow evaporation of the solvent at the liquid/thin film interface. Nearly all OTFTs benefit from deposition on heated substrates, or by post-deposition thermal annealing of the semiconductor film. Annealing drives the as-deposited morphology toward equilibrium, which results in increased conductivity (and hence mobility) along preferred crystalline directions (cf. Chapter 5.5). Exposure of a solution-deposited film to a solvent vapor also promotes morphological reorganization, again resulting in improved nano- and microcrystalline order (Lee et al., 2009).

Here, we introduce several additional methods for driving thin film morphologies toward a high mobility, equilibrium structure (Liu et al., 2009a, Klauk, 2010, Wang et al., 2011). Our discussion builds on the more general deposition processes discussed at length in Chapter 5. Since patterning and deposition are central elements of the OTFT fabrication process (Sirringhaus et al., 2006), we also include a discussion on patterning processes that result in thin dielectrics and short channel lengths.

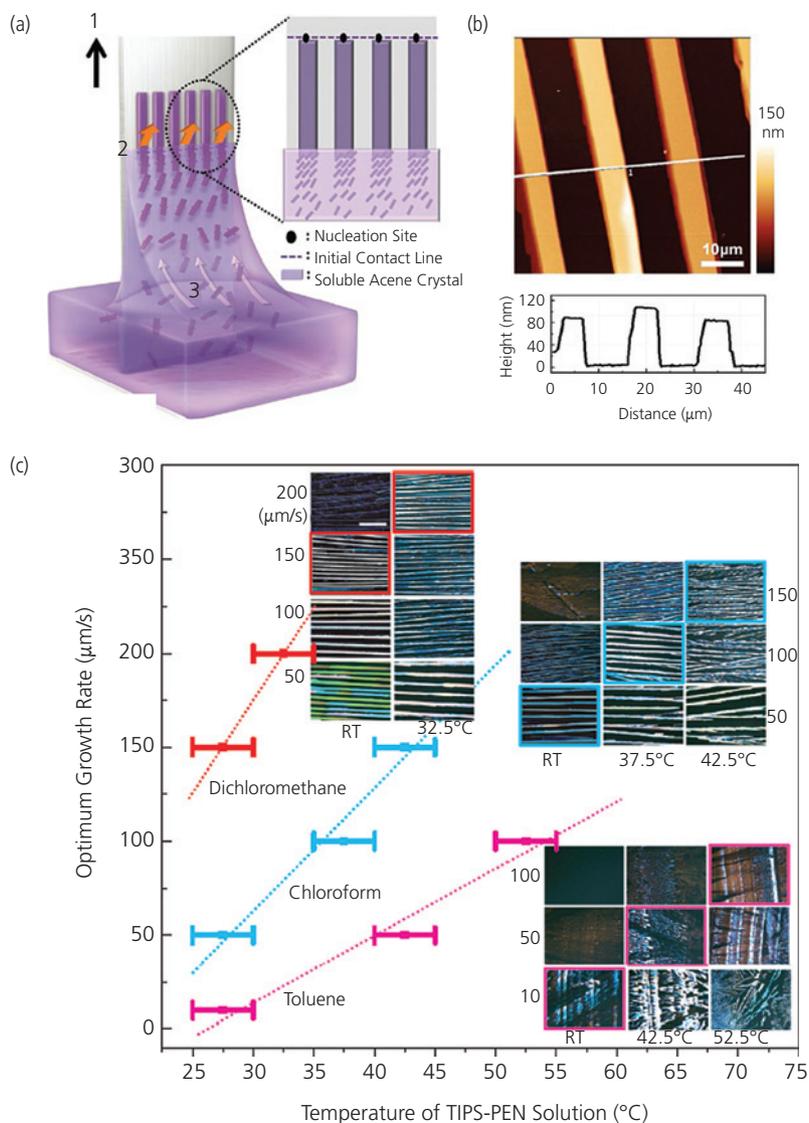

### 8.7.1 Molecular alignment via dip coating and associated techniques

In dip coating, the substrate is slowly withdrawn from a saturated solution of the target molecule (Tsao et al., 2009, Jang et al., 2012). This is analogous to solution

shearing, except that the substrate/liquid/air boundary constitutes free, unconstrained interfaces. Precipitation of the crystallites occurs at the liquid/air boundary due to fast evaporation of a volatile solvent. Initially the nucleation of crystallites is random. However, as the substrate is extracted from the solution, the growth is driven along the pulling direction, creating extended crystallites. This is analogous to the Bridgman method used to grow bulk crystals, whereby slowly withdrawing a seed crystal from the melt creates a growth interface at the liquid surface (see Section 5.4.1). Figure 8.87a shows the dip coating process that generates an array of parallel crystal strips that nucleate at the liquid/air boundary. The growth morphology depends on a balance between substrate pull rate, solution temperature, and molecular concentration. When the substrate is translated at high speed, the crystal thickness and width is decreased while the space between the strips is increased. The strips do not grow into each other due to local depletion of the solute, and the preference for the molecules to crystallize on the already-deposited film. Similarly, increasing the solution evaporation rate by increasing temperature or using a lower boiling point solvent has the same effect as increasing the pull rate. An AFM image of a TIPS-pentacene film grown by pulling from a DCM solution at 150  $\mu\text{m/s}$  is shown in Fig. 8.87b. The lower panel indicates a film thickness of 80–90  $\mu\text{m}$ , and a crystal strip width of  $\sim 10 \mu\text{m}$  (Jang et al., 2012).

The dependence of the optimum pull rate vs. temperature for TIPS-pentacene in solutions of DCM, CF, and toluene is shown in Fig. 8.87c. Also shown are polarization optical micrographs of the resulting films obtained at several growth rates and temperatures. The optimum growth rate and conditions are defined as those that yield the highest hole field effect mobility. Micrographs of the corresponding optimal film morphologies are outlined in colored boxes. As noted, the optimal growth rate increases with temperature and decreasing solution boiling point (the b.p. for DCM, CF, and toluene are 40.0, 60.4, and 110.6°C, respectively). At rates  $\geq 200 \mu\text{m/s}$  in DCM, the rate of substrate translation exceeds the growth rate and consequently, the strips become discontinuous. In the least volatile toluene solution, the films at low temperatures or slow growth rates no longer produce well-defined and uniform strips, since the nearly equilibrium conditions drive the growth of a three dimensional bulk structure.

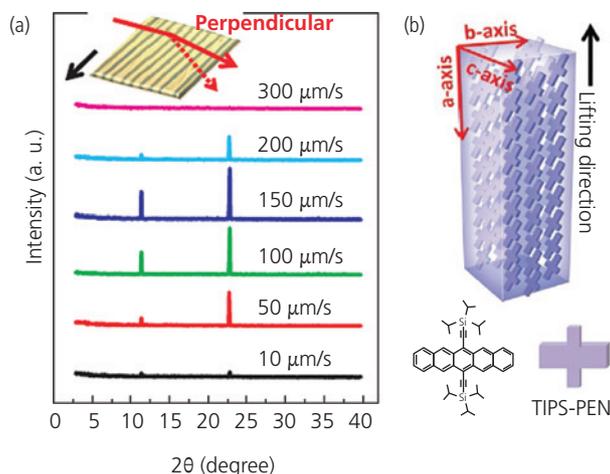

The dependence of stacking order on growth rate for TIPS-pentacene in DCM is quantitatively understood from the glancing incidence X-ray diffraction patterns in Fig. 8.88a. Only peaks along the in-

**Figure 8.87** (a) Illustration of the mechanism of crystal growth via dip coating. The substrate (1) is pulled from solution (3), forming crystalline strips (2) along the pulling direction. (b) AFM image of TIPS-pentacene strips pulled from a DCM solution. Below is shown the thickness profile of the crystallites. (c) Optimum pull rate vs. temperature for TIPS-pentacene in different solutions. The insets are polarization optical micrographs of growths at different temperatures and pull rates showing the crystal strips (Jang et al., 2012).

plane direction are observed, corresponding to an intermolecular spacing of  $d = 7.74 \text{ \AA}$ . This is consistent with the intermolecular  $\pi$ -stacking distance along the b-axis (Anthony et al., 2001). The weakest alignment is found for the sample drawn at  $10 \text{ \mu m/s}$ . The highest X-ray intensity, and hence order, is found for the  $150 \text{ \mu m/s}$  sample. (The film drawn at  $300 \text{ \mu m/s}$  is discontinuous). The low resistivity directions are found along the a- and b-axes: hence alignment of these axes along the channel as inferred from the X-ray data (Fig. 8.88b) should lead to the highest mobilities (Anthony et al., 2001).

The alignment produced by dip coating of a TIPS-pentacene/DCM solution has a significant impact on OTFT performance when the direction of growth is along the channel direction. A comparison of the characteristics of BG/TC transistors with an ALD-grown  $\text{Al}_2\text{O}_3$  dielectric at several different dip coating rates at room temperature is given in Table 8.7. The film deposited at  $150 \text{ \mu m/s}$  results in the highest  $\mu_{FEp}$ , but at the expense of a high  $V_T$  and a lower  $I_{on}/I_{off}$  than at other rates. The film grown closest to equilibrium corresponds to the slowest growth rate of  $10 \text{ \mu m/s}$ . This leads to thick films whose mobilities are two

Inset: Configuration of the X-ray measurement where the incident beam is perpendicular to the pull direction, and at a  $0.15^\circ$  angle relative to the substrate plane. (b) Schematic of the TIPS-pentacene crystal. The molecules are represented by the crosses shown in the lower diagram (Jang et al., 2012).

**Table 8.7** OTFT characteristics for several dip-coating rates for TIPS-pentacene in DCM (Jang et al., 2012)

Rate ( $\mu\text{m/s}$ )	$\mu_{FEp}$ ( $\text{cm}^2/\text{V s}$ )	$V_T$ (V)	$I_{on}/I_{off}$	$S$ (V/decade)
10	0.005	-7.4	48	6.4
50	0.13	-8.0	$8.5 \times 10^4$	1.89
100	0.6–1.0	-7.6	$1.6 \times 10^6$	1.66
150	0.85–1.3	-10.6	$7.6 \times 10^5$	1.3
200	0.05	-10.2	$4 \times 10^4$	1.54

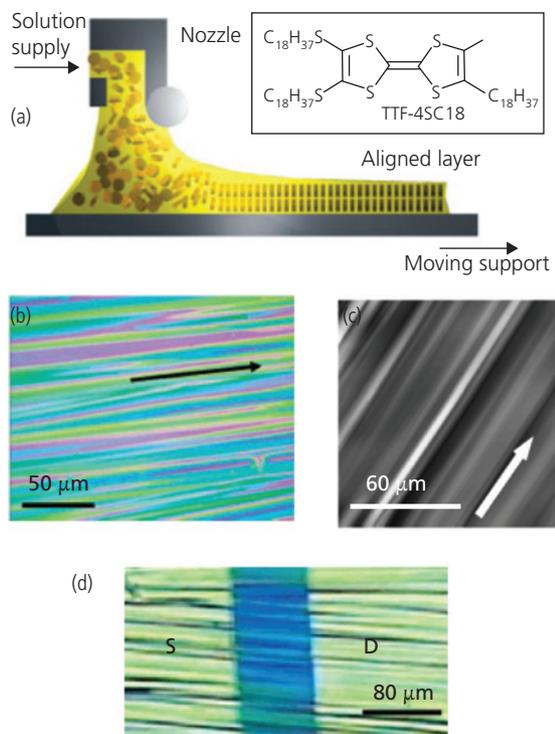

decades lower than the more organized crystal structure obtained at  $150 \mu\text{m/s}$ .

*Zone-casting* shown in Fig. 8.89a is a variant of dip coating. The solution containing the semiconductor solute is cast from a wide nozzle onto a moving substrate at a controlled rate (Pisula et al., 2005, Miskiewicz et al., 2006, Mas-Torrent et al., 2008). Crystals nucleate at the initial nozzle position. As the solvent evaporates, the molecules grow along the substrate translation direction. Films of TTF-4SC18 (see Fig. 8.89a, inset) dissolved in toluene are grown by zone-casting at a substrate temperature of  $80^\circ\text{C}$ . This is sufficient to volatilize the solvent, generating structures shown in Fig. 8.89b–d. The molecules stand with their alkyl groups oriented toward the substrate, forming  $\pi$ - $\pi$  coupled stacks between adjacent, planar TTF units. This places the high mobility direction along the substrate plane, as illustrated in Fig. 8.89a. The optical micrograph in Fig. 8.89b shows alignment of long thin crystallites along the substrate translation direction. The

molecular stacking axis is longitudinally oriented along the growth direction. The AFM image suggest that the surface morphology is terraced, with a roughness of approximately  $30 \text{ nm}$  (Fig. 8.89c) (Miskiewicz et al., 2006).

Bottom gate/top contact OTFTs were fabricated with the channel oriented parallel (Fig. 8.89d) and perpendicular to the casting direction. The gate dielectric comprises plasma enhanced, sequential depositions of  $100 \text{ nm Si}_3\text{N}_4$  followed by  $50 \text{ nm SiO}_2$ . With a gate of  $L = 50 \mu\text{m}$  oriented parallel to the casting direction,  $\mu_{FEp} = 0.015 \text{ cm}^2/\text{V s}$ ,  $V_T = -6 \text{ V to } -10 \text{ V}$ , and  $I_{on}/I_{off} = 10^4$ . When oriented perpendicular, these parameters are  $0.0017 \text{ cm}^2/\text{V s}$ ,  $-15 \text{ V to } -120 \text{ V}$ , and  $10^2$ – $10^4$ , respectively. The reduced performance is a result of misorientation of the  $\pi$ - $\pi$  stacks perpendicular to the transport direction, leading to a large number of crystalline grain boundaries that interrupt hole transport.

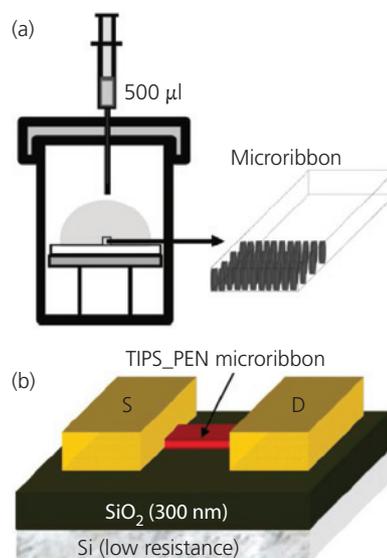

Zone casting, solution shearing, and dip coating rely on ordered crystallization via controlled evaporation. The actual morphology of the resulting film is ultimately determined by the likelihood that the material itself will self-assemble into  $\pi$ -stacks in the in-plane direction. Another method to develop crystalline order is *solvent exchange* illustrated in Fig. 8.90a. The molecular species is dissolved in a solvent where it has a high solubility (e.g. TIPS-pentacene in toluene). A small amount of this solution is introduced into a large volume of a poor solvent (e.g. acetonitrile). As the solution evaporates, the molecules precipitate from solution onto the substrate. The molecules stack into ribbons, driven by their own intermolecular interactions. The microribbons

**Figure 8.89** (a) Schematic of the zone casting process (Pisula et al., 2005). Inset: Molecular structural formula of TTF-4SC18 used in (b)–(d). (b) Optical micrograph and (c) AFM image of a TTF-4SC18 film grown by zone casting from a toluene solution. The direction of substrate translation is indicated by arrows. The maximum- to-minimum height in the image is  $\sim 30$  nm. (d) The S and D contacts of a BG/TC OTFT are shown with the channel. Crystallites are aligned parallel to the translation direction (Miskiewicz et al., 2006).

are coated with the S and D contacts to form the BG/TC OTFT in Fig. 8.90b. Unlike zone casting and related techniques, solvent exchange results in randomly positioned microribbons on the substrate. Indeed, neighboring ribbons may even overlap. This requires placement of each ribbon across individual transistor channels. In the following section, we will show that assembly of the macrostructure (i.e. the ribbons) may be oriented by pre-patterning “entrainment” structures on the target substrate. Field effect mobilities for OTFTs in Fig. 8.90b are as high as  $1.42 \text{ cm}^2/\text{V s}$  ( $I_{\text{on}}/I_{\text{off}} = 10^4$ ) compared to  $0.17 \text{ cm}^2/\text{V s}$  for TIPS-pentacene transistors deposited by conventional solution coating (Kim et al., 2007).

One final precipitation scheme to consider is *controlled drying* of a semiconductor-containing solution applied via inkjet printing. The dynamics of droplet formation and evaporation illustrated in Fig. 8.91 are also discussed in Section 5.6.5. In a heterogeneous solution, evaporative flow drives the solution to the droplet edges, which is countered by *Marangoni flow*

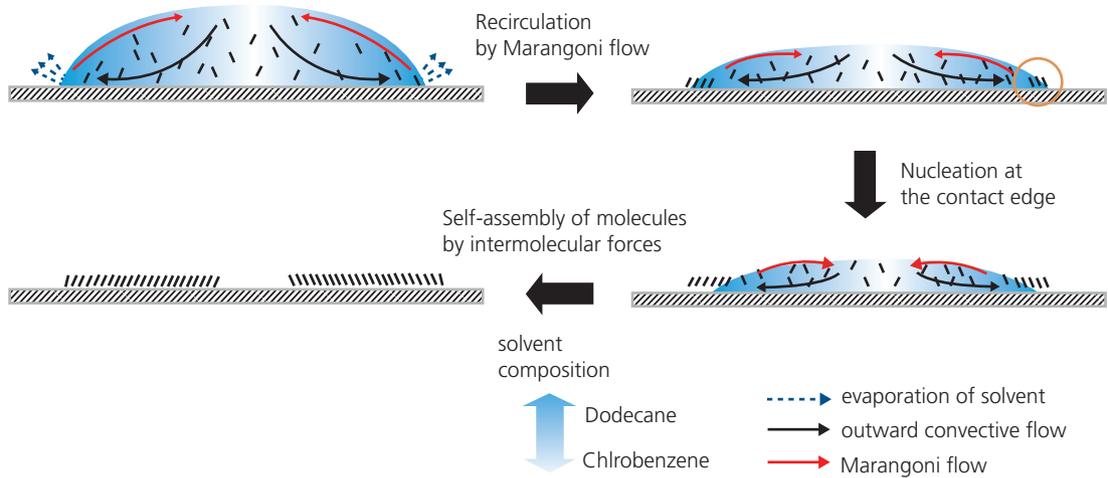

**Figure 8.90** (a) Schematic of solvent exchange crystallization. A small volume of solution is dropped onto a substrate via syringe within a larger volume containing a second solvent. The molecular material has a reduced solubility in the second (shown by the shaded hemisphere) vs. the first solvent. The solvent is allowed to slowly evaporate, leaving molecular stacks forming microribbons. (b) BG/TC OTFT with a TIPS-pentacene microribbon spanning the gap from S to D (Kim et al., 2007).

that is determined by the surface energy of the droplet. This leaves the precipitation of solute at the edges of the droplet as it shrinks. Provided the molecules tend to form  $\pi$ -stacks, they self-assemble into a “coffee ring” with the high conductivity direction oriented in a radial direction from the injection point. To exploit the radial crystalline orientation, the source and drain contacts need to be configured into concentric circles (Lim et al., 2008).

As with other precipitation methods, the rate of evaporation controls the ability of the solute to form an organized, equilibrium structure. Since it is not possible to precisely control the evaporation rate of a single component solvent, a second, high boiling point (b.p.) solvent is introduced. The second solvent counters the outward convective flow of the low b.p. solvent via Marangoni flow. The balance of these two flows is controlled by the solvent mixture, delivering the molecules to the droplet periphery at a rate that is optimal for self-assembly.

### 8.7.2 Molecular orientation on surface-modified substrates

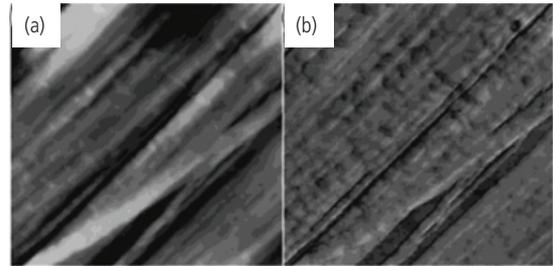

In Section 5.4.2, we showed that molecules can align to corrugations in the topography of the surface energy at the substrate when deposited under

**Figure 8.91** Formation of self-assembled  $\pi$ -stacked films of an organic semiconductor delivered to a substrate by inkjet printing (Lim et al., 2008).

appropriate conditions. This was discussed in the context of quasiepitaxy, whereby the substrate is prepared to create a low surface energy direction, followed by deposition of a layer whose comparatively stronger intermolecular binding forces drive self-assembly initiated by the substrate.

Numerous surface preparations have been developed that establish self-ordering in transistors (Liu et al., 2009a). These have resulted in significant anisotropies in charge mobility in the in-plane direction. For example, *rubbing* the substrate surface prior to deposition can influence alignment of liquid crystal molecules (Ishihara et al., 1989, Depp and Howard, 1993). The process uses a polymer coating that is mechanically rubbed, or brushed along a given direction. Subsequently deposited molecules assemble into anisotropically ordered morphologies induced by energetic corrugations impressed on the alignment layer. Rubbing has also been used to force alignment of organic semiconductors deposited in the channel of OTFTs to increase mobility (Sirringhaus et al., 2000b, Chen et al., 2001). Figure 8.92 shows the morphology of a 50 nm thick film of  $F_{16}CuPc$  (compound **26**,  $M = Cu$ , Fig. 8.79), vacuum deposited onto a 5 nm thick rubbed film of the same composition on a  $SiO_2$  layer on Si. The pre-deposited layer is rubbed at room temperature using a PTFE (or Teflon®) bar that is repeatedly and gently slid along the substrate approximately ten times. The striations in the AFM images have widths of 50–100 nm, and lengths of approximately  $10\mu m$  along the rubbing direction. The root-mean-square (rms) roughness of the ridges is 2.5 nm. Crystallographic and optical analysis suggests that these ridges are thin crystallites of molecular

**Figure 8.92** (a) Height and (b) phase contrast AFM images of a 50 nm thick  $F_{16}CuPc$  film on a 5 nm thick, pre-rubbed template layer of the same composition (Chen et al., 2001).

stacks of  $F_{16}CuPc$  that preferably align along the rubbing direction.

Top contact, bottom gate OTFTs using pentacene films grown on a 5 nm thick rubbed layer of the same composition on a  $SiO_2$  gate dielectric show large asymmetries in hole mobility, supporting the conclusion that rubbing entrains subsequently deposited material to  $\pi$ -stack along the rubbing direction. The mobility in channels oriented parallel to the rubbing direction is  $\mu_{FEp\parallel} = 0.24\text{--}0.25\text{ cm}^2/\text{V s}$ . The mobility anisotropy ratio is  $\mu_{FEp\parallel}/\mu_{FEp\perp} > 40$ , where the subscripts  $\parallel$  and  $\perp$  refer directions parallel and perpendicular to the rubbing direction respectively (Chen et al., 2001).

A more forceful means for aligning molecules is to initially form a highly directional template on the substrate surface, followed by deposition either from solution or vapor, of the semiconductor film. *Friction*

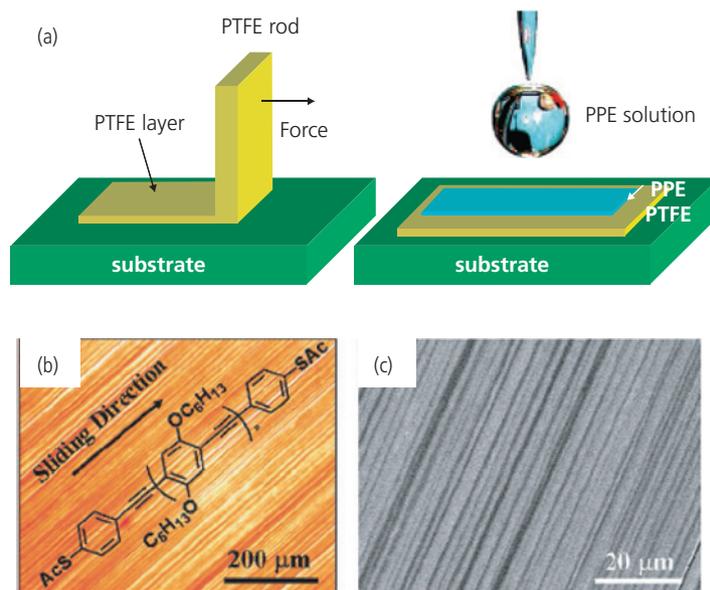

*transfer deposition* is one such templating method (Nagamatsu et al., 2003, 2004, Li et al., 2005, Dong et al., 2008). The PTFE alignment layer illustrated in Fig. 8.93a is deposited by applying a constant pressure to a PTFE rod or pellet, with the substrate heated to 280°C. At this temperature, the PTFE softens while being translated along the substrate. This leaves behind PTFE chains aligned along the drawing direction. Next, a rigid-rod polymer such as PPE with thioacetyl end groups (TA-PPE) in a THF solution is drop-cast onto the PTFE surface. The polymer orients along the PTFE chain direction as the solvent evaporates, apparent from the striated films shown in Figs. 8.93b and c. The photoconductivity of the aligned TA-PPE measured after depositing S and D contacts on the film surface increases by 20 times compared with unaligned films (Dong et al., 2008). This technique has also been used to align polymers in OTFTs, creating conductive anisotropies as large as  $\sigma_{\parallel}/\sigma_{\perp} = 100$  (Li et al., 2005).

Other substrate modification techniques that coerce the directionality of subsequently deposited films include deposition on structured surfaces by *nanoimprinting* (Zheng et al., 2007), and by exposure of a photosensitive layer to linearly polarized light. This latter *photoalignment* technique has been adapted from methods used to orient molecules in LCDs (Ichimura, 2000). A 100 nm thick polyimide layer deposited on a SiO<sub>2</sub> gate dielectric acted as a growth template of the 100 nm thick pentacene channel by exposing the polyimide with polarized UV light. The BG/TC OTFT

exhibited a maximum hole mobility of 0.75 cm<sup>2</sup>/V s with  $\mu_{FEp\parallel}/\mu_{FEp\perp} = 13 - 25$  (Chou and Cheng, 2004).

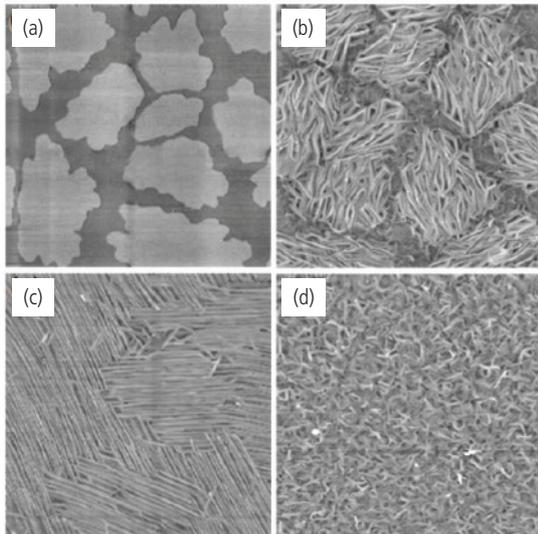

Small molecules have been aligned by deposition on a thin templating layer that self-assembles during deposition due to strong intermolecular van der Waals forces (Wang et al., 2007, Lassiter et al., 2010, Yook et al., 2011). For example, a 2 nm thick layer of p6P deposited by ultrahigh vacuum organic molecular beam deposition onto a SiO<sub>2</sub> substrate at 180°C forms  $\sim 2 \mu\text{m}$  diameter nanocrystalline islands (Fig. 8.94a). Next, ZnPc is deposited onto the p6P surface islands. The ZnPc molecules stand upright on the oligophenylene, p6P surface, with their crystalline direction imposed by the underlying p6P template lattice orientation (Fig. 8.94b and c) (Wang et al., 2007). In contrast, ZnPc deposited onto bare SiO<sub>2</sub> substrates showed small domain sizes that are comparatively rougher, and randomly oriented relative to each other, see Fig. 8.94d.

While this example shows that the ZnPc domains have random in-plane orientation with grain sizes of  $\sim 10 \mu\text{m}$ , the oligophenylene forces the ZnPc to stand up rather than lie flat on the substrate. This orientation improves in-plane intermolecular  $\pi$ - $\pi$  coupling, and hence the mobility along the channel. Indeed, ZnPc initiated on p6P films on BG/TC OTFTs result in  $\mu_{FEp} = 0.32 \text{ cm}^2/\text{V s}$  compared to only 0.022 cm<sup>2</sup>/V s for films grown on SiO<sub>2</sub> without the template. It is likely that a combination of the templating layer deposited on a directionally modified substrate surface

(e.g. via friction transfer, rubbing, etc.) would result in further orientation of the  $\pi$ -stacks along the channel from source to drain.

### 8.7.3 Direct printing of OTFT contacts

A discussion of numerous printing techniques of organics and their contacts has already been provided in Section 5.6. Several of these methods, such as gravure and flexographic printing have been employed to pattern the S, D and G contacts of OTFTs (Sirringhaus et al., 2006, Yan et al., 2009). Here, we discuss two methods that are particularly promising for contact patterning due to their potential for high resolution, and ability to print over large areas: inkjet and microcontact printing.

Well-defined inkjet printed contacts can be realized by functionalizing the substrate surface into regions that are variously hydrophobic and hydrophilic. Then, droplets dispensed onto the surface form regions whose boundaries are defined by the difference in energy of the solution and the surface on which it is deposited. Figure 8.95a illustrates how droplets are confined by variations in substrate surface energy to form OTFT contacts. The first step involves deposition of a 50 nm thick hydrophobic layer of PI on a glass substrate surface. After patterning, the surface is made hydrophilic by exposure to an  $\text{O}_2$  plasma that also removes PI from the source and drain regions. Next, a conducting PEDOT:PSS layer is dispensed from an inkjet nozzle near to the PI barriers. Due to

**Figure 8.95** Inkjet printing of contacts. (a) Droplets of conductive, aqueous PEDOT:PSS solution are dispensed onto a hydrophilic glass substrate with a patterned hydrophobic polyimide (PI) barrier that defines the source and drain contacts separated by the channel of length,  $L$ . (b) AFM image of the S and D contacts. (c) Completion of the OTFT by deposition of the F8T2 channel and PVP gate insulator, followed by a second inkjet printed PEDOT:PSS gate contact (Sirringhaus et al., 2000a).

the low surface energy of the substrate, the droplet flows until it comes into contact with the barrier, whose width,  $L$ , defines the channel length. Since the PI surface is hydrophobic, the droplet does not overtop the barrier, forming a pattern whose resolution is limited by photolithography. Droplets are continually

ejected onto the substrate surface as the inkjet nozzle is translated parallel to the barrier, defining the channel width. The rate of droplet dispensing is set by the inkjet nozzle speed to write a continuous conducting contact without necks or breaks.

The effects of the non-wetting barrier are visualized by the droplet shape in the AFM image of the contacts in Fig. 8.95b. The OTFT is completed by depositing F8T2 in a xylene solution (see Fig. 8.95c). This solvent is orthogonal to the aqueous PEDOT:PSS solution, thus preventing re-dissolving of the S and D contacts. Finally, the PVP gate insulator is applied, followed by a second inkjet printing of the PEDOT:PSS gate electrode.

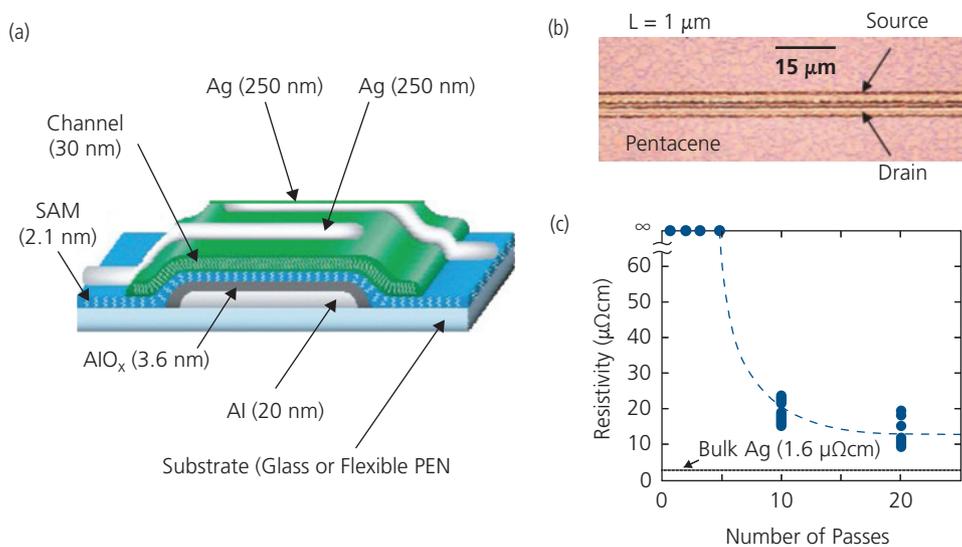

Unipolar inverter circuits featuring a pair of printed F8T2 transistors with  $L = 5 \mu\text{m}$ , interconnected by inkjet-printed conducting vias have been demonstrated (Siringhaus et al., 2000a). The vias are realized by dispensing a droplet of isopropanol onto the PVP, thereby dissolving it and allowing the drain of the load to connect to the source of the drive transistor.

It may not be necessary to dispense two droplets to separately define the S and D contacts. A single, larger droplet can alternatively be dispensed directly onto the center of the barrier. The droplet then splits into two, with each half falling into opposing wells (Siringhaus et al., 2006). Furthermore, controlling the volume of the droplet consisting of Ag nanoparticles suspended in a tetradecane solution to less than 1 fl has led to pattern resolutions of  $<1 \mu\text{m}$ , which is ultimately limited by the diameter of the droplets. The

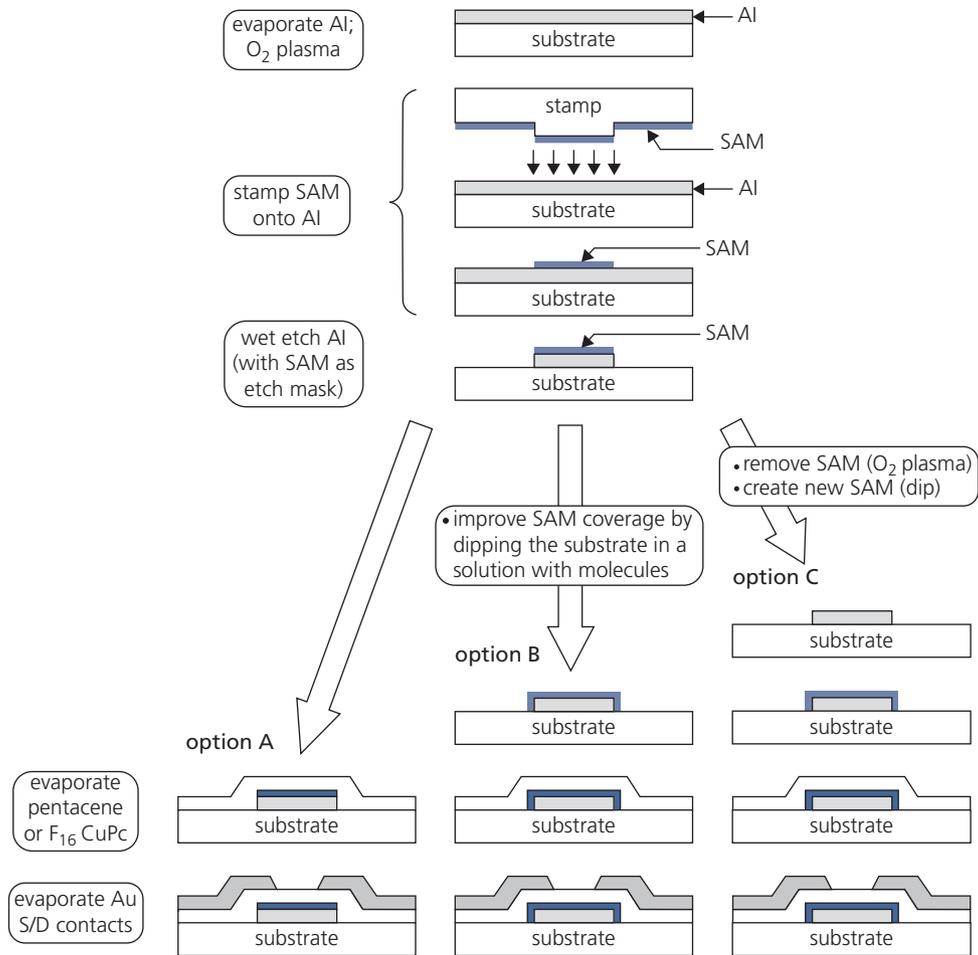

Ag particles form into conductive S and D electrodes when fused at  $130^\circ\text{C}$  for 1 h in  $\text{N}_2$ . An illustration of BG/TC OTFT employing printed Ag NP S and D contacts is shown in Fig. 8.96a, with a micrograph of the top of the device shown in Fig. 8.96b. The thickness, and hence the resistivity of the lines is determined by the number of printer passes. As the number of passes increases from 1 to 20, the thickness increases from 30 nm to 600 nm, and the resistivity approaches that of bulk Ag. The dependence of resistivity on the number of passes is shown in Fig. 8.96c. Due to the very thin  $\text{AlO}_x$  gate insulator functionalized by an n-octadecylphosphonic acid SAM, the operating voltage of the OTFT is  $<3 \text{ V}$ , making the devices useful for high gain, low power circuits operating at  $\sim 1 \text{ MHz}$  (Sekitani et al., 2008). A position-sensitive pressure sensor discussed in Section 8.9 has been realized with integrated arrays of such printed transistors (Noguchi et al., 2006).

Contact printing of electrodes is an alternative to inkjet printing. In Section 5.6.4, we introduced the concept of cold-welding as a method for transferring very high resolution metal or organic patterns from a stamp to a receiving surface to fabricate OLEDs, detectors and other organic electronic devices (Kim et al., 2000, Kim and Forrest, 2003, Xu et al., 2008). A variation of the stamping process has been used to both functionalize and pattern the gates of BG/TC OTFTs.

The patterning process is illustrated in Fig. 8.97 (Zschieschang et al., 2008). The fabrication of the OTFT begins by coating the substrate (in this

**Figure 8.96** High resolution inkjet-printed pentacene OTFT. (a) Schematic of the OTFT with thicknesses of each layer indicated. (b) Micrograph of the OTFT channel region with  $L = 1 \mu\text{m}$ . (c) Resistivity of the inkjet printed S and D contacts vs. number of printing passes (Sekitani et al., 2008).

example, glass) with a layer of Al. The substrate is exposed to an O<sub>2</sub> plasma to form a 3.6 nm thick oxide surface that serves as the gate insulator in the BG/TC OTFT. Next, a PDMS elastomeric stamp with the gate patterns occupying raised portions is formed by photolithographic patterning followed by etching recesses in a master (typically Si or glass). The master is filled with PDMS, which is subsequently cured and peeled from the master. The stamp is dipped in a solution containing the appropriate functionalizing SAM such as *n*-octadecylphosphonic acid, which attaches to the PDMS surface. The stamp is pressed against the AlO<sub>x</sub> surface on the substrate, leaving behind the 2.1 nm thick SAM, which is stabilized by heating and drying. Areas covered by the SAM are protected from the wet acid etchant used to remove the Al/AlO<sub>x</sub> in the exposed regions. At this point,

there are three options for completing the device. **A:** vacuum deposit the organic channel layer, followed by deposition of the source and drain electrodes that are patterned using a shadow mask. **B:** The substrate is dipped in a solution of phosphonic acid to improve coverage along the exposed edges of the Al gate to prevent leakage into the channel. This step also repairs damage to the top gate surface SAM incurred on wet etching and handling of the sample during the gate etch step. The remainder of the process is as in option **A**. **C:** Assuming that the gate etching step irreparably damages the SAM, it is completely removed in an O<sub>2</sub> plasma, and the substrate is dipped in the SAM solution. Subsequent steps then are once more identical to option **A**. The disadvantages of options **B** and **C** are that they are slightly more complex than **A**, but this is counterbalanced by the

**Figure 8.98** Complementary inverter transfer characteristics based on pentacene p-channel and  $F_{16}CuPc$  n-channel OTFTs fabricated by the three options in Fig. 8.97. The transfer characteristics shown by red lines are referred to the left axes, and the gate leakage current shown by blue lines refer to the right axes (Zschieschang et al., 2008).

advantage of improved device performance and yield due to reduced gate leakage.

This process has been implemented to fabricate complementary inverters based on pentacene p-channel and  $F_{16}CuPc$  n-channel OTFTs. The field effect mobilities were  $\mu_{FEp} = 0.4 \text{ cm}^2/\text{V s}$  and  $\mu_{FE n} = 0.01 \text{ cm}^2/\text{V s}$ , respectively. Importantly, the gate leakage current,  $I_{GS}$ , decreased from  $10^{-8} \text{ A}$  for option A, to  $<10^{-10} \text{ A}$  for B, to  $<10^{-11} \text{ A}$  for C. This results in significantly lower power dissipation in the inverter quiescent mode. With a peak  $I_D = 1 \mu\text{A}$ , the ratio  $I_D/I_{GS} = 100, 10^4$ , and  $>10^5$ , for options A, B, and C, respectively (Zschieschang et al., 2008).

The dependence of the inverter transfer characteristics on process procedure is shown in Fig. 8.98. Owing to the very thin gate insulator comprising the  $AlO_x/SAM$  combination, the operating voltages are  $<3.0 \text{ V}$ . The gate leakage (blue lines) as  $V_{in} \rightarrow 0 \text{ V}$  is related to the quiescent circuit power dissipation. The repair and replacement of the SAM following gate etching has a dramatic effect on reducing the leakage from  $\sim 40 \text{ nA}$ , to  $110 \text{ pA}$ , to  $12 \text{ pA}$  for circuits fabricated by options A, B, and C, respectively. This corresponds to respective power dissipations of  $114 \text{ nW}$ ,  $330 \text{ pW}$ , and  $36 \text{ pW}$ , a substantial difference when employed in large integrated circuits where each gate contributes to the total circuit power. Other performance parameters of the inverters such as voltage gain and operating voltage are relatively independent of process procedure.

The stamping process has numerous variants, as described in Section 5.6.4. The apparent ease with

which direct printing can produce high performance, low power dissipation circuits is emblematic of one of the signature advantages of organic electronics. The adaptability of processing techniques that are largely inaccessible to inorganic semiconductors allows for their implementation over very large areas, and they may even be adapted to continuous R2R manufacturing processes. Ultimately, this can lead to low cost, provided that the performance of the devices thus produced is sufficient to meet the demands of their intended applications.

## 8.8 Reliability of organic transistors and circuits

Integrated circuits are expected to provide reliable operation from days to years, while being exposed to environments that may require hermetic packaging. However, the stability requirements for OTFTs may not always be as demanding as for other organic electronic devices such as OLEDs and OPVs, especially where the circuit is employed for chemical sensing, or in one-time use, disposable medical applications.

Unstable device operation is identified by time-dependent changes in the threshold voltage, sub-threshold slope, transistor “off” current, channel mobility, output (or channel) conductance, gate leakage, and hysteresis in the drain current as  $V_{DS}$  is swept across the transistor operating range in the positive vs. the negative directions, etc. If we rule out catastrophic failure due to shorts or dielectric breakdown, the most common sources of device aging are

time-dependent charge trapping at interfaces and grain boundaries due to morphological changes in the thin films, ingress of contaminants from the environment, decomposition of the organic semiconductors, migration of ions within the dielectric and into the channel, and deterioration of the source and drain contacts, also potentially due to material decomposition or even electromigration of the S and D metals into the organic layer.

We have seen that the noise margin determines the circuit reliability, that is, larger noise margins in a logic stage result in a greater probability that the subsequent stage will correctly identify its input as a high or low state. The gains and threshold voltages of the individual transistor stages, in turn, determine the noise margin. Clearly, the threshold voltage must be stable, and within a minimal spread of values for a large integrated circuit to operate properly. Hence a preponderance of work on understanding and improving OTFT reliability has focused on mechanisms that affect  $V_T$ . In the following sections, we describe methodologies used to quantify and understand changes in  $V_T$  and other operating characteristics, and several theories as to the source of these phenomena.

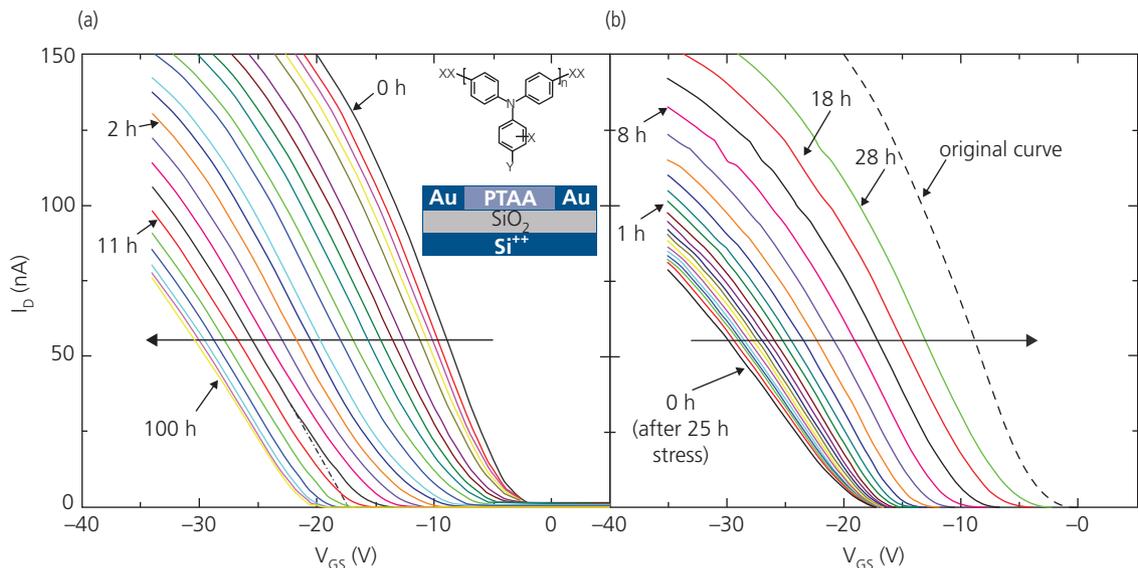

### 8.8.1 Tracking and understanding threshold voltage shifts

The lifetime of the transistor is quantified in terms of its duration of use (*operating lifetime*) and storage (*shelf life*). The device is under far higher stress during

operation, and hence this is the most important mode of aging. However, the devices must be stable even when not in operation to ensure that the circuit is fully operational when it is eventually “plugged in.” The latter failure mode occurs on a much longer time scale than the former, and is almost always due to the use of unstable organic molecules or exposure to contaminants during storage or fabrication. For this discussion, we assume that the shelf life of the device is long, and is not of primary concern since its origins are almost always extrinsic.

Intrinsic aging processes that limit the operating lifetime are not easily eliminated by improved processing or packaging. They are studied by applying a d.c. or a.c. signal to the gate while measuring the transfer characteristics over an extended period. Degradation can be accelerated by using a high voltage stress, elevated temperature, or large drain current, although test conditions are generally those used under normal operating conditions (Lee et al., 2012b, Jia et al., 2018).

The drift of the transfer characteristics (or the drain current at fixed  $V_{GS}$ ) over an extended period of a PTAA BG/TC transistor employing an HMDS-coated  $\text{SiO}_2$  gate insulator are shown in Fig. 8.99a. The characteristics are obtained by applying a constant stress of  $V_{DS} = -3$  V and  $V_{GS} = -20$  V while periodically halting the test to measure the  $I_D$ - $V_{GS}$  characteristics (Sharma et al., 2009). Several time-dependent changes are noticed in these characteristics. The threshold voltage, which is estimated by the extrapolation of

**Figure 8.99** (a) Transfer characteristics of the device in the inset as a function of time. The stress conditions used during aging are  $V_{DS} = -3$  V and  $V_{GS} = -20$  V. (b) After the stress is applied for 25 h and then removed, the transfer characteristics slowly return toward their original values. The original transfer curve (dashed line) is not entirely recovered within the time of the test (Sharma et al., 2010).

the linear region of the characteristics to  $I_D = 0$  (dashed line and arrow, Fig. 8.99a), shifts to larger negative voltage (i.e. in the direction of the applied gate potential) for this p-channel device. The threshold voltage appears to reach an asymptote after  $\sim 100$  h at the gate stress bias of  $-20$  V. Also, the slope of the  $I_D$ - $V_{GS}$  characteristics decreases with aging, indicating a decrease in the mobility and sub-threshold slope,  $S$ . Once the stress is removed after its application for 25 h, the drift in the transfer characteristics reverses direction, returning toward their original values (dashed line, Fig. 8.99b). However, the characteristics rarely recover completely, showing a permanent offset in  $V_T$  from its original, as-grown value.

The drift in  $V_{GS}$  has been attributed to defects that gradually migrate into the channel, or reside at the organic/insulator interface. This induces in a change in the fixed charge concentration in the dielectric bulk or at the interface that reduces the field in the channel for a given  $V_{GS}$ . This, in turn, reduces the drain current (Sharma et al., 2009, 2010). The shift in threshold voltage is given by

$$\Delta V_T(t) = (V_T(t) - V_T(0)) = \frac{q\Delta N_{tr}(t)}{C_i}, \quad (8.75)$$

where  $\Delta N_{tr}(t)$  is the time-dependent change in insulator and/or interface charge concentration.

The drift has been fit to a model used to describe metastable defect formation in hydrogenated amorphous Si transistors that show similar long-term behavior (Jackson et al., 1989). While the mechanism of hydrogen defect formation is clearly not active in organic transistors, the model is based on the existence of an exponential distribution of trap energies that results in dispersive diffusion of defects over time, similar to that observed for the charge mobility in the presence of an exponential density of defect states (see Section 4.3.2). The diffusion constant follows

$$D(t) = D_{00}(\nu t)^{m-1}, \quad (8.76)$$

where  $D_{00}$  is a constant,  $\nu$  is the attempt frequency for diffusion (i.e. the frequency with which a defect attempts to move from site  $i$  to  $i\pm 1$  in the solid), and  $m = T/T_0$ . The characteristic temperature,  $T_0$ , defines the exponential defect distribution (cf. Eq. 4.140). That is, the defect distribution follows,  $h_{tr}(E) = h_{tr0} \exp(-E/E_T)$ , where  $h_{tr0}$  is a constant,  $E_T$  is the characteristic defect energy, and  $E$  is the energy.

The change in defect density with time is then (Jackson et al., 1989)

$$\frac{d\Delta N_{tr}}{dt} = -AD(t)\Delta N_{tr} = -AD_{00}(\nu t)^{m-1}\Delta N_{tr}, \quad (8.77)$$

where  $A$  is a constant. The solution to this equation is the familiar *stretched exponential* that provides a good fit to the time rate of change of other electronic devices such as OLEDs and OPVs. That is, from Eq. 8.77 we obtain

$$\Delta N_{tr}(t) = \Delta N_{tr}(0) \exp\left(-\frac{t}{\tau}\right)^m, \quad (8.78)$$

which yields a time dependent threshold voltage of

$$\Delta V_T(t) = \Delta V_T(\infty) \left(1 - \exp\left(-\frac{t}{\tau}\right)^m\right). \quad (8.79)$$

The maximum threshold voltage shift at  $t = \infty$  cannot exceed the gate voltage, thus,  $\Delta V_T(\infty) \rightarrow V_{GS}$ . The time constant for  $\Delta V_T$  is given by

$$\tau = (2\pi\nu)^{-1} \exp(E_T/k_B T), \quad (8.80)$$

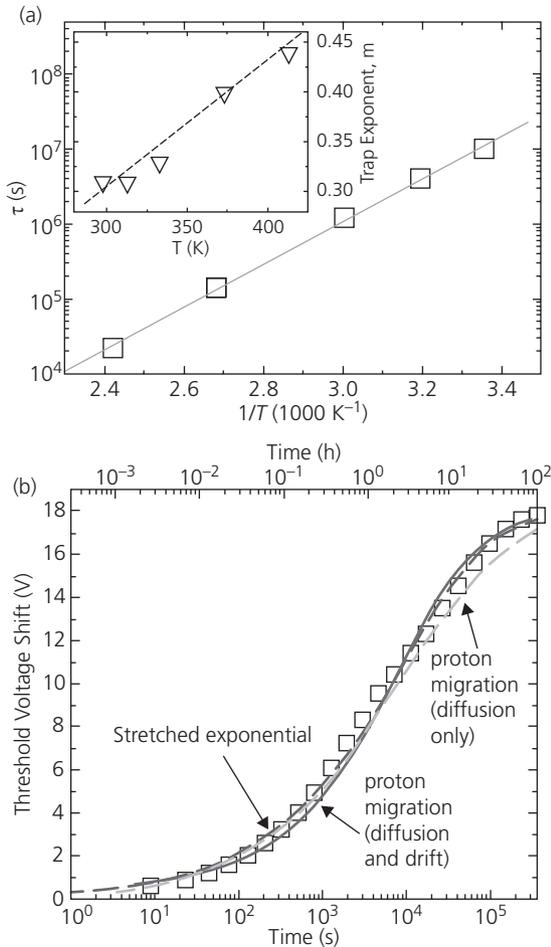

which has activation energy:

$$E_T = k_B T_0 \log\left(\frac{2\pi\nu m}{AD_{00}}\right). \quad (8.81)$$

Hence, the rate of threshold voltage shift is thermally activated with energy,  $E_T$ . The activation energy is the energy required for the defects to form or migrate into the channel, and thus provide a site for charge trapping.

The defect diffusion model has been applied to PTAA OTFTs in Fig. 8.99 with results shown in Fig. 8.100 (Mathijssen et al., 2007). The thermal activation of the characteristic time constant for  $\Delta V_T$  is obtained from the fit to stretched exponential data following Eq. 8.79 at several different temperatures in Fig. 8.100a. The fit yields a time constant of  $\tau = 10^7$  s (approximately 2800 h) at room temperature, and  $m = 0.3$  using an attempt frequency of  $\nu = 1$  kHz. The thermal activation energy for defect migration is  $E_T = 0.6$  eV, which differs significantly from  $E_T \sim 1$  eV for more thermally active hydrogen defects in a-Si (Deane et al., 1998). In Fig. 8.100a, inset, the trap exponent,  $m$ , is plotted vs. temperature. As noted above, the model predicts that  $m \propto T$ , which is indeed found for the PTAA transistors. The slope gives  $T_0 = 900$  K, which is comparable to  $T_0 = 720$  K for a-Si.

The stretched exponential fit to the threshold voltage shift provides an accurate representation of the data (see Fig. 8.100b). The applied voltage stress is  $V_{GS} = -20$  V at  $T = 140^\circ\text{C}$ . The parameters used to fit the data are  $m = 0.43$  and  $\tau = 10^4$  s. Data similar to those in Fig. 8.100 are also obtained during recovery. The  $T_0$  is the same as obtained under stress, since the trap density distribution does not change with time. However, the activation energy during recovery is 0.3 eV, or only half that during stress. Likewise the attempt frequency is only 4 Hz, compared to 1 kHz (Mathijssen et al.,

**Figure 8.100** (a) Characteristic time ( $\tau$ ) of the threshold voltage shift ( $\Delta V_T$ ) of the PTAA transistor in Fig. 8.99. The straight line fit to the data yields an activation energy of 0.6 eV. Inset: Characteristic trap exponent vs.  $T$  (Mathijssen et al., 2007). (b)  $\Delta V_T$  vs. time with a fit to a stretched exponential (blue dashed line), a model based on proton migration from the dielectric bulk (green dashed line), and proton migration due to both diffusion and drift (solid line) (Bobbert et al., 2012).

Copyright © 2012 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

2007). These differences suggest that trapped charge relaxation occurs once stress is removed, resulting in a much longer time for the charge to be neutralized.

The thermal activation of the aging time,  $\tau$ , suggests that degradation can be accelerated at elevated temperatures. For example, in pentacene films with  $\tau_0 = 10^{-8}$  s and  $E_T = 0.67$  eV, aging for 30 min at  $80^\circ\text{C}$  is equivalent to aging for 2 days at room temperature (Lee et al., 2012b).

Figure 8.101 illustrates how the pinch-off voltage (and analogously, the threshold voltage) depends on charge trapped in the dielectric. Prior to the application of stress (Fig. 8.101a), the threshold voltage of the p-channel OTFT is positive due to negatively trapped charges within the dielectric, or at the

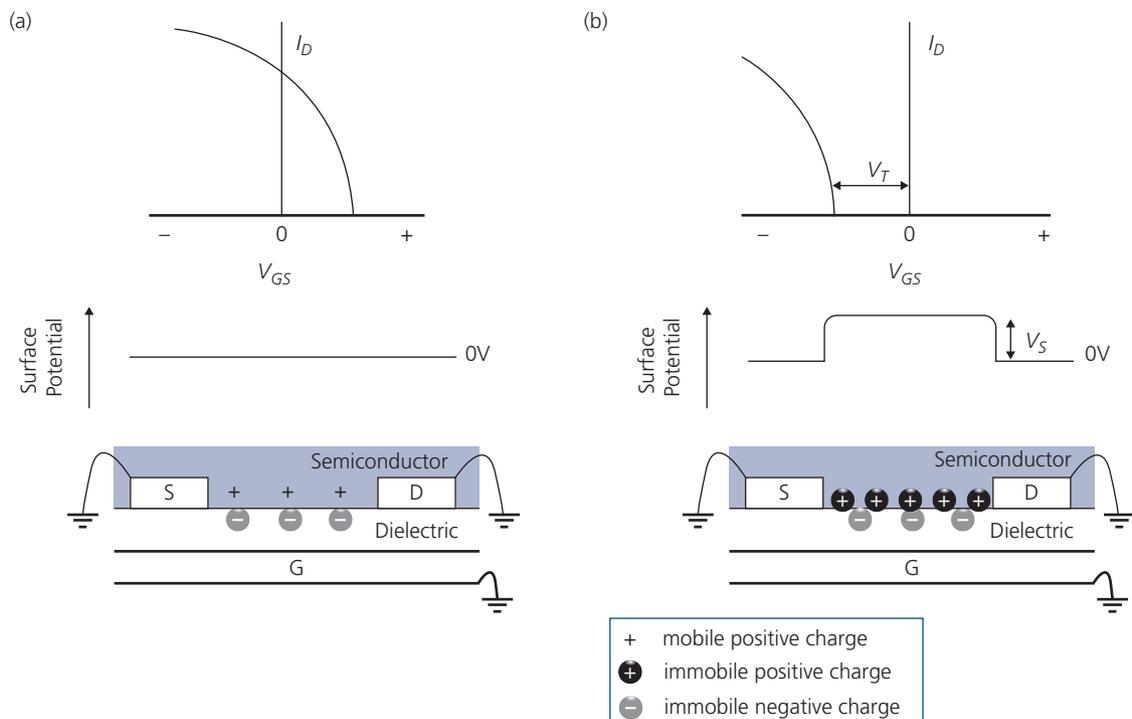

interface. At equilibrium (i.e. all the contacts are grounded), the number of holes in the channel exactly compensates the immobile trapped charges. This causes the potential at the dielectric/channel interface to vanish, that is, the surface potential is  $V_S = 0$ . For drain current to flow, a negative  $V_{GS}$  is applied to increase the mobile holes to a concentration that exceeds the immobile negative charge in the gate insulator. The injected holes are trapped, resulting in a positively charged trap concentration that exceeds that of the residual trapped electrons. In this case,  $V_S > 0$  at equilibrium, and  $V_S$  and  $V_T$  become negative, as shown in Fig. 8.101b.

Charge trapping has been observed along the OTFT channel by measuring the spatial dependence of the surface potential using a modification of AFM, known as *scanning Kelvin probe microscopy* (SKPM) (Nonnenmacher et al., 1991, Bürgi et al., 2002), shown schematically in Fig. 8.102a. In SKPM, the potential between a conducting AFM tip and the sample surface is  $V_{tip}(x) = \Delta\phi_{TS} + \psi_S(x)$ , where  $\Delta\phi_{TS}$  is the difference in work functions between the probe tip and the sample, and  $\psi_S(x)$  is the local value of the surface potential. In the AFM non-contact mode, a small vibration of the tip at frequency,  $\omega$ , induces a change in capacitance,  $\Delta C$ . This, in turn induces a current:

$$i(t) = \omega \Delta C V_{tip} \cos(\omega t). \quad (8.82)$$

In SKPM, the voltage across the tip is set to  $i = 0$ , and then the force between tip and sample at a position  $x$  is inferred from the voltage-induced oscillation of the tip as it is translated along the sample surface. The oscillations, which yield  $\psi_S(x)$ , are detected using a beam of light that is reflected from the top surface of the probe (Martin et al., 1988).

The potential along the channel of HMDS-functionalized  $\text{SiO}_2$ /PTAA OTFTs was measured by first stressing the transistor, measuring  $\psi_S(x)$  along the channel by SKPM, and then peeling away (i.e. exfoliating) the PTAA channel. Then  $\psi_S(x)$  was measured once more. The organic was removed by attaching a piece of adhesive tape to its surface, and mechanically lifting it off from the dielectric. As shown in Fig. 8.102, initially  $V_P$ , the pinch-off voltage, is positive due to excess negative charge in the  $\text{SiO}_2$ . As a consequence, the surface potential after PTAA removal is negative (data point 1, Fig. 8.102b and c). With the channel semiconductor in place, holes are drawn in from the source and drain to compensate the negative charge, resulting in  $\psi_S(x) = 0$  across the entire channel length (point 2). After stress,  $V_P$  becomes negative since the surface potential is positive due to filling of surface traps with positive charge drawn in from the channel contacts (point 3). This immobile positive charge

**Figure 8.101** Schematic illustration of the transistor transfer characteristics (top panels) and how the charge distribution in the dielectric (bottom panels) influences  $V_T$ . The center panels illustrate the potential at the organic/dielectric interface (the surface potential,  $V_s$ ) when all OTFT contacts are grounded. (a) Before application of stress, negative charge is trapped in the dielectric. (b) Following stress, injected holes become trapped and the  $V_T$  shifts to positive  $V_{GS}$ . Adapted from Mathijssen et al. (2010).

remains even when the PTAA is attached. Since the charge is not removed along with the channel semiconductor, it must be present in the insulator itself. Charge residing in the gate insulator or at the insulator/semiconductor surface gives rise to the drift in  $V_T$  with time. Similar phenomena, but with opposite polarities have also been observed in  $n$ -channel OTFTs employing polymer (Chua et al., 2005, Barra et al., 2010) or vacuum-deposited perylene derivative-based channels on an HMDS-functionalized  $\text{SiO}_2$  gate dielectric (Mathijssen et al., 2010).

### 8.8.2 Effects of water on transistor stability

The source of trapped charge is obviously different than hydrogenation of  $a$ -Si implicated in the threshold voltage drift in those devices. The long durations observed in the voltage drifts suggest that the effects are due to ionic motion within the gate insulator. Adsorbed water on  $\text{SiO}_2$  is known to increase its surface conductivity. Large concentrations of electrons and holes at the  $\text{SiO}_2$  surface near the source and drain electrodes produces redox reactions that introduce mobile charge species, via

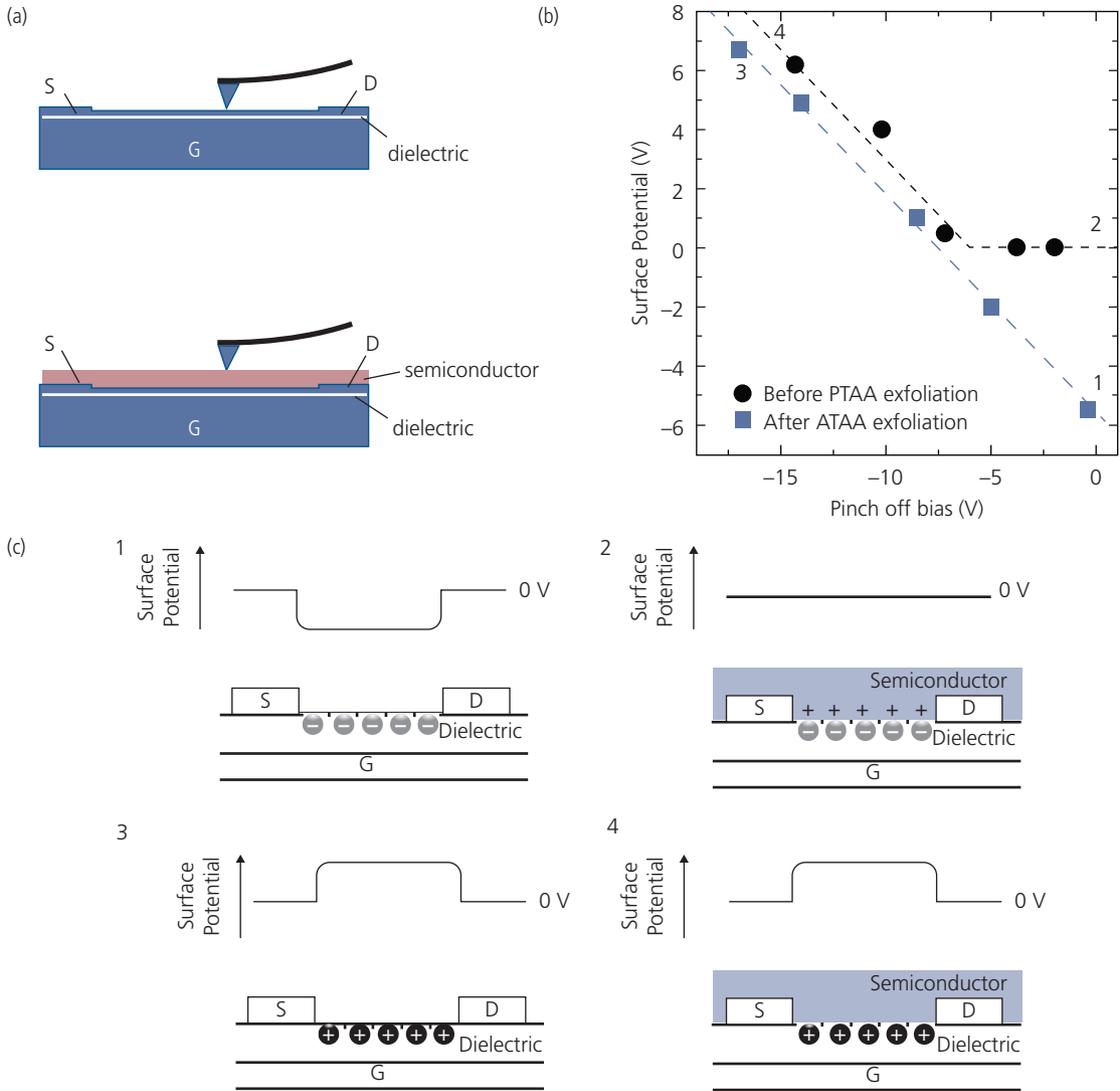

That is, water electrolysis results in the production of protons and electrons on the insulator surface. The charges are mobile and, hence, are easily neutralized by charges within the accumulation layer. A slower diffusion of charge into the insulator, therefore, must also be active. It has been proposed that the electrons in the redox reaction Eq. 8.83 are neutralized by holes in a  $p$ -channel OTFT, leaving an excess of protons (Sharma et al., 2009, 2010). The surface protons subsequently and reversibly migrate into the insulator on a time scale consistent with that observed in the drift of  $V_T$ .

The volume concentration of protons in the dielectric bulk should be linearly proportional to the areal hole concentration, viz.

$$[\text{H}^+] = a[\text{h}^+], \quad (8.84)$$

where  $a$  is a constant. Hence, a higher drain current results in a higher  $[\text{H}^+]$  concentration, leading to a more rapid and larger drain current drift over time. A fit to  $\Delta V_T(t)$  in Fig. 8.100b that takes only proton diffusion into account (green dashed line) results in noticeable differences with the data, suggesting that this simple model is insufficient to describe charge

**Figure 8.102** (a) Schematic of the scanning Kelvin probe microscope (SKPM) experiment for measuring the local surface potential on the dielectric (top) and on the organic semiconductor channel of an OTFT. (b) Surface potential in the channel of a HMDS-SiO<sub>2</sub>/PTAA OTFT measured by SKPM before and after removal of the PTAA from the dielectric surface. The numbers (1–4) correspond to surface potentials measured for otherwise identical OTFTs with, and without PTAA after periods of stress ranging from no stress (points 1, 2), to 2 h of stress at  $V_{GS} = -60$  V (points 3, 4). (c) Schematic of the measured surface potentials due to the corresponding charge distributions within the channel (Mathijssen et al., 2010).

diffusion. The fit to the stretched exponential function is more accurate when the presence of the electric field under the gate is included (solid line). The fit employs only two parameters,  $\alpha = 2.2 \text{ nm}^{-1}$  and  $D = 1.6 \times 10^{-19} \text{ cm}^2/\text{s}$ , from which one infers that, after a stress of  $4 \times 10^5 \text{ s}$ , the protons penetrate into the insulator to a distance of 30 nm (Sharma et al., 2009, Bobbert et al., 2012). The protons in the dielectric contribute to an electric field at the semiconductor/insulator interface that results in charge scattering. Consequently, the charge mobility is

reduced along with the drift in  $V_T$ , both leading to a reduction of  $I_D$  and  $S$  with time.

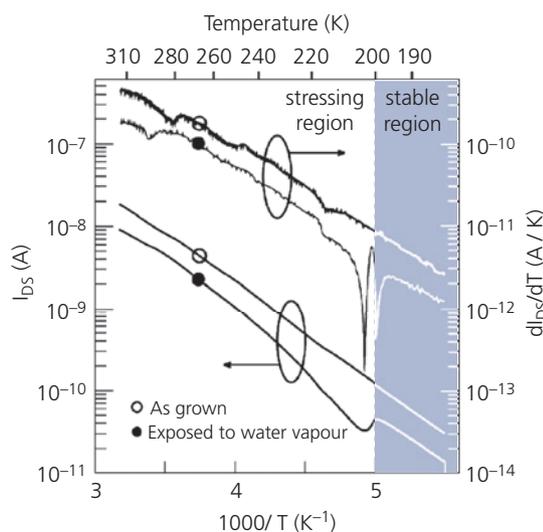

Note that the threshold recovery also follows a stretched exponential, albeit with a different time constant as noted previously. During recovery,  $[\text{h}^+] \rightarrow 0$ . Since the proton concentration is in equilibrium at the insulator surface, protons reverse their migration out of the dielectric where they react with solvated oxygen to form holes once the stress is removed (cf. the redox reaction, Eq. 8.83). This causes  $V_T$  to relax back toward its initial value.

The model is specific to SiO<sub>2</sub> gate dielectrics independent of the organic semiconductor used as the channel material. The time constant for the stretched exponential is given by

$$\tau = \frac{1}{\pi a^2 D}, \quad (8.85)$$

where  $a$  and  $D$  are properties only of the dielectric (Sharma et al., 2010). Similar mechanisms may also be active in other dielectrics since the redox reaction only requires the presence of water.

The effects of water on drift during bias stress have been inferred from the dependence of the drain current vs. temperature for several BG/BC OTFTs employing different channel materials (poly(3-sexithiophene), polyarylamine, and sexithiophene) on an HMDS-treated SiO<sub>2</sub> gate insulator. The devices were exposed to a humid environment for 24 h following fabrication, and then excess moisture was removed by exposure to vacuum for 20 min prior to electrical characterization. All devices showed that the drain current increases monotonically with temperature, independent of the channel material used, until approximately  $T = 200$  K. At this point, the drain current dips and rises once again until approximately 273 K when a second, smaller decrease in  $I_D$  is observed (see Fig. 8.103). The as-grown devices (i.e. those not exposed to the humid environment) did not show either of these features;

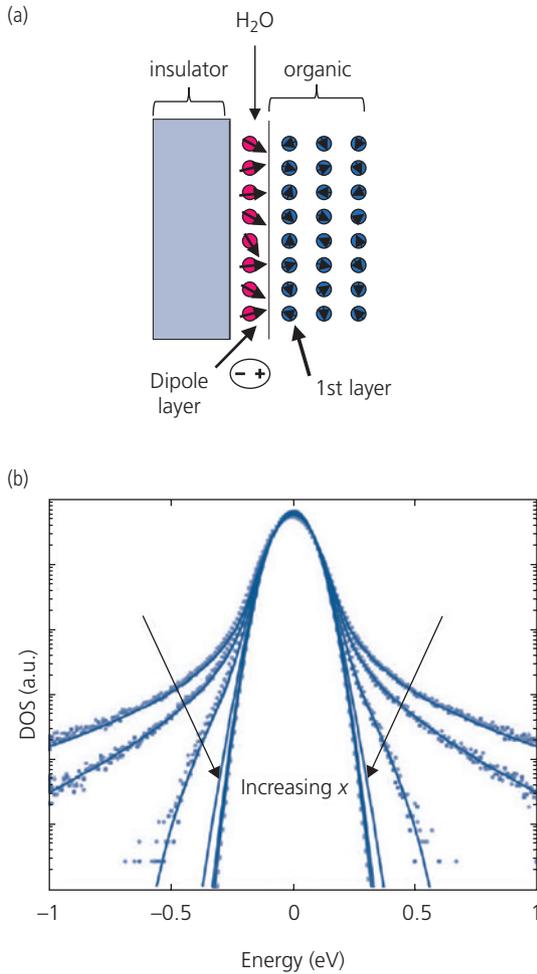

**Figure 8.103** The dependence of drain current on temperature for a BG/BC poly(arylamine) OTFT using an HMDS-functionalized SiO<sub>2</sub> gate insulator. The as grown sample is compared to one intentionally exposed for 24 h to water vapor, and then exposed to high vacuum prior to measurement. The derivative of the drain current vs. temperature is also shown to emphasize changes at  $T = 273$  K and 200–220 K (Gomes et al., 2006).

$I_D$  simply increases with temperature across the entire range tested (Gomes et al., 2006). Water in confined environments (e.g. water molecules dispersed at the semiconductor/insulator interface, or in the insulator bulk) are supercooled in the liquid phase below  $\sim 273$  K. In this environment, water transitions to the solid phase only when  $T = 200$  K. The additional feature at 273 K corresponds to freezing of water that does not undergo a supercooled phase transition. Only liquid water can undergo the reaction in Eq. 8.83 that results in protonation of the insulator.

The drain current unexposed to water is higher than in its presence, and shows none of the anomalies of the latter devices. Furthermore, the fact that these features are found in each of the organic channel layers whether they are vacuum deposited (in the case of sexithiophene) or cast from solution (for the polymer channels) suggests that the water-related defects are either attached to the insulator surface, or diffuse into its bulk. These experiments show that cooling discontinuously changes the drain current at precisely those temperatures at which water undergoes a liquid–solid phase transition, reinforcing the conclusion that water plays an important role in transistor instability (Gomes et al., 2006).

We have shown in the foregoing discussion how protons generated from a water redox reaction, and that subsequently diffuse into the gate insulator at a rate largely independent of the presence of a SAM (Chua et al., 2005), can cause threshold voltage drifts by electric field screening in the channel. Another possible effect of water arises from its dipole moment of  $p = 1.85$  D. We showed in Section 4.6.3 that dipoles at the surface of an organic can affect the density of transport states (Baldo and Forrest, 2001). In the context of an OTFT, the dipolar water molecules adsorbed onto the dielectric surface induce a broadening of the transport DOS within the channel, as illustrated in Fig. 8.104a (Richards et al., 2008). The H<sub>2</sub>O dipole alignment at the interface is disordered. This creates a distribution of local electric fields experienced by organic molecules near the interface. This, in turn, broadens the charge carrier DOS in the channel, as apparent from the calculated profiles in Fig. 8.104b (Richards et al., 2008), with the broadening extending several nanometers into the charge accumulation region (Sharma et al., 2011).

The Gaussian disorder model in Chapter 4 provides an empirical dependence of mobility on the width in the DOS ( $\sigma_{GDM}(z)$ ) at distance,  $z$ , from the dielectric surface. That is (Novikov et al., 1998, Hertel and Bäessler, 2008),

**Figure 8.104** (a) Schematic illustration of surface dipoles at the insulator/organic interface. (b) Calculated density of states (DOS) in a PTAA channel due to a surface dipole of moment  $p = 2 \text{ D}$  as a function of distance from the interface ( $x$ ) ranging from 0 to 5 Å. Adapted from Richards et al. (2008).

$$\mu(z) = \mu_0 \exp\left(-\left(\frac{3\sigma_{GDM}(z)}{5k_B T}\right)^2\right). \quad (8.86)$$

Here  $\mu_0$  is the mobility at  $T \rightarrow \infty$ . The field effect mobility,  $\mu_{FE}$ , is then

$$\mu_{FE} = \int_0^{z_{\max}} \mu(z) p(z) dz, \quad (8.87)$$

where  $z_{\max}(V_{DS}, V_{GS})$  is the width of the accumulation region and  $p(z)$  is the hole concentration. Equation 8.86 shows that  $\mu$  is a decreasing function of the width of the Gaussian DOS. Hence, the presence of water (or any dipolar contaminant) at the dielectric surface results in a decrease in mobility,

and hence a decrease in  $I_D$ . With increased exposure time during device operation, the amount of water adsorbed at the gate dielectric/organic interface is also expected to increase, resulting in a shift in  $V_T$ .

The decrease in mobility with dipole strength has been observed by comparing  $\mu_{FEp}$  obtained for PTAA OTFTs using either a high ( $\epsilon_i = 3.8$  for PMMA) or low dielectric constant ( $\epsilon_i = 2.1\text{--}2.3$  for a fluorene-thiophene copolymer, poly(9,9-dioctylfluorene-*co*-bithiophene)) gate insulator. The mobilities for the low  $\epsilon_i$  insulators were found to exceed the PMMA-based devices by nearly an order of magnitude. The higher  $\epsilon_i$  corresponds to a larger polarizability, and hence a higher dipole moment (Veres et al., 2003). The trend in  $\mu_{FEp}$  for these devices is, therefore, consistent with the prediction of Eqs. 8.86 and 8.87.

While the change in mobility due to water adsorption must affect the mobility as described, the time constant of the shifts in  $V_T$  should be relatively short, determined by the rate of water adsorption and desorption. This is inconsistent with the very long time constants ( $10^4\text{--}10^7 \text{ s}$ ) associated with  $\Delta V_T$  in Figs. 8.99 and 8.100. Hence, proton diffusion is more likely than water adsorption to be the source of the long term drifts in current and voltage. However, it is also clear that dipolar broadening of the DOS can indeed affect the transistor transfer characteristics. This can lead to hysteresis in  $I_D$  when sweeping  $V_{DS}$  in the positive *vs.* the negative direction observed in many OTFTs after exposure to atmosphere. Hysteresis may also be due to trapping of charge within the near-interface region (Noh et al., 2006, Uemura et al., 2014).

The time dependent drifts in the drain characteristics can be reduced by employing a bilayer dielectric, whereby the drift due to charge trapping in one insulator interface is compensated at the second interface by a mechanism in the opposite direction. This has been demonstrated in OTFTs employing channels that are microcrystalline ( $\mu\text{c}$ ) blends of TIPS-pentacene or dif-TES-ADT and PTAA. The gate dielectric comprises 35 nm CTYOP directly layered onto the semiconductor channel, followed by a layer of  $\text{Al}_2\text{O}_3/\text{HfO}_2$  of approximately the same total thickness. The secondary dielectric is deposited in five alternating layers of the two constituents by ALD. Its  $\Delta V_T$  approximately compensates the drift due to the CYTOP insulator, although the mechanism for these two competing processes was not explained. Nevertheless, the devices showed minimal drifts even when immersed in water or air. Indeed, the minor drifts encountered by direct immersion in water were largely reversed when the devices were placed in vacuum at  $100^\circ\text{C}$  for 16 h (Jia et al., 2018).

The deleterious effects of water and other environmental contaminants can also be mitigated, at least to some degree, by device packaging, similar to that employed to extend the lifetime of OPVs and OLEDs. The primary goal of encapsulation is to passivate the semiconductor, that is, to make it less vulnerable to changes when operated in ambient. A passivating coating should have the following properties: (i) it should prevent ingress of contaminants into the device active region, (ii) its application should be non-destructive to the device on which it is deposited, and (iii) it should prevent or retard degradation at elevated temperatures by preventing the organics from vaporizing. (iv) Since OTFTs are often used in circuits that need to conform to an irregular substrate or are bent during operation, encapsulations may also need to allow for device flexibility.

A BG/BC pentacene OTFT with a flexible polyether sulfone substrate has been coated with a polymer passivating layer to decrease time-dependent drifts in  $I_D$ ,  $\mu_{FE}$ , and  $V_T$  (Han et al., 2006). The passivating layer consists of a 500 nm thick dichromated PVA film, capped with a 1  $\mu\text{m}$  thick photoinitiated acrylate, see inset, Fig. 8.105a. After patterning the acrylate layer, the devices were rinsed in water and then baked in vacuum at 80°C for 4 h. Following this treatment, the devices showed  $\mu_{FEp} = 0.80 \text{ cm}^2/\text{V s}$  and  $V_T = -9.2 \text{ V}$ .

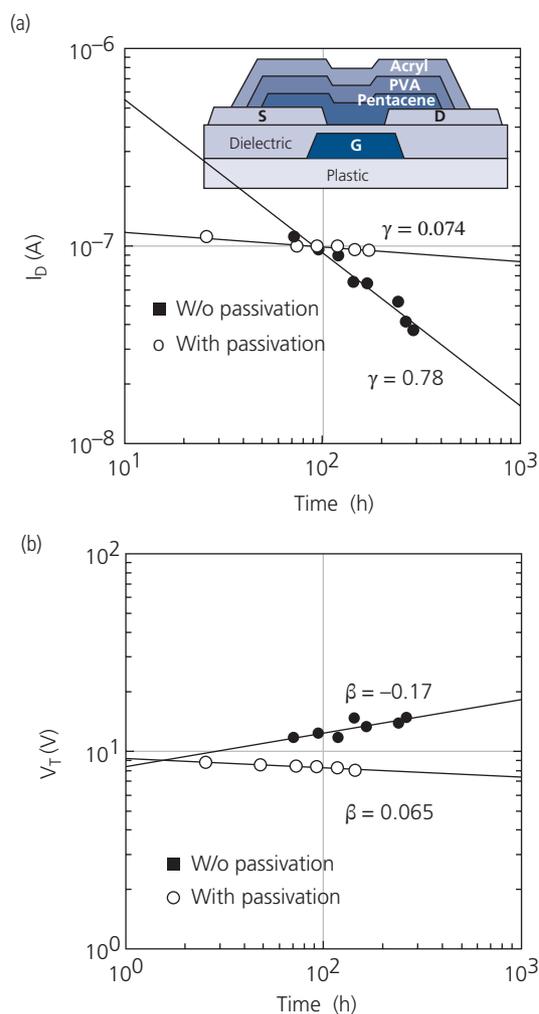

The drain current and  $V_T$  characteristics vs. time are shown in Fig. 8.105a and b, respectively. The  $I_D$  data were collected in the linear regime at  $V_{GS} = -30 \text{ V}$  and  $V_{DS} = -1 \text{ V}$ . The empirical dependences of  $I_D$  and  $V_T$  are shown by the straight line fits to the data using

$$I_D(t) = I_{D0} \exp(-\gamma t) \quad (8.88a)$$

and

$$V_T(t) = V_{T0} \exp(-\beta t), \quad (8.88b)$$

where  $I_{D0}$  and  $V_{T0}$  are the values of drain current and threshold voltage at  $t = 0$ , and  $\gamma$  and  $\beta$  are degradation rate constants. The passivated devices have considerably lower degradation rates than unpassivated ones, suggesting that the bilayer coating is effective in reducing drifts in the operating characteristics. Interestingly, while the slopes of the  $I_D$  data are both negative (i.e.  $I_D$  decreases with time) the rates of change in  $V_T$  are opposite for the passivated and unpassivated OTFTs. This is attributed to negatively charged traps due to water at grain boundaries in the pentacene film, requiring increasing the gate voltage over time in the unpassivated devices. The opposite slope for passivated devices is presumably due to oxygen

**Figure 8.105** (a) Drain current vs. time for both a passivated (i.e. coated) and uncoated pentacene OTFTs. (b) Threshold voltage vs. time for the devices in (a). Lines are fits to Eqs. 8.88a and b. Adapted from Han et al. (2006).

entering the film, which forms a negatively charged oxygen ion (Han et al., 2006). Regardless of the origins of the effects, coating the devices is effective in extending their operational lifetime by reducing their exposure to the environment.

To summarize this section, ionic migration that is widely observed in conventional MOSFETs and MISFETs is undoubtedly also active in OTFTs. When stressed by an external potential, there is a change in the total electric field in the channel. This, in turn, causes both the threshold voltage and current to change with time, ultimately leading to circuit failure as the changes exceed the acceptable noise margin. Importantly, the mechanistic studies described highlight the vulnerability of OTFTs to exposure to moisture and other atmospheric contaminants, which

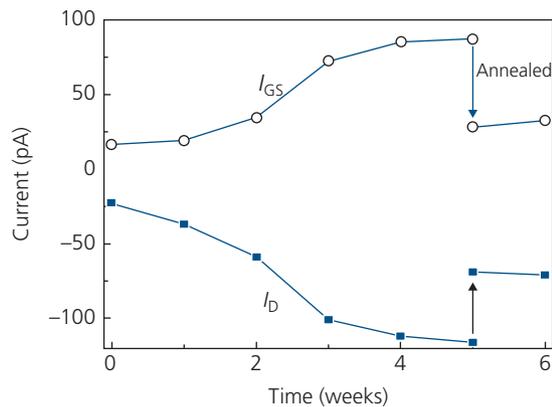

must be considered when adapting this technology for a particular application such as displays, RFIDs, or sensing.

### 8.8.3 Other sources of instabilities in OTFT performance

Thus far, we have focused almost entirely on the effects of moisture on the transistor characteristics. Here we will describe a few of the other possible causes that reduce operational lifetimes. This should give a view of a few of the more important effects among a complex range of phenomena.

*Gate leakage:* Recall that the gate leakage must be minimized to reduce the off current, and hence the power dissipation in complementary logic circuits. In addition, very thin insulator layers are required to achieve low voltage operation. But thin insulators often have a tendency to have pinholes, and can undergo dielectric breakdown at 1–10 MV/cm, leading to catastrophic failure (Halik et al., 2004).

Figure 8.106 shows the leakage of a polystyrene gate insulator on a pentacene channel for a device in its off state ( $V_{GS} = 0$  V and  $V_{DS} = -30$  V) in air over a period of weeks. The drain current tracks the gate leakage. That is,  $I_D$  increases at the same rate as  $I_{GS}$ , although the current polarities are opposite. After annealing in air at 70°C for 5 min, both  $I_{GS}$  and  $I_D$  are decreased by the same amount. Analysis of the C–V characteristics of a metal–polystyrene MIS capacitor indicates that aging results in an increase in positive trapped charge within the insulator. The positive charge shifts the gate potential, resulting in the observed changes in  $I_D$ . The positive charge arises

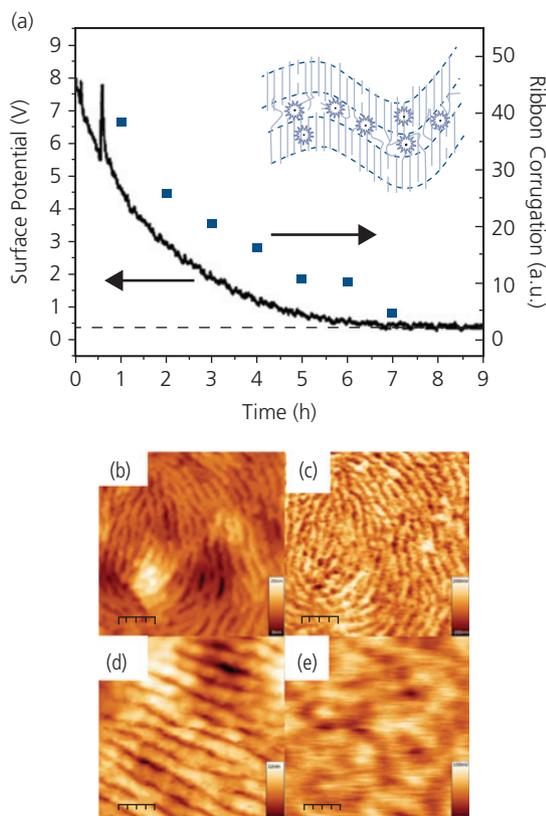

**Figure 8.106** Gate and drain current vs. time of a BG/TC pentacene OTFT in the off state with a polystyrene gate dielectric. The aging is in air at  $T = 24^\circ\text{C}$  and 42% relative humidity. Annealing conditions are 70°C in air for 5 min (Hong et al., 2008).

from diffusion of moisture into the bulk, which is removed by high temperature annealing that restores the original gate and drain leakage currents (Hong et al., 2008). This is consistent with the proton diffusion model in Section 8.8.2.

Interestingly, gate leakage also accelerates the aging of single crystal tetracene OTFTs in the on state, even when it is several orders of magnitude smaller than the drain current (De Boer et al., 2005). While no definitive reason has been given for this effect, it was suggested that high energy electrons accelerated through the high dielectric constant metal oxide dielectric induce damage in the tetracene near the dielectric/organic interface.

*Bulk defects:* Charges trapped within the channel can result in changes in current, just as the charges at the insulator surface. Both result in a local change in potential that influences the charge density in the accumulation region. Indeed, many reports suggest that charge trapping in the semiconductor bulk can result in threshold and drain current drifts (Salleo and Street, 2003, Chang and Subramanian, 2006), and in the hysteresis in the transistor output characteristics observed during positive and negative sweeps of  $V_{GS}$  and/or  $V_{DS}$  (Ucurum et al., 2008). Unfortunately, it is difficult to definitively determine the location of the traps. Hence, most reports of bulk trapping are based on inferential analyses. An exception is obtained using spatially resolved SKPM, where the location of the charge trapping sites can be directly correlated with grain boundaries between domains within the channel semiconductor thin film (Tello et al., 2008, Hallam et al., 2009). Figure 8.107 provides one such direct study of charge trapping in the bulk of a p-channel pBTTT on an untreated  $\text{SiO}_2$  gate dielectric in a BG/TC OTFT. The polymer is known to form a “ribbon” morphology when annealed at 260°C.

To study charge trapping, the OTFT was stressed at  $V_{GS} = -80$  V for 60 min in ultrahigh vacuum, with the intention of filling deep traps within the film. During stress, the drain current decreased by >50% resulting from a shift in  $V_T$ . Once the stress was removed ( $V_{GS} = V_{DS} = 0$  V),  $I_D$  recovered to 80% of its original value over the ensuing 4–6 h due to trapped charge release. The average surface potential in the channel following stress is shown in Fig. 8.107a. The change in surface potential of 8.5 V corresponds to a total surface trapped charge density of  $6 \times 10^{11} \text{ cm}^{-2}$  for an insulator capacitance of 11 nF/cm<sup>2</sup>. The surface potential returns to its original value prior to stress (horizontal dashed line) over approximately 6 h. Also shown is the average relative amplitude of the potential corrugations across the channel before

**Figure 8.107** Average channel surface potential vs. time measured by SKPM after the removal of bias stress for a  $\text{SiO}_2$  gate insulator/pBTTT OTFT. The blue points are the relative heights of the potential corrugations. Inset: Schematic of the ribbon-like phase of pBTTT with charge trapped between the ribbons. (b) AFM and (c) SKPM image of the pBTTT surface after a stress for 1 h at  $V_{GS} = -80$  V. (d), (e) As in (b), (c), respectively, prior to stress. All images approximately  $1.8 \times 1.8 \mu\text{m}$  (Hallam et al., 2009).

and after stress (Figs. 8.107c and e). These corrugations decrease in amplitude during recovery; they tend to diminish over the same period that the surface potential relaxes to its pre-stress value.

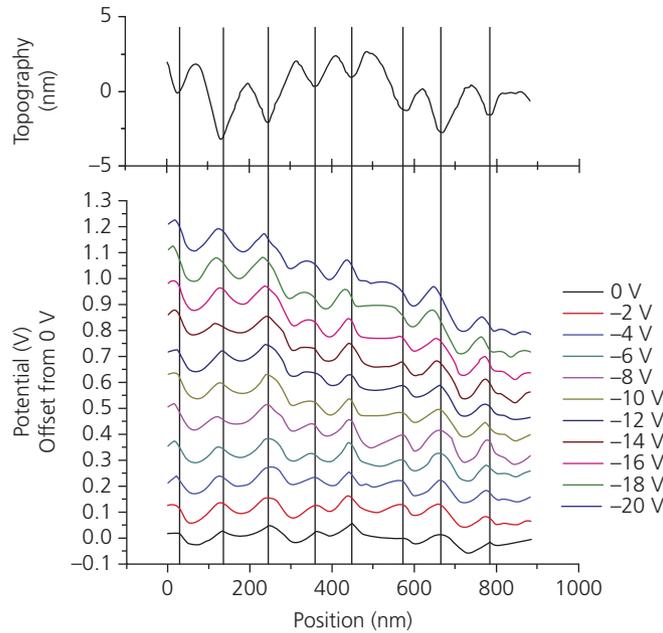

The topographical AFM images in Figs. 8.107b and d show the ribbon-like domains. The potential corrugations of the stressed film (Fig. 8.107c) match the topographic pattern. The white areas of the SKPM image are more positive than the shaded regions. The correspondence between the AFM topographic data and the SKPM derived potential indicate that the trapped charge resides at the grain boundaries between the individual ribbons. The relative lack of contrast of the unstressed film (Fig. 8.107e) indicates the absence of trapped positive charge in regions between the domains (Hallam et al., 2009).

The surface potentials of the OTFTs were measured during operation to further understand the nature of bulk charge trapping. Figure 8.108 (top scan) shows the topographic roughness of the films. The ribbon domains are at the high points of the profile, and the grain boundaries are at the valleys. The SKPM profiles acquired during operation in the linear and saturation regimes (depending on  $V_{DS}$ ) are shown in the lower figure. Within the grains, the potential is relatively flat, corresponding to a very small internal electric field. In contrast, there is a peak in the potential at each grain boundary, indicating a high density of positive charge associated with trapping at these locations. Note that even at  $V_{DS} = 0$  V, the peaks exist. This suggests that the potential maxima between grains result from immobile charge and not current, since at  $V_{DS} = 0$ ,  $I_D$  also vanishes.

Surface potential measurements have also implicated structural boundaries in vacuum deposited pentacene films as trapping sites leading to long-term changes in transistor characteristics, particularly as the film thickness is reduced to the point where it incompletely covers the insulator (Tello et al., 2008). Finally, trapping within the channel bulk is inferred from the dependence of drain current under bias stress on pentacene layer thickness. The thickness dependence indicates the bulk is the source of traps, as opposed to the surface (Chang and Subramanian, 2006).

While the SKPM measurements, and the observed thickness dependence of drifts in  $V_T$  and  $I_D$  on channel layer thickness point to the importance of trapping in the bulk semiconductor layer, the origins of the trapping sites remain unclear, and indeed may not be the same for all semiconductors. For example, reduced orbital overlap between molecules across the grain boundaries can be a source of levels deep in the energy gap that inhibit charge transport between grains, and hence result in accumulation of charge in the channel. Alternatively, the grain boundaries may provide sites for the ingress of impurities (e.g.  $\text{H}_2\text{O}$ ) that also can trap charge. Independent of the mechanism for the formation of traps, their presence in the bulk has been established as an important cause of stress-induced changes in device performance.

*Contact degradation:* Contact resistance may change as defects form in the channel, or from *electromigration* of metal into the channel at high drain currents. This generally manifests itself as a decrease in channel output conductance, as well as an apparent decrease in field effect mobility (cf. Eqs. 8.23 and 8.24). The rate and magnitude of the changes depend on whether a top or bottom contact configuration is

**Figure 8.108** Surface topography acquired via AFM (top) and the surface potentials (bottom) measured by SKPM along the 20  $\mu\text{m}$  long channel of the pBTTT OTFT in Fig. 8.107 as a function of  $V_{DS}$  (legend) at  $V_{GS} = -30\text{ V}$  (Hallam et al., 2009).

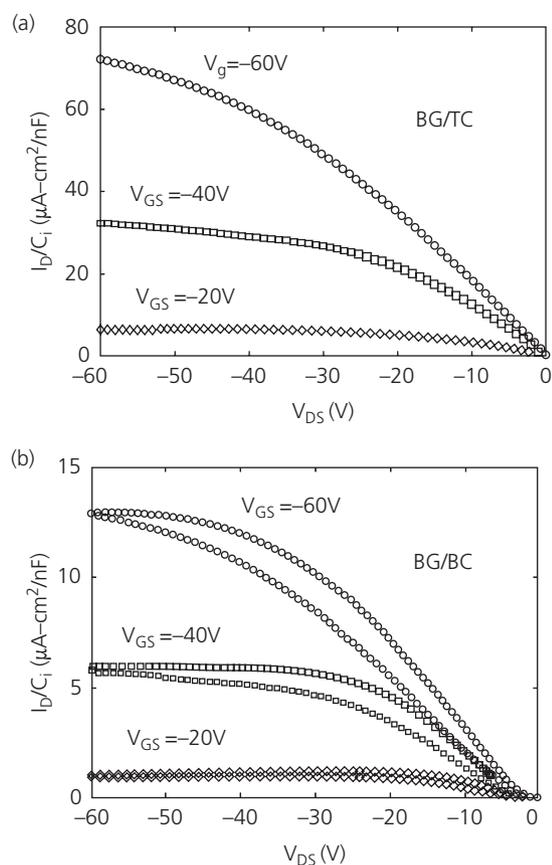

Reprinted figure with permission from Hallam, T., Lee, M., Zhao, N., Nandhakumar, I., Kemerink, M., Heeney, M., McCulloch, I. & Sirringhaus, H., *Physical Review Letters*, 103, 256803. Copyright 2009 by the American Physical Society.

employed. In TC OTFTs, the source and drain metals contact a large channel surface area. Since the electric field lines extend to the opposite (dielectric) surface of the channel, injection can occur over most of the metal contact area. The injection area also increases with the amount of overlap between the S and D contacts and the gate, which extends the accumulation region well into the channel contact area. In contrast, bottom contacts result in preferential injection from the edge of the metal layer into the very thin, charge accumulation layer. The differences in contact areas are reflected in the contact resistances: 1–2  $\text{M}\Omega\text{ cm}$  vs. 0.2–0.5  $\text{M}\Omega\text{ cm}$  for the BC vs. TC devices, respectively (Richards and Sirringhaus, 2008). The edge-on contact of the BC configuration also results in several orders of magnitude higher current *densities* needed to achieve the same drain current compared to the top contact structure. This is more likely to cause local heating and the formation of defects in the channel than at lower currents, as we have seen for OLEDs and OPVs. The stress-induced defects lead a reduction of contact area that ultimately results in shorting or reduced injection efficiency over time.

The output characteristics of BG/TC and BG/BC F8T2 transistors are shown in Fig. 8.109a and b, respectively. Although the devices have different gate

dielectrics (polystyrene for the BG/TC, and  $\text{SiO}_2$  for the BG/BC device), the current in the BC OTFT is several times lower than in the TC case. This, presumably, is due to the larger contact area in the latter structure. Also, there is hysteresis for the BC OTFT that is noticeably absent in the TC device. This suggests a more stable injection efficiency for the S and D contacts of the TC transistor.

Gate bias stress of the BG/BC OTFT applied for several minutes induces a noticeable reduction in the drain current, and an increase in  $V_T$  and source resistance, with a much smaller fractional increase in drain resistance. The degradation of the contacts becomes important only when the contact resistance equals, or exceeds that of the channel. The channel resistance in accumulation is given by  $R_{ch} = L/Wpq\mu_{FEp}$  for a p-channel device. This sets a minimum channel length for a contact resistance of  $R_C$  of  $L_{min} = pq\mu_{FEp}R_C$ . Thus, when  $R_C > WR_{ch}$ , the contact resistance dominates the output characteristics. Potentiometry suggests that injection from the source is limited by bulk ohmic contact resistance along with injection into the depletion region at the contact, whereas  $R_C$  alone determines the drain resistance (Bürge et al., 2003). Hence, it is the change in source (vs. the drain) resistance over time that is responsible for the contact-limited operational lifetime in some OTFTs.

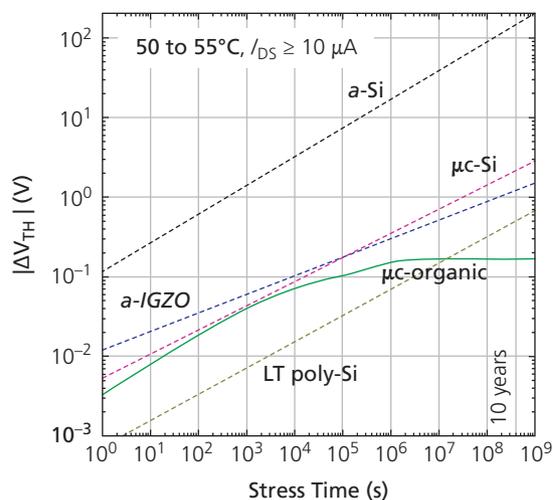

**Figure 8.109** Drain current characteristics of OTFTs employing a p-channel F8T2 polymer channel on a (a) polystyrene gate insulator in a BG/TC configuration, and (b)  $\text{SiO}_2$  gate insulator in a BG/BC configuration. The current is normalized to the gate capacitance for  $L = 20 \mu\text{m}$  and  $W = 1 \text{ cm}$  (Richards and Sirringhaus, 2008).

### 8.8.4 Achieving reliable OTFTs

We have shown that OTFTs are susceptible to bias-stress-induced changes to the threshold voltage, drain current, mobility, contact resistances, and so on. Mobile charge in the gate insulator, at the insulator/channel interface, and within the channel itself and at the contacts all contribute to aging, with water being the most deleterious impurity observed in almost all OTFTs.

The most effective means extending OTFT lifetime, therefore, is to prevent or delay water entry into the channel region. This can be accomplished by packaging or encapsulation. However, one of the most attractive features of OTFTs is their flexible and/or conformable form factor. Flexible encapsulation as in Fig. 8.105 is only marginally effective in retarding the aging process. Beyond using improved encapsulation, there have been reports of both *n*- and *p*-channel organic semiconductors and composites that are comparatively immune to contamination from ambient

**Figure 8.110** Comparison of the change in threshold voltage under bias stress at elevated temperatures for several different thin film transistor technologies (Jia et al., 2018).

water or oxygen (Roberts et al., 2008, Lei et al., 2011, Kuribara et al., 2012, Feng et al., 2016). A combination of all of these strategies can significantly extend the OTFT stability.

Ultimately, the reliability that is achieved must meet the demands of the target application. Since thin film transistor technology serves a wide range of applications, from driving display elements, to chemical and medical sensing, to RFID transmit and receive circuits, it is useful to compare the stabilities of several TFT materials systems. Figure 8.110 shows the change in threshold voltage over time for TFT technologies compared with microcrystalline ( $\mu\text{c}$ )-OTFTs with a TIPS-pentacene:PTAA channel and a bilayer CYTOP/ $\text{Al}_2\text{O}_3$ / $\text{HfO}_2$  gate insulator (Jia et al., 2018). The inorganic transistors based on a-Si, amorphous indium gallium zinc oxide (a-IGZO),  $\mu\text{c}$ -Si, and *low temperature polycrystalline Si* (LTPS) all show long term drifts that are on the order of, or larger than the organic device (Arai and Sasaoka, 2011). Care must be taken in making such comparisons, however, since the choice of devices is necessarily selective, and their performance characteristics vary over a wide range. Nevertheless, we can conclude that OTFTs can have competitive reliability and electrical performance compared to many inorganic thin film technologies, and indeed may have operational lifetimes well over 10 years in some cases.

## 8.9 Organic transistor circuit applications

When considering the possible applications of a new technology, we must first understand the incumbent

technologies that stand to be replaced or augmented. We must ask, what is compelling about the new technology, and what new applications can it fill that otherwise are not served by existing solutions? In the case of OLEDs and OPVs the answer is clear. OLED displays offer high efficiency, a large color gamut, and flexibility that are unique and not well served by existing LCD or quantum dot/LED/LCD (QLED) displays. Likewise OPVs can be efficient and can serve the building integrated solar markets in ways that cannot be replicated using Si or compound semiconductor solar energy harvesting devices. The case for organic transistors is less clear. There is little doubt that enormous progress has been made in improving OTFT performance and reliability, and numerous examples of ICs such as logic circuits, RFIDs, ring oscillators, etc. have been reported (Crone et al., 2000, H. Klauk, 2006, Gelinck et al., 2010, Taylor, 2016). Yet, the electronics market is completely dominated by Si ICs that are low cost, high performance, extremely sophisticated and complex, reliable and adaptable to an almost limitless range of applications. Hence, prior to discussing particular applications where OTFTs may find use, we list several attributes of the technology that distinguish it from its competitors, including those based on crystalline, polycrystalline, and amorphous inorganic semiconductor, and metal oxide thin film transistors.

- *Adaptability to large area circuits:* Almost all applications envisioned for OTFTs entail their use as active matrix pixel address arrays in sensing and display applications. Their appeal in this regard is the same as for almost all other organic electronic devices: the ability to deposit materials over large areas on any reasonably flat substrate. Hence, OTFTs are ideally suited for use in pixel address circuits. The competition in this space is thin film Si (LTPS) and metal oxide transistors that can also be deposited over large areas.
- *Flexibility, stretchability, and conformability:* A distinguishing feature of OTFTs is their ability to be deposited at room temperature. This allows for the use of plastic substrates that are flexible and conformable, and uniquely, on stretchable surfaces. Whereas other transistor technologies (most notably metal oxide TFTs) can also be deposited at low temperature, an apparently unique feature of OTFTs is their compatibility with ultrathin ( $\sim 1 \mu\text{m}$ ) substrates that opens completely new application areas, particularly in wearable electronics.
- *Potential low cost when fabricated over large areas:* In Section 5.7, we have seen that room temperature

R2R deposition on flexible plastic or metal foil substrates is a path to very low manufacturing costs. Thus, large area arrays of pixel address transistors for detection, sensing, and displays can be manufactured at very large volumes using R2R methods. This can potentially lead to significant cost reductions compared to technologies based on conventional, inorganic semiconductors that are more suitably processed in batches.

The competitive edge of OTFTs, therefore, lies in delivering large area electronic circuits on flexible substrates at very low cost. While this provides a motivation for developing OTFT applications requiring these attributes, it is equally important to understand where OTFTs are deficient. This chapter has focused on the performance of OTFTs, and the following properties of these devices have shown to present some limitations compared to inorganic transistor technologies:

- *Low output current:* The low output conductance of an OTFT (which is a result of their low field effect mobilities and large contact resistances) limits the current that they can deliver compared to many inorganic transistors. For this reason, an OTFT is more suitable as a voltage than a current source. While organic transistors have been proposed and even demonstrated for OLED pixel drivers (Yagi et al., 2008, Noda et al., 2011), a large, in-plane OTFT footprint is necessary to provide the current that can source sufficient current to attain high OLED brightness. Hence, while using OTFTs for OLED backplanes is possible, it is not optimal for realizing high resolution and intense OLED displays. As shown in Section 8.4.3, vertical transistors may be suitable for this purpose. In general, however, OTFTs are more useful as voltage sources for field-driven displays.
- *Limited stability:* Drain current drift during operation leads to a decrease in noise margin and hence instabilities in integrated circuit operation. OTFTs share this deficiency with a-Si TFTs, although drift can be lower in polycrystalline Si transistors. Very long term operation ( $>10$  years) typical of inorganic semiconductor transistors have not been reported for OTFTs, although as we have seen in Fig. 8.110, a few OTFT designs are showing promise of reliabilities competitive with inorganic TFTs. In this context, many sensors, such as those found in medical diagnostics, do not need to be used over long periods, and hence may provide an application domain that can take advantage of the low cost and conformability of OTFTs.

- *Low cutoff frequency:* OTFTs have 3 dB bandwidths typically less than a few MHz. This places another constraint on the operating space available. Radio frequency circuits (e.g. RFIDs operating well into the MHz range), and fast logic circuits are beyond the reach of almost all OTFT technologies. However, many display and medical sensing applications do not require circuits with high bandwidth capabilities, providing a potentially rich domain for their application.

In the remainder of this section we provide three potential application areas for OTFT-based electronics: voltage-driven displays, tactile, chemical and other sensor applications, and “imperceptible” devices for medical electronic sensing. All of these applications have the common needs for large area and flexible circuits. The demand for device performance and stability varies, depending on the application. There are of course, other emerging areas where OTFTs are finding use at the laboratory level, but these three examples should serve to illustrate the potential utility of the technology.

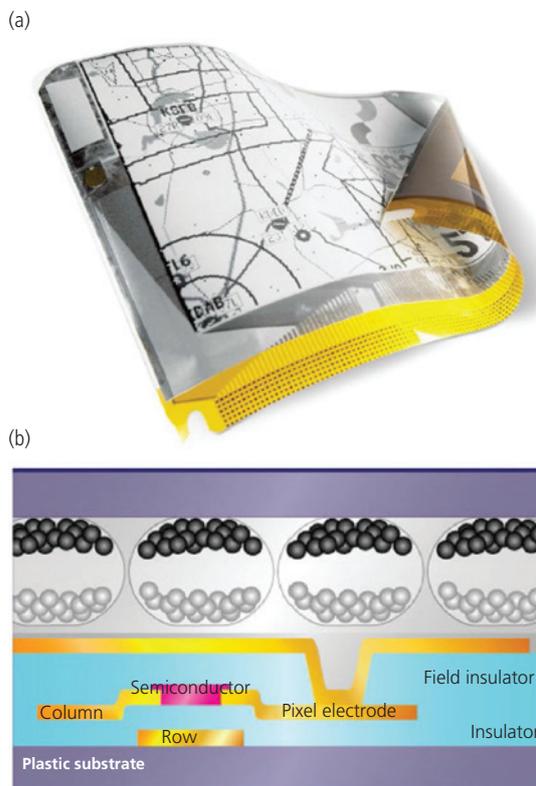

### 8.9.1 Flexible display backplanes

Organic transistor arrays are well-suited for information display backplanes to activate voltage-driven pixels (Gelinck et al., 2006, Yoneya et al., 2006). These displays include LCDs and electrophoretic displays. While a-Si TFTs can serve as the pixel driver, their fabrication requires high temperature processing that is incompatible with lightweight, flexible plastic substrates that are often used for this application. A  $320 \times 240$  pixel, 4.7” quarter video graphics array (QVGA) electrophoretic display driven by a solution-processed pentacene OTFT backplane is shown in Fig. 8.111a (Gelinck et al., 2006). The backplane is fabricated on a  $25 \mu\text{m}$  thick PEN substrate, with a single BG/BC address transistor per pixel. The backplane is fabricated by attaching the substrate to a rigid “handle,” and then patterning the contacts and the semiconductor layer via conventional photolithography. The solution-processable, 100 nm thick pentacene, and the 350 nm thick PVP gate insulator are deposited by spin-coating. Following completion of the OTFTs, a second PVP field insulator is spin-coated onto the transistor surface to separate the Au pixel electrode from the semiconductor surface while defining the pixel dimensions (see Fig. 8.111b). Once the backplane fabrication is complete, it is peeled off of the handle.

The display front plane comprises a sheet of microcapsules filled with reflective, electronegative white

particles and less electronegative black particles suspended in a transparent fluid (Comiskey et al., 1998). The top surface of the sheet is coated with an ITO counter electrode, resulting in a total display-plus-back-plane thickness of  $100 \mu\text{m}$ . Applying a potential across the microcapsules causes the white and black particles (typically  $1\text{--}5 \mu\text{m}$  in diameter) to migrate to the opposite top and bottom surfaces of the capsule. When the white particles are at the top, the display is more reflective than when the black particles are on top. Switching is achieved via a reversal of the pixel electrode potential.

Physical and electrical characteristics of the display are provided in Table 8.8. The properties of electrophoretic displays, including low frame rates, modest drive voltages, high on/off current ratio, bendability over a radius of only 7.5 mm, and ultra-light weight (1.6 g) are enabled by the properties of the backplane OTFTs. Patterning the gates with  $L = 5 \mu\text{m}$  uses stamp transfer, or transfer from a rigid handle. The pixel size is considerably larger than the total area defined by the OTFT gate dimensions, resulting in a display with a very high aperture ratio (97.5%),

**Figure 8.111** (a) Photograph of a flexible,  $320 \times 240$  pixel, 4.7 inch QVGA electrophoretic display with an OTFT address backplane. (b) Schematic illustration of the backplane transistor and the electrophoretic display elements. The total thickness of the integrated structure is  $100 \mu\text{m}$  (Gelinck et al., 2006).

**Table 8.8** Characteristics of the electrophoretic display in Fig. 8.111 (Gelinck et al., 2006)

Parameter	Value
Backplane OTFTs	
$L/W$	5 $\mu\text{m}/140 \mu\text{m}$
$\mu_{FE}$	0.01 $\text{cm}^2/\text{V s}$
$I_{on}/I_{off}$	1 $\mu\text{A}/6 \text{ pA}$
$V_T$	0.2 V
Backplane characteristics	
Row voltages	$\pm 25 \text{ V}$
Column voltages	$-15 \text{ V}/0 \text{ V}/+15 \text{ V}$
Common electrode voltage	4 V
Display	
Panel size	4.7" (72 $\times$ 96 $\text{mm}^2$ )
Pixel size	300 $\times$ 300 $\mu\text{m}^2$
Display bend radius	7.5 mm
Resolution	320 $\times$ 240 (85 ppi)
Aperture ratio	97.5%
Thickness	100 $\mu\text{m}$
Frame rate	50 Hz
Image update time	1.5 s
No. gray levels	4
Contrast	10:1
Maximum reflection	35–40%
Weight	1.6 g

defined as the fraction of area occupied by the display device to the total area of the pixel.

### 8.9.2 Sensors and sensor arrays

Organic transistors have been used in numerous sensing applications. One example is the detector *focal plane array* (FPA). In the previous chapter, we showed that passive matrix arrays can be shaped into hemispheres to create an imaging system with the size, relative optical simplicity and some critical functionalities of the human eye (Xu et al., 2008, 2009). Passive matrix addressing, however, has the disadvantage of generating large background, or sneak currents (see Section 7.2.2). A passive matrix is comprised of  $N$  rows and  $M$  columns of detectors that are addressed by an array of electrodes (busses) connected to all of the detector cathodes, and an orthogonal array of column electrodes connected to all of the anodes. Then, if the reverse dark current of each device is  $i_D$ , the total dark current measured

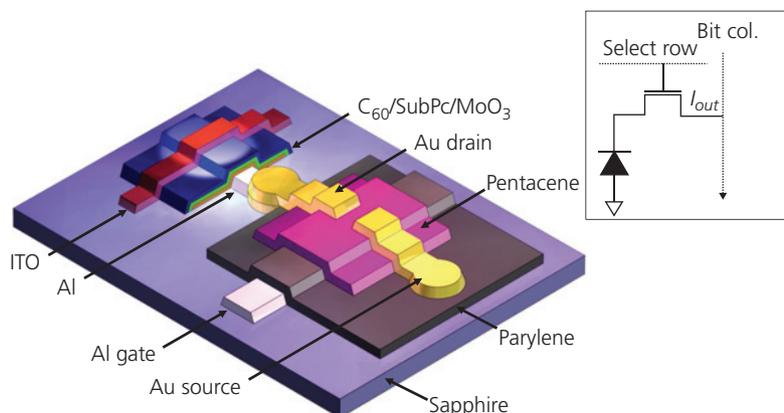

between each pair of column and row busses is  $Ni_D$ . Since the mean square shot noise current per unit bandwidth is  $\langle i_s^2 \rangle = 2qNi_D$ , the added shot noise from the array decreases the sensitivity as the FPA size increases.

To reduce the dark leakage currents in passive matrix FPAs, it is conventional practice to use an active matrix backplane that places one or more transistors at each detector as the pixel addressing element. The circuit may consist of five or more transistors as well as a charge storage capacitor to serve the multiple purposes of pixel addressing, pre-amplification and impedance matching. While the more complex circuit (known as an *active pixel sensor*) can result in very high bandwidth, ultralow noise operation, the size of the transistor circuits may ultimately limit the *pixel pitch*, that is, the number of detectors per length along a column or row (Bigas et al., 2006). Given the limited current sourcing capacity of an OTFT, the transistors must be considerably larger than their inorganic counterparts to achieve a large FPA dynamic range,  $DR$ , given by

$$DR = 20 \log_{10} \left( \frac{I_{max}}{I_{min}} \right) \text{ (dB)}, \quad (8.89)$$

where  $I_{max}$  is the maximum photocurrent prior to deviating from a linear detector response (and hence constant efficiency), due to series resistance, heating, etc. The  $I_{max}$  is identified when the current falls below a predetermined linearity criterion, for example, when the difference between the responsivity of the pixel falls 1 dB below its value at lower input optical powers. Also,  $I_{min}$  is the photocurrent required to give a minimum acceptable *signal-to-noise ratio* (SNR). The  $I_{min}$  is the current *noise floor* determined by the detector and input transistor.

To achieve a very high pixel pitch (corresponding to a high image resolution) using OTFTs, a single transistor *passive pixel sensor* (PPS) provides a useful compromise (Renshaw et al., 2010, Tong and Forrest, 2011). An example pixel structure along with its circuit schematic is shown in Fig. 8.112. The photodetector is a bilayer consisting of the donor/acceptor pair of 90 nm thick SubPc/50 nm thick  $C_{60}$  with a 30 nm thick  $\text{MoO}_3$  buffer. The device has an ITO anode and an Al cathode connected to a Au drain contact. The BG/TC OTFT consists of a parylene gate insulator and a 50 nm thick pentacene channel. The bias between the Al gate and the Au source addresses the pixel (Fig. 8.112, inset). All layers are deposited in vacuum and defined by shadow masks. The detector dimensions are 100  $\mu\text{m} \times$  800  $\mu\text{m}$ , and the OTFT dimensions are  $W/L = 500 \mu\text{m}/30 \mu\text{m}$ .

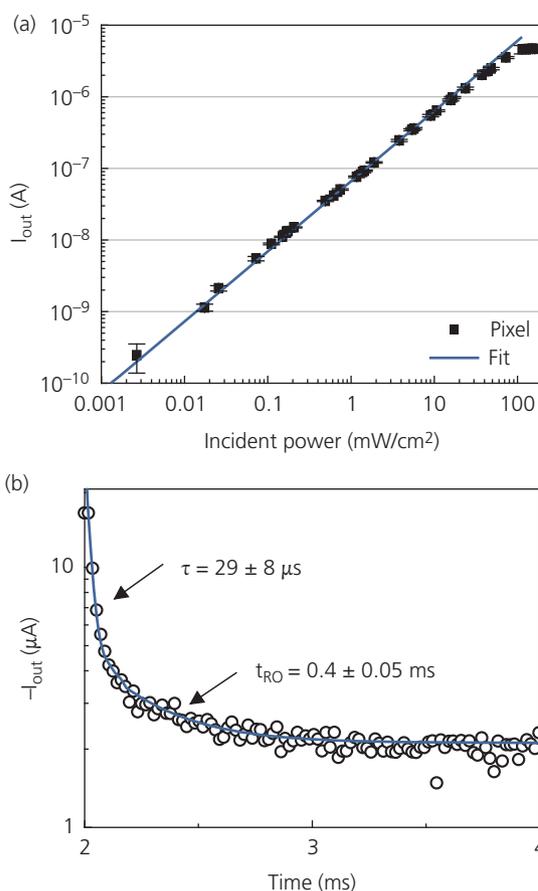

**Figure 8.112** Perspective illustration of an organic passive pixel sensor (PPS). Inset: Circuit diagram of the PPS (Tong and Forrest, 2011).

The response of the photocurrent (i.e.  $I_{out}$  in Fig. 8.112) is linear over four decades, showing a departure from linearity at  $I_{max} = 6 \mu\text{A}$ . Also, the minimum detectable photocurrent is  $I_{min} = 300 \text{ pA}$  (see Fig. 8.113a). These detection limits yield  $DR = 20\log(I_{max}/I_{min}) = 86 \text{ dB}$ .

The external quantum efficiency of the detector is 18.2% at a wavelength of 580 nm, and the speed of response of the circuit, shown in Fig. 8.113b yields a pixel readout time of  $\sim 400 \mu\text{s}$ . This is limited by the OTFT output conductance, given the relatively low  $\mu_{FEp} = 0.09 \text{ cm}^2/\text{V s}$ . The on-off current and particularly the dark leakage of this device ultimately determines the ability of the PPS to fully turn off and contribute only negligible noise when used in an array. Here,  $I_{on}/I_{off} = 10^5$ , with a pixel off-current of  $I_{out} = 31 \text{ pA}$  (Tong and Forrest, 2011). The pixel is too large for use in high resolution FPAs, and the small aperture ratio leads to a reduced SNR. Nevertheless, the circuit shows that even a rather modest performance OTFT can serve as an effective switch in an FPA. The transistor can be made smaller and the aperture ratio can approach unity by vertically integrating the detector and OTFT, and by using more precise patterning via photolithography or direct pixel printing.

Tactile sensors, with uses in robotics, personal entertainment, pressure sensing, etc., present significant integration and materials challenges when implemented in active matrices. A tactile sensor can comprise a transducer whose resistance changes with pressure. The sensor arrays often must be flexible, and even conformal to fit a human extremity or other irregular surface. To obtain spatial information, the sensor can be connected to the drain of an OTFT in a cross-point array similar to the PPS in Fig. 8.112, inset, except where the photodiode is replaced with the pressure-sensitive element.

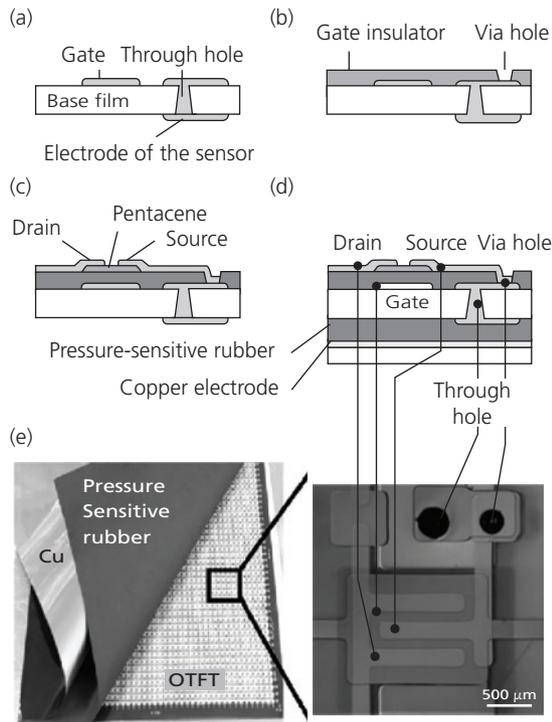

**Figure 8.113** (a) Dynamic range of the passive pixel sensor in Fig. 8.112 showing the output current vs. incident optical power at a wavelength of 580 nm. The line shows the linear response of the PPS. (b) Temporal response of the PPS. Fit to a biexponential (line) gives an RC time constant of  $\tau = 29 \mu\text{s}$  and a readout time of  $t_{RO} = 400 \mu\text{s}$  (Tong and Forrest, 2011).

The fabrication sequence used to produce one such tactile sensor array is shown in Fig. 8.114. Figure 8.114a shows the flexible PEN base film with via holes cut by

laser drilling, and then back-filled by thermally evaporated gate and via contacts on the top and bottom film surfaces. In this example, patterning is based on shadow masks, although inkjet printing has also been used (Noguchi et al., 2006). A 500 nm thick polyimide layer is deposited and thermally cured (Fig. 8.114b), and laser drilled to access the metal pad connected to the sensor electrode. The 50 nm thick pentacene channel is deposited in Fig. 8.114c, followed by deposition of the source and drain electrodes. The source makes contact to the back side sensor electrode via the two, laser-drilled vias. Finally, a pressure variable resistive film with a Cu electrode is laminated to a polyimide film, and is subsequently attached to the back surface of the base film (Fig. 8.114d).

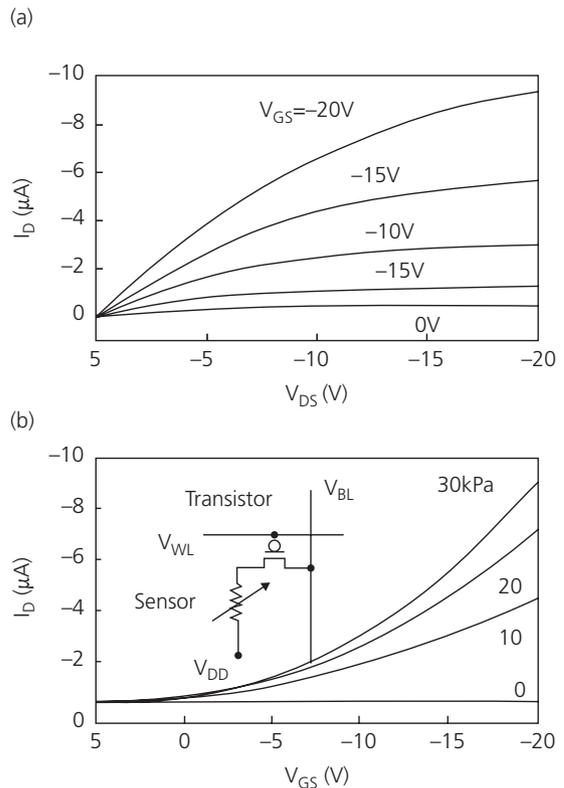

The pressure-sensitive transducer is a colloid of conducting graphite particles in a PDMS film. Application of pressure compresses the film. This, in turn, increases the total contact area between the particles, decreasing the resistance between the Cu plane and the pixel transistor source electrode. Since the source electrode defines the pressure sensitive area, the Cu counter electrode covers the entire surface of the array. This is similar to the architecture used in the electrophoretic display described in Section 8.9.1.

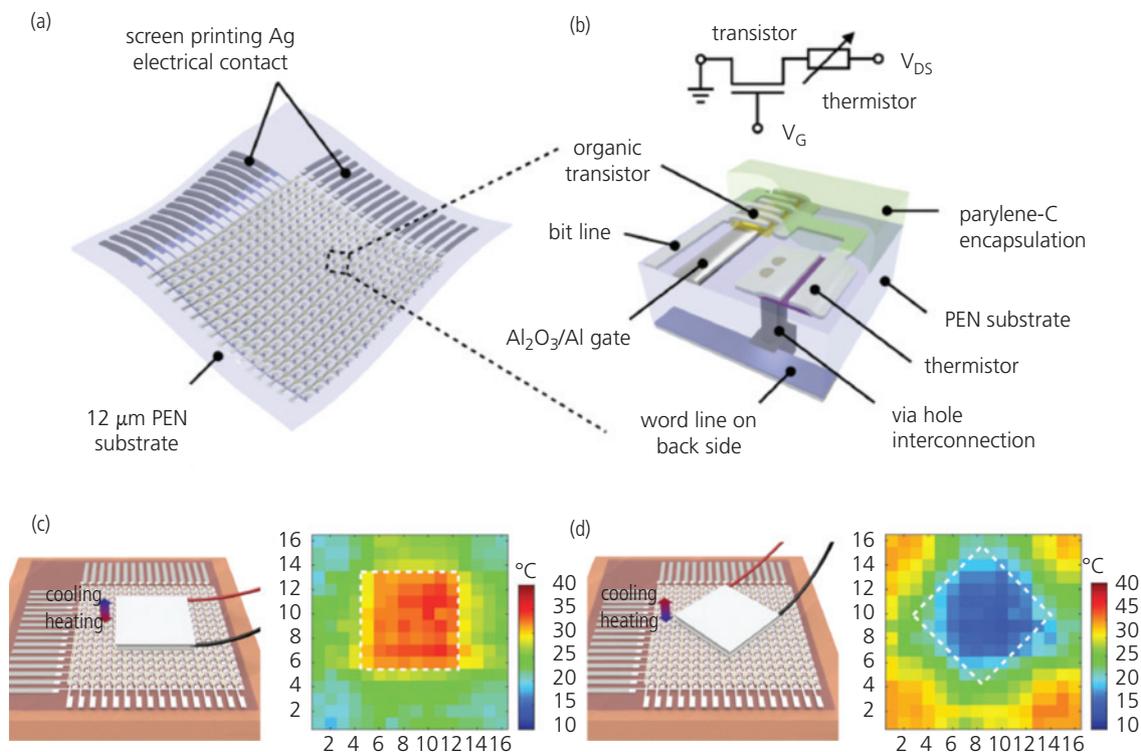

**Figure 8.114** (a–d) Fabrication sequence for a pressure sensor array with an OTFT pixel address backplane. (e) View of the array showing a detailed image of an individual pixel (right). The scale bar is 500  $\mu\text{m}$ . Adapted from Someya et al. (2004) and Noguchi et al. (2006).

The  $32 \times 32$  pixel array fabricated using the process sequence in Fig. 8.114 has a sensor pitch of 2.54 mm, which is equal to the dimension of the transistor in Fig. 8.114e. The OTFT characteristics are provided in Fig. 8.115a, with  $\mu_{FEp} = 1.4 \text{ cm}^2/\text{V s}$  with  $I_{on}/I_{off} = 10^6$ . These characteristics lead to the transfer characteristics in Fig. 8.115b. The drain current is determined by the resistance of the pressure transducer for  $V_{DS} = -20 \text{ V}$ : it varies from 10 M $\Omega$  at pressure,  $P = 0$ , to 1 k $\Omega$  at  $P = 30 \text{ kPa}$ . Pixelation allows pressure contact patterns to be reproduced to within the spatial resolution of the transistors. Also, there is only a small change in characteristics as the array is bent over radii as small as 10 mm. Changes in response are observed when the bend radius is reduced to 2 mm, although the array remains functional even in that case (Someya et al., 2004).

A type of temperature sensor is the *thermistor*. In array format, the sensors provide spatially resolved information that can have applications to health monitoring, robotics, and monitoring of local environments. A  $16 \times 16$  flexible thermistor array on a 12  $\mu\text{m}$  thick PEN substrate is shown schematically in

**Figure 8.115** (a) Drain current characteristics for the transistors in the sensor array in Fig. 8.114. (b) The  $I_D$  vs.  $V_{GS}$  of a pixel on the array as a function of pressure. Inset: Pixel circuit schematic (Someya et al., 2004).

**Figure 8.116** (a) Illustration of the  $16 \times 16$  temperature sensor array with (b) an illustration of an individual sensing pixel and its circuit schematic. By placing a thermoelectric heater onto the array, both (c) heating and (d) cooling thermal images are produced, as shown to the right of each illustration. The thermal scale in (c) is  $10\text{--}40^\circ\text{C}$  and in (d) is  $30\text{--}70^\circ\text{C}$ . Blue indicates the coolest regions, red are the hottest (Ren et al., 2016).

© 2016 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

Fig. 8.116a and b. The thermistor is a temperature-variable resistor connected to the OTFT drain contact. As temperature increases, the resistance decreases, resulting in an increased  $I_D$ . For accurate thermometry, the characteristics of the transistor itself must not be temperature sensitive. The array in Fig. 8.116 operated between temperatures of  $20^\circ\text{C}$  and  $100^\circ\text{C}$ , a range over which the transfer characteristics of the BG/TC DNNT transistors (employing Al gate contacts and oxidized Al/octadecylphosphonic acid SAM gate insulator) in Fig. 8.116b were thermally stable (Ren et al., 2016).

The thermistor itself comprises a layer of 5 nm Ag NPs sandwiched between two, 20 nm thick pentacene thin films. The temperature coefficient of resistance of a transducer comprising 3 nm Ag NPs is thermally activated, as shown in Fig. 8.117a. We have shown in Chapter 7 that ultrathin Ag layers deposited onto organics do not wet the organic layer, but rather forms NPs that are uniformly dispersed over the organic surface (and may also penetrate a considerable distance into the organic film). The NPs are too dispersed to contact each other, and thus the enhanced conductivity and significant increase in thermal activation energy compared with neat pentacene is due to NP-

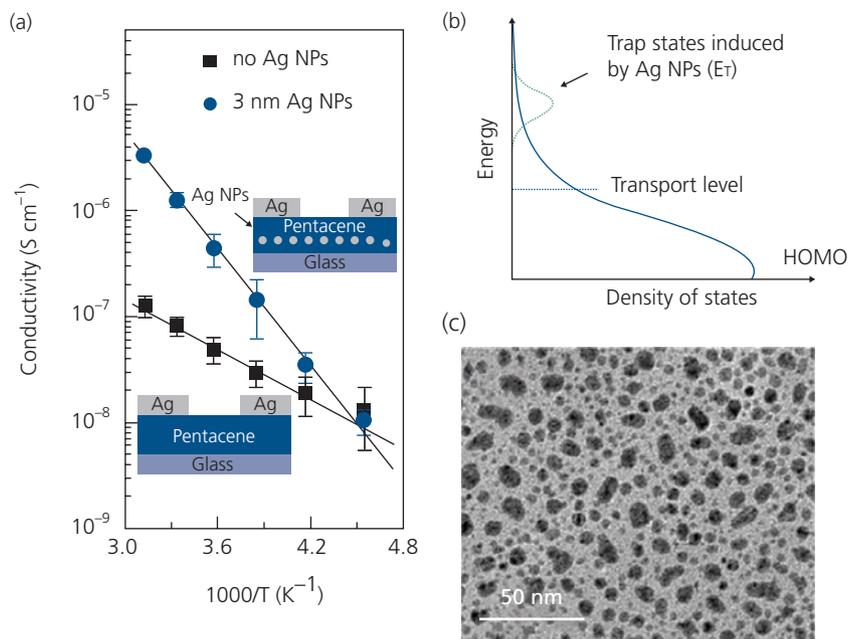

induced trap states in the pentacene (Fig. 8.117b and c). The traps lie above the pentacene transport level in the HOMO tail states. The traps may result from damage induced in the pentacene from impact of the high kinetic energy, evaporated Ag atoms during deposition (see Section 4.6.3).

The energy difference between the states is the activation energy,  $E_A$ . Then the conductivity is thermally activated following:  $\sigma = \sigma_0 \exp(-E_A/k_B T)$ , where  $\sigma_0$  is the conductivity at  $T \rightarrow \infty$ . It follows that the *temperature coefficient of resistance* of the thermistor is

$$TCR = \frac{1}{R} \frac{dR}{dT} = -\frac{E_A}{k_B T^2}. \quad (8.90)$$

The devices in Fig. 8.117a have  $E_A = 332$  meV, compared to a pentacene film with 157 meV. Further, we observe that the conductivity decreases by 300 times as the temperature is decreased from room temperature to 220 K. Hence, the thermistor provides a very sensitive element with a temperature resolution of  $0.4^\circ\text{C}$  and  $TCR = 0.044/^\circ\text{C}$  between  $20^\circ\text{C}$  and  $100^\circ\text{C}$ .

The DNNT transistors used in the array have performance similar to those discussed previously (cf. Fig. 8.23) in that they exhibit both low voltage ( $V_{GS} \sim 4$  V) and low gate leakage (50 pA), required for high

**Figure 8.117** (a) Thermal activation of pentacene and a pentacene layer with 3 nm (average) Ag NPs deposited near the center of the pentacene film. Schematics of the two resistors are shown as insets. (b) Proposed DOS of the pentacene channel leading to thermal activation of the conductivity. (c) Transmission electron micrograph of the Ag NPs on pentacene (Ren et al., 2013).

sensitivity thermal monitoring. Also, by encapsulating the transistors with 6  $\mu\text{m}$  parylene, the electronics are located very near the *neutral strain point* (see Section 8.9.3). Thus, the arrays were bent  $10^4$  times over a radius of 3.2 mm without changes in their operating characteristics (Ren et al., 2016). Imaging of both the hot and cold surfaces of a  $2 \times 2 \text{ cm}^2$  Peltier heater is shown in Fig. 8.116c and d, respectively. The spreading of the thermal image due to thermal conduction ultimately limits the spatial resolution of this device (Fig. 8.116d). However, the resolution can be improved by using less thermally conducting substrates or encapsulation layers.

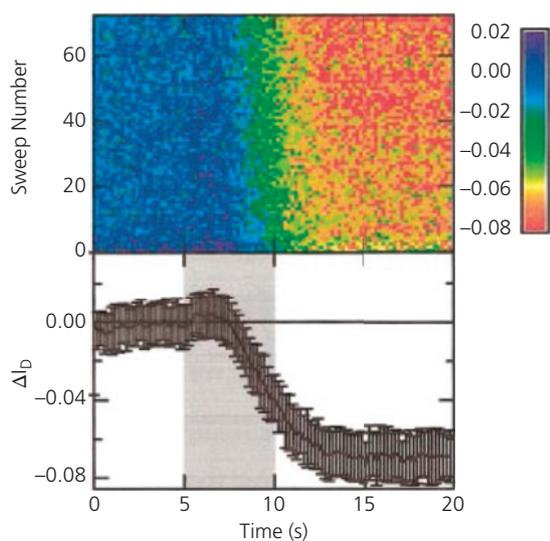

The sensitivity of an OTFT to environmental factors discussed in Section 8.8 has led to their use for sensing a variety of analytes, ranging from water, oxygen, nitrous oxide, and organic solvents (Crone et al., 2001, Mabeck and Malliaras, 2006, Roberts et al., 2008, Marinelli et al., 2009, Zhang et al., 2015, Feng et al., 2016). This might seem a case of “turning lemons into lemonade” by exploiting the unwanted sensitivity of OTFTs to the environment into an advantage. Hence it is useful to clarify the characteristics of practical chemical sensors. They are: (i) *Selectivity (or specificity)*. The sensor must be able to distinguish between analytes within the test environment. (ii) *Sensitivity*. The sensor must respond with an easily detectable SNR to the target analyte at the lowest possible concentrations. (iii) *Linearity*. A linear response is desirable to provide

an output signal that is directly proportional to the analyte concentration over a wide dynamic range. (iv) *Response time*. This should be as short as needed, particularly when detecting toxic or corrosive substances that must be rapidly identified to protect life and equipment in time to reduce or eliminate the source of exposure. (v) *Reversibility*. Following the termination of exposure to the subject analyte, the sensor should rapidly recover to its original, pre-exposure condition, and hence be ready for reuse. (vi) *Reproducibility*. The sensor itself should have predictable and reproducible characteristics to avoid extensive calibration, or recalibration between uses.

An OTFT sensor uses a bottom gate configuration. This gives the analyte access to the sensitive channel and dielectric zones of the device. The target analyte creates or neutralizes traps within these regions or at interfaces, resulting in a change in operating parameters. Most commonly, changes in drain current are monitored over time as a signature of the presence or absence of a particular species. A high performance sensor generates a time-dependent change in drain current,  $\Delta I_D(t)$ , that is easily measured even at trace concentrations of the target analyte. Specificity and speed of response is achieved by the choice of semiconductor and/or dielectric, or by functionalizing the semiconductor surface with compounds that selectively react with the target molecules.

A demonstration of a sensor family that provides repeatable, selective, and rapid response to exposure to organic solvents is based on a series of thiophenes functionalized with increasingly longer end groups. The channel semiconductors are:  $\alpha$ -sexithiophene ( $\alpha$ -6T), dihexyl  $\alpha$ -6T (DH  $\alpha$ -6T), didodecyl  $\alpha$ -6T (DD  $\alpha$ -6T), and dioctadecyl  $\alpha$ -6T (DOD  $\alpha$ -6T) used in BG/TC OTFTs with an SiO<sub>2</sub> dielectric. The change in drain current in saturation,  $\Delta I_D(t)$ , of a DH  $\alpha$ -6T sensor before, during, and after 72 consecutive, 5 s exposures to 1-hexanol is shown in Fig. 8.118. The recovery period is 1 min, which can be accelerated by an electrical bias applied after each sweep. The drain current recovers to within 2% of its initial, unexposed value after reach cycle (Crone et al., 2001). Analysis of the DD  $\alpha$ -6T OTFT transfer characteristics due to exposure to 1-octanol indicates that  $\Delta I_D(t)$  is in response to a change in  $V_T$ , whereas  $\mu_{FEp}$  is unaffected. Exposure to ketones and nitriles produce changes in both parameters. These results indicate selective detection of molecules that variously affect charge trapping in the bulk (and hence  $V_T$  and  $\mu_{FE}$ ), or at the interface (which primarily affects  $V_T$ ).

The selectivity “map” of several OTFTs vs. analyte is provided in Fig. 8.119. From the diversity of responses, an array of OTFTs with different channel materials can be used to develop a “fingerprint” for each analyte, thus creating a sensing system that can

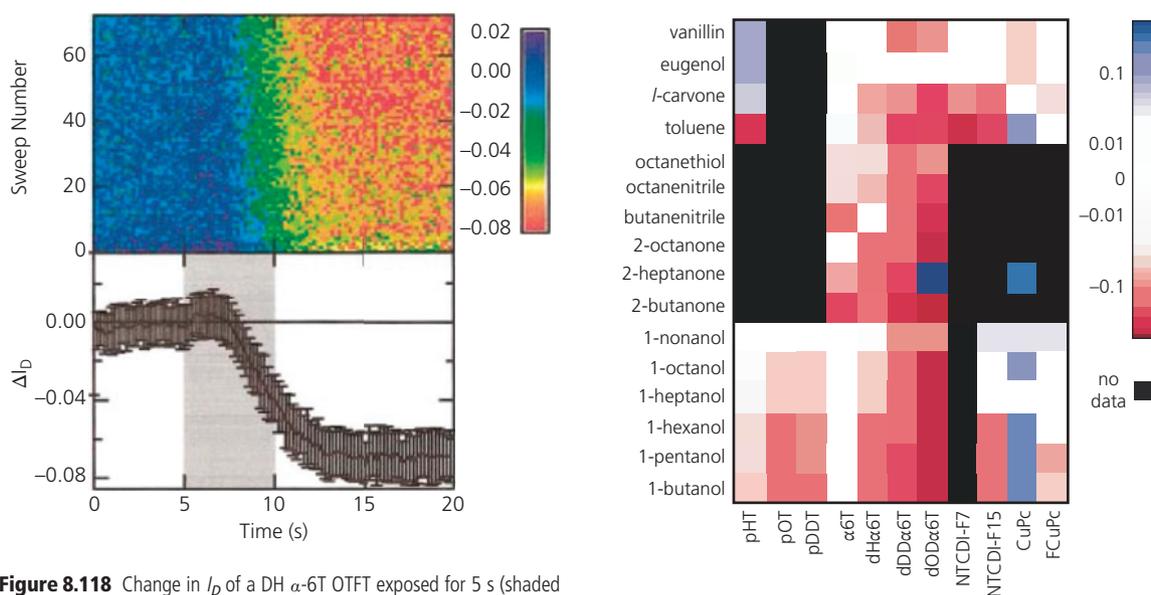

**Figure 8.118** Change in  $I_D$  of a DH  $\alpha$ -6T OTFT exposed for 5 s (shaded area, lower panel) to 1-hexanol vapor. The upper panel shows the fractional change in current (scale bar on right) for 72 exposures. The lower panel shows the change and deviations of the response from the data in the upper panel. The 1 min recovery between each sweep is not shown (Crone et al., 2001).

readily distinguish between substances to which it is exposed.

The sensitivity and selectivity to trace amounts of three different impurities of a BG/BC p-channel OTFT comprising a D<sub>3A</sub> film spin-coated onto a SiO<sub>2</sub> gate dielectric (Marinelli et al., 2009) is illustrated in Fig. 8.120. The response and recovery are reproducible, and occur over times of 50–100 s. The sensitivity of the detector shows that NO<sub>2</sub> concentrations as low as 500 ppb are readily detected, whereas there is a lower sensitivity of 1 ppm for NO. The device is also selective, as there are no changes observed from exposure to CO. However, the sensor lacks the ability to distinguish between the different nitriles. Without prior knowledge of the analyte concentration, distinguishing between exposure to NO<sub>2</sub> or NO is not possible.

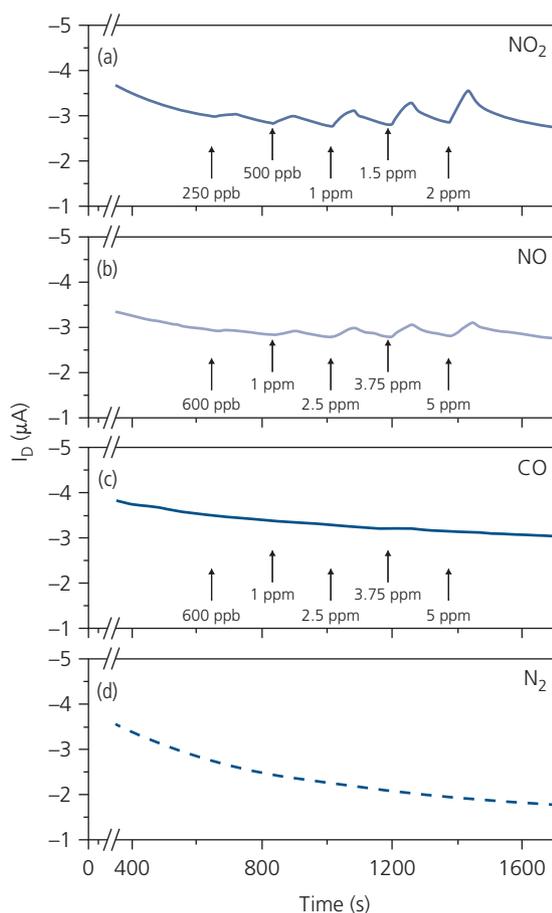

Analysis of the transistor transfer characteristics indicate that the changes in drain current are the result of changes in  $\mu_{FEp}$ , whereas  $V_T$  is almost unchanged for all concentrations of NO<sub>2</sub>. The change in mobility indicates that the analyte affects the conductive properties of the channel semiconductor, or the dielectric/semiconductor interface. The nitriles have a strong electron accepting nature. Introduction of these impurities in the channel can neutralize negatively charged traps, shifting the threshold voltage to more positive values. This, in turn, is equivalent to increasing the applied field in the channel,

**Figure 8.119** The fractional change in  $I_D$  for 16 analytes (vertical axis) exposed to OTFTs with 11 different channel materials (horizontal axis). A positive change in current is shown in blue, a negative shift is shown in red, and black indicates no data are available (Crone et al., 2001).

leading to a higher drain current at a fixed  $V_{GS}$ , as observed.

The ability to deposit OTFTs on virtually any reasonably flat surface provides an opportunity for OTFT sensors to find applications that are inaccessible to competing technologies. For example, high yield OTFT arrays and circuits deposited on banknotes have been shown to have performance characteristics similar to those deposited on more conventional plastic and glass substrates (Zscheschang et al., 2011). This allows for the direct integration of organic transistor-based RFIDs onto paper currency as an anti-counterfeit measure. While this solution has yet to be adopted, and indeed may ultimately prove to be impractical, demonstrations such as this can open up new possibilities for applications of organic electronic circuits and devices.

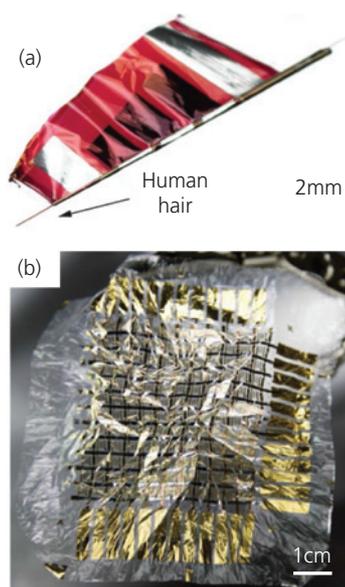

**Figure 8.120** (a–c) Drain current vs. exposure of a  $D_{3A}/SiO_2$  OTFT at  $V_{GS} = -40$  V to three different analytes. The concentrations of the analyte vapors are indicated. (d) The drift due to operation in  $N_2$  is used to remove the baseline response from the data in (a–c) (Marinelli et al., 2009).

### 8.9.3 Ultrathin, stretchable, and biocompatible electronics

A most compelling application with the potential to make a significant impact in the fields of medicine, robotics, and entertainment has been termed *imperceptible electronics* (Kaltenbrunner et al., 2013). This concept applies to electronics that are so thin, lightweight, and conformable that they cannot be felt when worn on the body, nor do they disturb the organism to which they are attached (e.g. to internal organs, limbs, etc.). Imperceptibility is achieved by fabricating devices on ultrathin and stretchable substrates, such that they conform to the natural topography of skin, the tissue of internal organs, etc., even as these tissues are naturally stretched or bent *in vivo* (Sekitani et al., 2010). Images in Fig. 8.121 show electronic circuits on ultrathin and lightweight substrates that can be bent over very small radii, or even crumpled without suffering losses in performance.

Achieving these goals requires more than just being able to handle such thin and easily distorted substrates. Bending over small radii requires that the device avoid excessive strain that can damage the active electronic layers. Also, long-term operation

**Figure 8.121** Examples of ultrathin imperceptible organic electronics. (a) A polymer, P3HT/PCBM solar cell on a  $1.4 \mu\text{m}$  thick PET substrate wrapped around a human hair with a  $35 \mu\text{m}$  radius (Kaltenbrunner et al., 2012). (b) A crumpled  $12 \times 12$  matrix of tactile sensor pixels on a  $1.2 \mu\text{m}$  thick PEN substrate (Kaltenbrunner et al., 2013).

Reprinted by permission from Springer Nature, Nature, An ultra-lightweight design for imperceptible plastic electronics. Kaltenbrunner, M., Sekitani, T., Reeder, J., Yokota, T., Kuribara, K., Tokuhara, T., Drack, M., Schwödiauer, R., Graz, I., Bauer-Gogonea, S., Bauer, S. & Someya, T. Copyright 2013.

requires encapsulation that does not impede flexibility. The examples in Fig. 8.121 are flexible, but not conformable: a property that requires stretching of the substrate. This places additional constraints, such as the ability for the interconnects to remain conductive even when significantly strained.

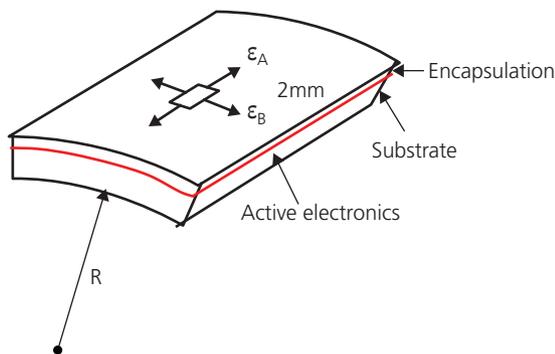

Encapsulation can be used to eliminate, or greatly reduce the strain on flexing if the active electronics are located at the neutral strain point in the multilayer package. This is illustrated in Fig. 8.122 for a film is bent over a radius,  $R$ . The bottom surface is under a negative compressive strain,  $\epsilon_B$ , and the top surface is under a positive tensile strain. The *axial strain*,  $\epsilon_A$ , or *proportional deformation*, is constant along the entire film. Thus, there is a location (the neutral strain point) within the film where the strain,  $\epsilon_B = 0$ . For a homogeneous film, this point lies at its center. For the general case where the *Young's modulus* of the substrate is  $Y_{sub}$  and that of an encapsulating film is  $Y_e$ , then the neutral point for substrate and encapsulation layer thicknesses of  $d_{sub}$  and  $d_e$ , respectively, are related via (Suo et al., 1999)

$$\frac{d_{sub}}{d_e} = \sqrt{\frac{Y_e}{Y_{sub}}}. \quad (8.91)$$

The Young's modulus is the ratio of stress to strain, that is, it measures the extension or shrinkage of a material under tensile or compressive stress. Thus,

$$Y = \frac{\sigma(\epsilon)}{\epsilon} = \frac{\mathcal{F}L_0}{A\Delta L}, \quad (8.92)$$

where  $\sigma$  is the uniaxial stress,  $\mathcal{F}$  is the tensile force,  $L_0$  is the initial length of the object and  $A$  is its area perpendicular to the force, and  $\Delta L = L - L_0$  is the length change. When the active electronics are placed at the point of zero strain, it can be bent over very

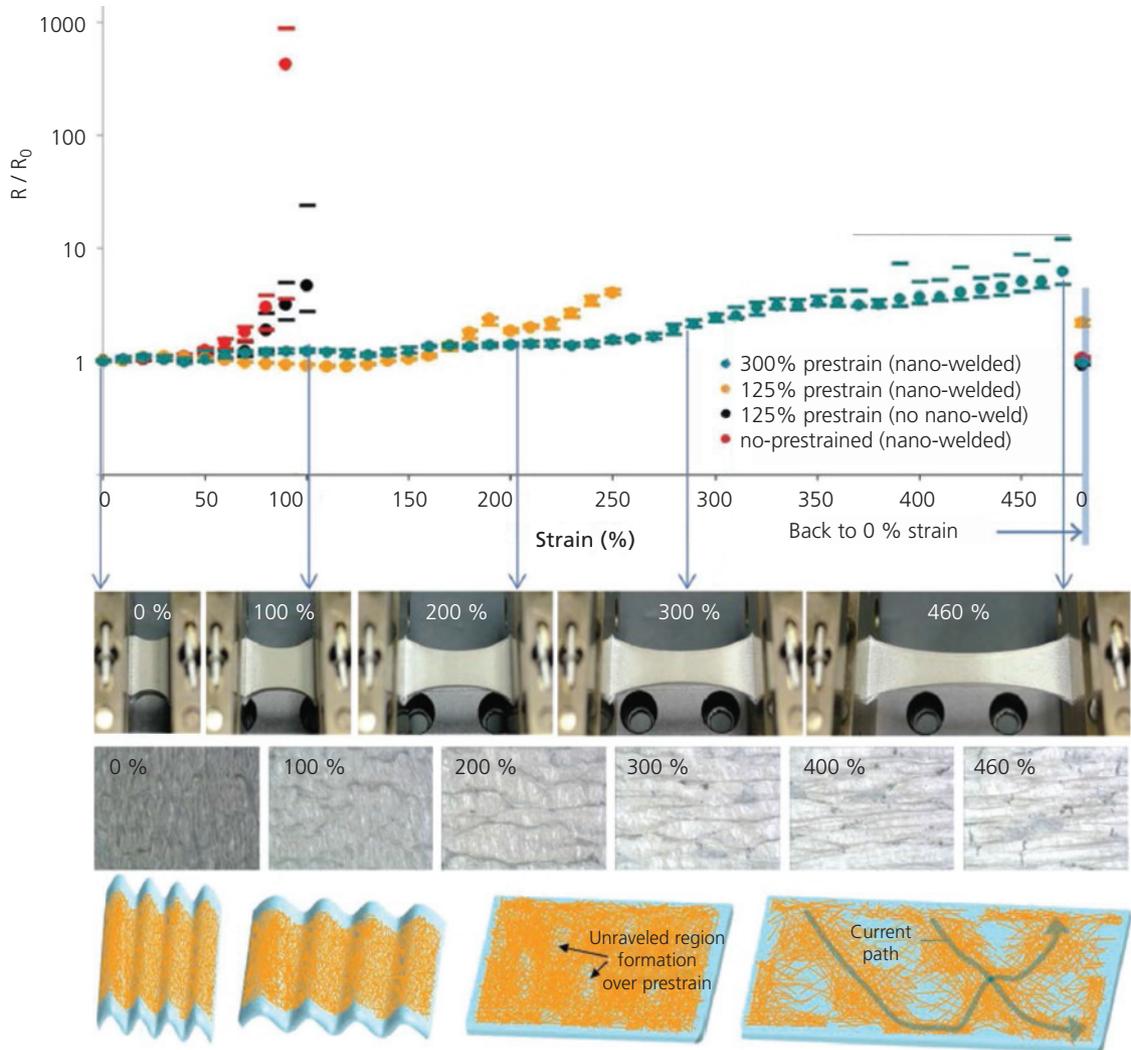

**Figure 8.122** Active electronics on a thin substrate and encapsulated by a top thin film is bent over radius  $R$ , inducing an axial ( $\epsilon_A$ ) and bending strain ( $\epsilon_B$ ).

sharp radii, which is required for ultrathin substrates as in Fig. 8.121.

Elastic conductors are another essential component of bendable and conformable electronics. The interconnects between active devices must remain conductive, ideally without a significant change in resistivity as they are distorted. One method to achieve a stretchable interconnect is to pattern a metal meander, coil or flexible bridge between active circuit elements that expands as the elements are separated, for example on the surface of a plane that is distorted into a 3D shape (Huang et al., 2007, Gonzalez et al., 2008, Ko et al., 2008). While this may accommodate very large strains, it involves complicated processes that may violate the condition for low cost. An alternative is to introduce bundles of conducting carbon nanotubes (CNTs) or metal nanowires into a prestrained (i.e. stretched) elastomer such as PDMS (Lee et al., 2012c, Sekitani and Someya, 2012). The contacts between the long conducting tubes and wires form percolating paths along the length of the composite. The stress applied during film formation is relaxed once the curing process is complete, allowing the film to shrink. It can then be repeatedly stretched to its initial length, and then relaxed without a change in the resistance.

An example of a conducting film comprising a matrix of Ag nanowires in an elastomeric matrix that can withstand strains as high as 900% without failure is shown in Fig. 8.123. The nanowires are grown by a solution process that results in a very high aspect ratio: the diameters range from 100 to 150 nm over lengths of 100–200  $\mu\text{m}$ . The nanowire films achieve 90–96% transparency and a resistivity from 9–70  $\Omega/\text{sq}$ . (Lee et al., 2012c). Improved contact between nanowires (and hence a lower resistivity and higher tolerance to strain without failure) is obtained by thermally annealing the composite during curing. Results of the prestrained films and the dependence of resistance on the amount of strain applied during fabrication are shown in Fig. 8.123. Strains as high as 460% are applied without failure (indicated by an abrupt and very large increase in  $R/R_0$ , where  $R_0$  is the resistance at zero strain). No significant changes in resistance are observed after 200 stretching cycles. The figure also shows illustrations of the nanowire composite under several different strain conditions. On the bottom, left hand side, the prestrained film is in its relaxed state, where the Ag nanowires (orange region) form a dense conducting network. As the film is stretched, the nanowire network spreads out, until at the

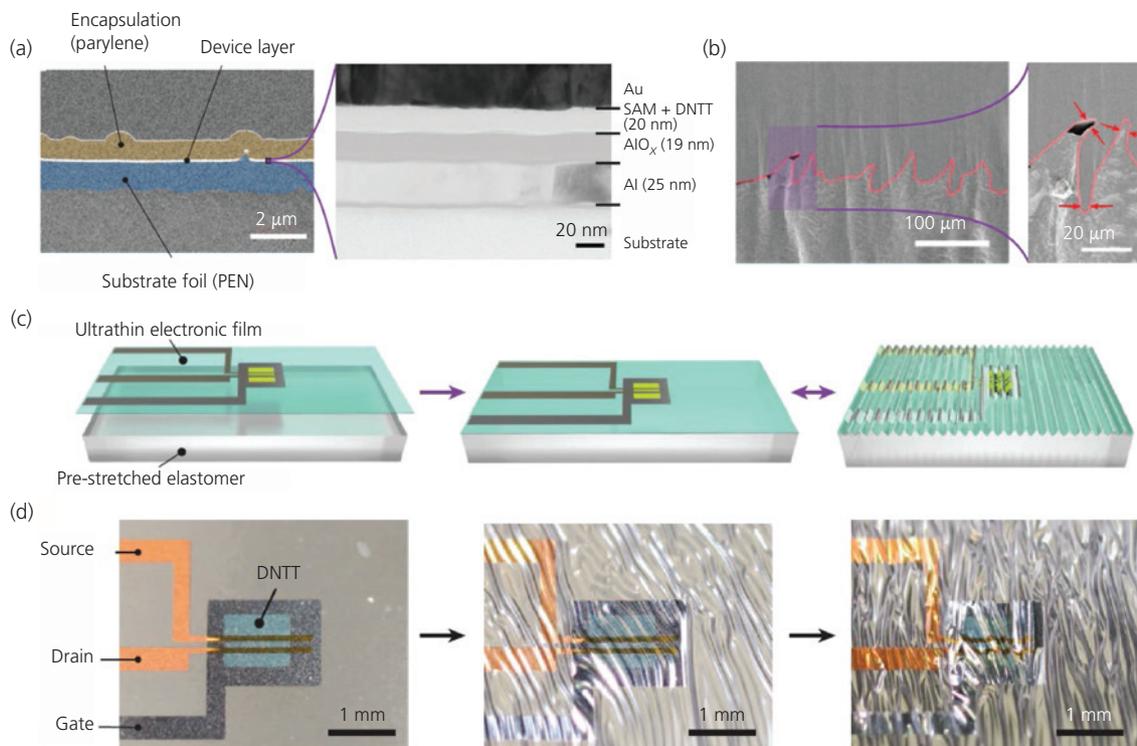

**Figure 8.123** Top graph shows the resistance ( $R$ ) of pre-strained Ag nanowire films normalized to their values under zero strain ( $R_0$ ). The photos show the macroscopic and microscopic views of the strained films, and the illustrations at bottom show the conductive pathways in unstrained (left), and highly strained (right) films (Lee et al., 2012c).

highest strains applied, the network opens up, but percolating conducting pathways (arrows) remain. The resistance in this case is somewhat higher than at zero strain. From the top graph, however, we see that it has only increased ten-fold even at  $\epsilon = 460\%$ . At higher strains, the networks break apart and the resistance abruptly increases.

There are many different approaches to achieving very high conductivity using mechanical meshes, nanowires, CNTs, etc. For a more complete description of these techniques that are a central element of highly flexible and conformable electronics, the reader is referred to the extensive literature on this subject (Hammock et al., 2013, Lipomi and Bao, 2017).

Transistors in tactile matrix arrays such as that in Figs. 8.114 and 8.121b represent early demonstrations of an imperceptible electronic application that use prestrained transistors such as in Fig. 8.124. A DNNT transistor is fabricated on the neutral plane sandwiched between a  $1.2\ \mu\text{m}$  thick PEN substrate and a perylene encapsulation layer of approximately the same thickness (Fig. 8.124a). Since the Young's moduli of the two materials are approximately equal, Eq. 8.91 indicates that the neutral strain point for the electronics is in the center of the sandwich. The structure of the BG/TC transistor comprises a  $25\ \text{nm}$  thick Al gate, a  $19\ \text{nm}$  thick potentiostatically anodized  $\text{AlO}_x$  gate insulator, an  $n$ -tetradecyl phosphonic acid

**Figure 8.124** (a) A thin film transistor used in the tactile sensor backplane array of Fig. 8.114b. It is fabricated in the neutral plane between the 1.2  $\mu\text{m}$  thick PEN substrate and an equally thick perylene encapsulation. (b) Cross-section of the film after it is compressed following the procedure in (c). The red line is the transistor plane. (c) Process for wrinkling the transistor in (a) by placing the fabricated, ultrathin OTFT on a pre-stretched substrate and then allowing it to relax. (d) Micrographs of the transistor before and after relaxation (Kaltenbrunner et al., 2013).

SAM, and a p-channel layer comprised of DNTT. The source and drain metallization used VTE grown Au. The OTFTs showed  $\mu_{FEp} = 3 \text{ cm}^2/\text{V s}$ .

The cross-sectional SEM image of the transistors in Fig. 8.124b after wrinkling shows folds with radii as small as 5  $\mu\text{m}$  within the device area. The folds are formed by fabricating the transistors on a flat, rigid handle. The devices are then peeled off from the handle and attached to a stretched, elastomeric substrate. The substrate is allowed to relax, crumpling the transistor, creating deep folds as shown in Fig. 8.124b and d. Interestingly, even with such deep and sharp creases, there is no perceptible change in  $I_D$ ,  $V_T$ , and  $\mu_{FEp}$  up to tensile strains of 233%, and compressive strains of 80%. Radial compressive strains of 40% were also achieved without changes in performance. The devices were cycled through compressive and tensile motions up to 200 times, also without significant changes in device characteristics (Kaltenbrunner

et al., 2013). This demonstrates that fabrication at the neutral strain position enables electronic devices that are nearly immune from flexing and stretching.

A potential application of electronics on such thin substrates is the *in vivo* and real time monitoring of a beating heart by wrapping it in a biocompatible array of electrical sensors (Sekitani et al., 2016, Park et al., 2018). The sensor inputs are the nerve impulses that trigger the contraction of the heart muscle. These impulses, however, are only 1–2 mV. An integrated voltage amplifier at each pixel is needed to generate an electrocardiogram with an SNR that is easily monitored without error.

The circuit schematic of the heart sensor is shown in Fig. 8.125a. A biocompatible multiwalled CNT gel electrode is placed in contact with the heart tissue to be monitored. The electrode connects to one plate of the input capacitor that, in turn, is connected to the gate of the input transistor of a

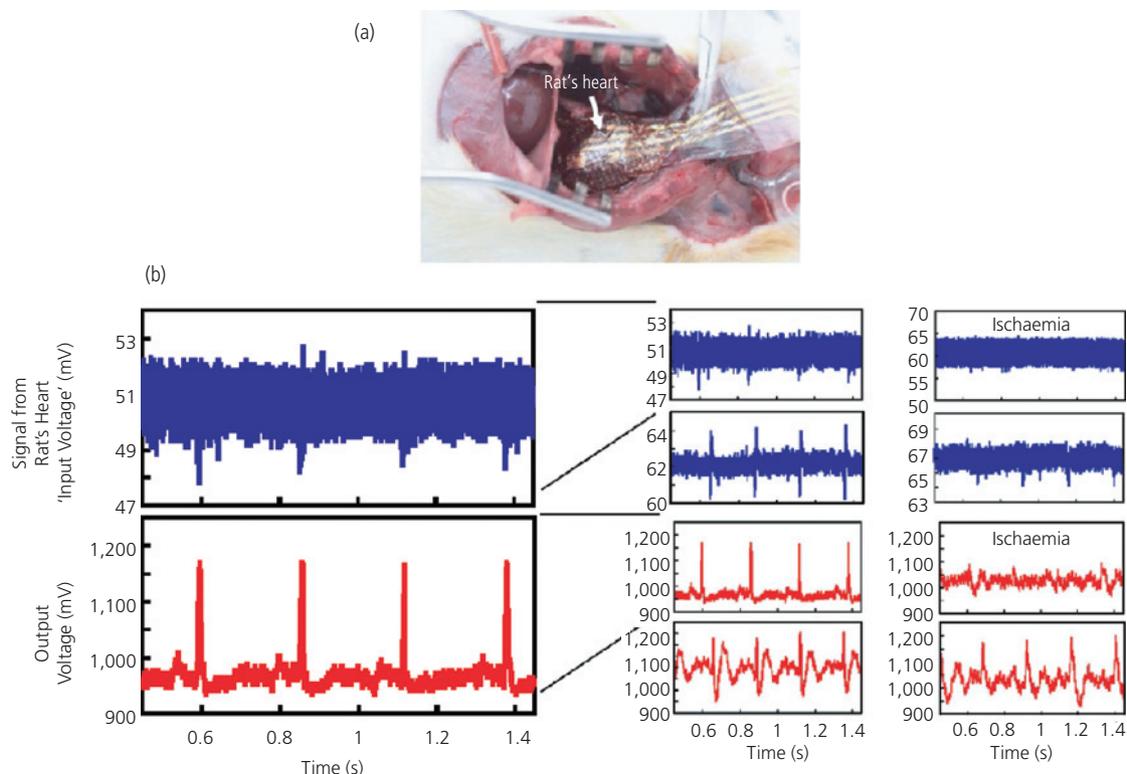

**Figure 8.125** (a) Amplifier circuit consisting of a carbon nanotube (CNT) gel contact, input capacitor and voltage amplifier circuit. (b) Schematic illustration of the multilayer, ultrathin amplifier array. (c) Image of the completed array (Sekitani et al., 2016).

single stage voltage amplifier circuit. This differentiating voltage amplifier enables detection of the small voltage pulses transmitted from the nervous system encasing the heart muscle. The success of this application relies on two key features: (i) biocompatibility of the electrode in contact with the heart, and (ii) ultralight weight and flexibility that prevents irritation, and otherwise does not affect the normal function of the organ.

The electrode itself consists of a stretchable and soft aqueous polyrotaxane-based gel with a moveable cyclodextrin/polyethylene cross-linker mixed with multiwall CNTs. The sheet in the array shown in Fig. 8.125b and c is produced by drop casting the gel onto a PTFE sheet. The array is attached to the capacitor sheet comprising a SAM/ $\text{AlO}_x$  dielectric sandwiched between Au electrodes. The active devices are p-channel DNTT OTFTs employing structures similar to those used in the tactile sensor arrays in Fig. 8.114. In this case, the gate dielectric is a 4 nm thick layer of  $\text{AlO}_x$  formed by oxygen plasma treatment of the Al gate electrode. This is followed by deposition of a 2 nm thick *n*-octadecylphosphonic acid SAM prior to deposition of the DNTT and the Au source and drain electrodes. The entire array has a 3 dB frequency roll-off of  $\sim 20$  Hz, as determined by the input capacitor. The transistors themselves show  $f_T = 42.7$  kHz. Due to the use of the ultrathin ( $1.2 \mu\text{m}$ ) PEN substrate, transistor operation is unaffected by bends around a  $50 \mu\text{m}$  radius.

Electrocardiograms taken by wrapping the circuit around a rat's heart (Fig. 8.126a) are shown in Fig. 8.126b. The gel electrode in contact with the heart had a thickness of 1 mm and an outer dimension of  $6 \times 6 \text{ mm}^2$ . The electrical input of 1.2 mV was amplified 200 times to result in a 220 mV output signal, increasing the SNR from 0.53 to 64 before and after amplification.

Biocompatibility also requires that the devices withstand exposure to extreme conditions found in autoclave sterilization. This entails exposure to steam at temperatures exceeding  $120^\circ\text{C}$ . Experiments on DNTT transistors have shown that they are sufficiently robust to withstand such treatments for up to 30 min without inducing large changes in their operating characteristics. To withstand high humidity and temperature, the devices are fabricated on moisture-impermeable and rigid Si substrates. Furthermore, the top parylene encapsulation layer is replaced by a trilayer comprised of 300 nm parylene, followed by 200 nm thick Au, and a cap of a second 1  $\mu\text{m}$  thick parylene layer. The initial parylene layer protects the OTFT surface from the Au coating. However, the parylene water vapor transmission rate (see Section 5.8) is too high to prevent degradation at elevated temperature and humidity, and hence the Au layer is inserted as a moisture barrier. The parylene cap provides the final, biocompatible coating. The trilayer, along with the environmentally impervious Si substrate,

**Figure 8.126** (a) Photograph of the electrocardio transducer attached to a rat's heart. (b) Electrocardiograms of the unamplified (blue) and amplified (red) heart impulses for different input conditions, including the ischemic state under myocardial infarction (Sekitani et al., 2016).

leads to stable OTFT performance up to 150°C (Kuribara et al., 2012).

One additional feature that can be added to make the electronic device precisely and softly conform to a surface is to mount the circuits on a polymer with shape memory. *Shape memory* is the property where a deformed material can return to its original 3D conformation once the stimulus that has shaped it is removed. Thus, the material can “remember” its original form. *Shape memory polymers* (SMPs) can therefore be used to conform to surfaces by heating above their glass transition temperatures,  $T_g$ , whence they are “pretrained” to fit into a particular shape. Reheating the material causes it to assume its original conformation (Liu et al., 2009b, Nair et al., 2010). For use with living organisms, the  $T_g$  of the SMP must be sufficiently low to prevent injury during deformation.

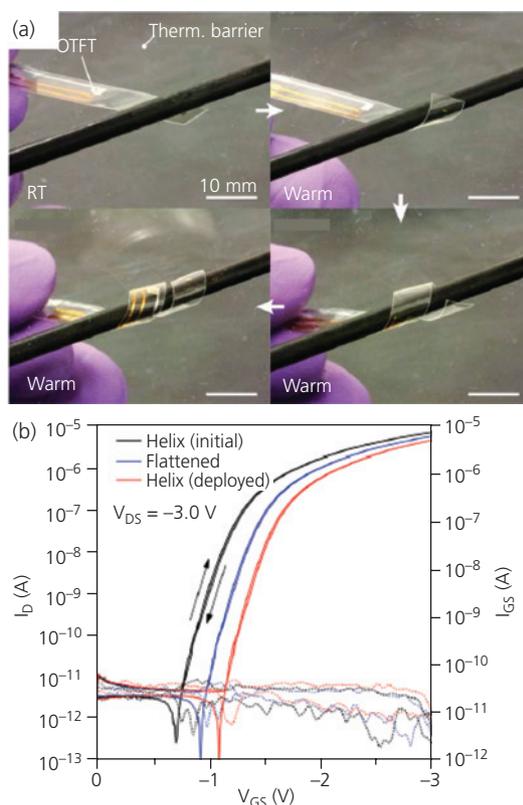

An example of a 25  $\mu\text{m}$  thick thiolene/acrylate SMP on a parylene-coated DNTT OTFT on a 1.4  $\mu\text{m}$  thick PEN substrate is shown in Fig. 8.127a. The system is initially formed into a 2.5 mm radius helix by post-cure annealing above  $T_g$ . It is then passed through a slot in a thermal barrier at  $T > T_g = 70^\circ\text{C}$ . This causes it to reform into its original helical shape where it wraps

itself around a cylinder of similar dimension (Reeder et al., 2014). The transistor characteristics are shown in Fig. 8.127b when the OTFT is in its original configuration, in its flattened state, and when the helix is recovered by heating. There is a small shift of  $V_T$  to more negative voltages with deformation, but no apparent change in  $\mu_{FEp}$  as inferred from the similar slopes of the curves.

Conformation of the SMP OTFT circuit *in vivo* in Fig. 8.128 shows its biocompatibility and its possible utility for monitoring biological functions in real time. The device is implanted into the living tissue of a rat (Fig. 8.128a) where it is shaped due to a rise in temperature in its subcutaneous location. After 24 h (Fig. 8.128b) the device has conformed to the tissue shape. Once removed, it retains its initial, heat-induced conformation (Fig. 8.128c).

These several demonstrations, while still at early stages, point to the promise of utilizing imperceptibly thin electronic circuits for medical purposes. It is indeed remarkable that organic devices can meet many of the most rigorous demands of sterilization and biocompatibility that are pillars of modern medical practice. These versatile attributes,

therefore, may lead to the opening up of the exceedingly broad applications space of biological and medical sensing that cannot readily be accessed using conventional, inorganic semiconductor-based electronics.

**Figure 8.127** (a) Images of a SMP OTFT undergoing thermal relaxation (clockwise from top left) into a 2.5 mm radius helix when inserted through a thermal barrier. The far side of the barrier is at room temperature (RT). (b) Transistor transfer characteristics when the DNNT OTFT is in its original, flattened and deployed helical shapes (Reeder et al., 2014).

## 8.10 Summing up

In this chapter we described the remarkable advances made in OTFTs over the more than three decades since their first demonstrations. The operating voltages have dropped by an order of magnitude, and the mobilities have increased from  $<0.01 \text{ cm}^2/\text{V s}$  until today, when they are routinely  $>1 \text{ cm}^2/\text{V s}$ . The OTFTs operate in the accumulation mode, which is distinct from conventional CMOS that operates in the depletion or inversion regimes. Materials for both n- and p-channel operation enable complementary logic with nearly identical characteristics for transistors based on these different carrier types. And we have seen that the channel as well as the gate dielectric layers can be deposited with monolayer control. Finally, many of the most important materials have shown good stability when operated in low humidity environments.

Similarly significant advances in device architecture have complemented advances in materials. Large area circuits with hundreds of devices for RFIDs, oscillators, and array backplanes employ OTFTs that are lithographically defined on substrates ranging from glass to ultrathin plastic. Split gate, dual gate OTFTs, and high performance vertical transistors have been used in a variety of circuit applications. Photosensitive transistors, or phototransistors, offer responsivities that are significantly higher than HJ photodiodes due to inherent transistor gain. Unfortunately, higher responsivities lead to a concomitant reduction in bandwidth.

As in all photonic and electronic devices, reliability during long term operation is essential. Considerable work, therefore, has been devoted to understanding how the operating characteristics change during extended use. Most of the work on device reliability has focused on drifts in  $V_T$ ,  $I_D$ , and  $\mu_{FE}$  that are accelerated under bias-stress conditions. The most pervasive

**Figure 8.128** *In vivo* conformation of an SMP OTFT to the tissue of a rat. (a) As initially implanted, (b) after 24 h, and (c) after removal from the organism (Reeder et al., 2014).

contaminant leading to changes is moisture. The dipolar water molecule can invade the dielectric, attach itself to the dielectric/semiconductor interface, or bind to structural defects within the semiconductor itself. Water contamination, and contamination by other impurities effectively screens the electric field induced by the gate voltage, and hence shifts the  $V_T$  required to achieve a given charge concentration in the channel. As in the case of OPVs and OLEDs, encapsulation of the transistor circuits can provide an effective barrier to contamination, ultimately delaying degradation.

While there have been significant and impressive advances in OTFTs, there is as yet no large-scale application that has adopted this new transistor platform. Should such an application arise, it will exploit the unique features of OTFTs that are common to all organic electronic devices: flexibility, conformability, ultralight weight, and potentially low cost when deployed over large areas. We have shown that OTFTs provide unique capabilities in tactile sensing, identification of analytes through gas sensing, and as photodetector FPA pixel addressing circuits. Importantly, the ability to fabricate very high performance circuits on ultrathin substrates has enabled a new genus of biocompatible, “imperceptible” electronic appliances. Early demonstrations of their application to monitoring organ activity suggest that OTFT circuits may find unique opportunities in medical monitoring, imaging, entertainment, and robotics. It remains to be seen which of these applications will first emerge. But there is little doubt that the unique form factors and relatively high performance of OTFTs will enable numerous applications currently not adequately served by conventional inorganic semiconductor-based electronics.

### Problems

1. Write expressions for the high and low frequency capacitance-voltage characteristics for an n-channel metal/insulator/organic semiconductor device. Assume the dielectric constant of the insulator is  $\epsilon_i$  and that of the organic are  $\epsilon_s$ , work functions are  $\phi_M$  and  $\phi_S$ , respectively, a bulk charge concentration of  $N_D$ , and for a surface state density of:
  - (a)  $N_{ss} = 0$ .
  - (b)  $N_{ss}$  large, and negative.
  - (c) Assuming the trapping rate is  $10^{-4}$  s, plot the characteristics for  $\phi_M = 4.5$  eV,  $\phi_S = 4.8$  eV,  $\epsilon_i = 3.5$ ,  $\epsilon_s = 3.2$ ,  $N_D = 10^{15}$  cm $^{-3}$ , and  $N_{SS} = 0$  at a capacitance measurement frequency of 20 kHz. Indicate  $V_{FB}$  on the plot.
  - (d) As in (c) but  $N_{SS} = -5 \times 10^{12}$  cm $^{-2}$ .
2. Consider a p-channel OTFT with dimensions  $L = 50$   $\mu\text{m}$ ,  $W = 5$  mm, and  $t_i = 50$  nm for the gate length, width, and insulator thickness, respectively. For  $\mu_{FE} = 1$  cm $^2$ /V s and a threshold voltage of  $V_T = 2.5$  V using an SiO $_2$  gate insulator and  $V_{GS} = 0$  to  $-40$  V,
  - (a) Plot the drain current vs. drain-source voltage characteristics of this device.
  - (b) What is the background doping concentration of the channel?
  - (c) What is the surface potential at  $V_{GS} = 0$ ?
3. The equivalent circuit of a p-channel OTFT in Problem 2 is shown in Fig. P8.3. Here,  $v'_G$  is the gate voltage in the absence of external resistance,  $R_S$ , and  $i_D$  is the small signal drain current. Based on this equivalent circuit,

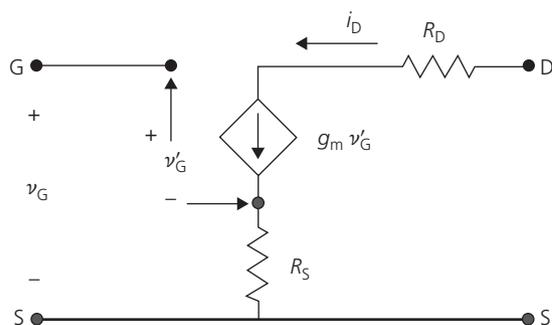

Figure P8.3 Equivalent circuit of an OTFT.

- (a) Show that the measured transconductance and drain (or output) conductance are given by Eqs. 8.23 and 8.24, respectively.
  - (b) For the device in Fig. P8.3, show the drain current characteristics in the presence of  $R_D = 5 \Omega$  and  $R_S = 1 \Omega$ .
4. Equation 8.48 shows the effective field effect mobility,  $\mu_{FEeff}$ , in the presence of contact resistance derived in the linear regime. Derive an expression for  $\mu_{FEeff}$  in the saturation regime.
  5. Derive a general expression for the Johnson noise channel current for an OTFT in saturation. Show that to good approximation, the noise current is given by  $S_{in} = I_{in}^2 = \frac{8}{3} (k_B T) g_m$ .
  6. In an ambipolar OTFT, the voltage  $V(x)$  varies along the channel from source (at  $x = 0$ ) to drain (at  $x = L$ ). Assuming that there is 100% recombination of electrons and holes at the point  $x_0$  along the channel,
    - (a) Derive an expression for the voltage  $V(x)$  vs.  $x/L$  along the channel for a threshold voltage of  $V_{Tn} = V_{Tp} = V_T = 0.1V_{GS}$  and  $V_{Ds}/V_{GS} = 0.5, 1, 5$ .
    - (b) Plot the normalized drain current ( $I_D / (\mu_{FEp} W L C_i)$ ) characteristics in the linear, saturation and ambipolar regimes of operation of an ambipolar OTFT for  $\mu_{FEp} = 10\mu_{FEe}$  for  $V_{Ds}/V_{GS} = 0.5, 1, 5, 10$ .
    - (c) Derive an expression for the transconductance in an ambipolar OTFT in each of the three regimes of operation. Plot the normalized transconductance vs.  $V_{GS}$  for each of the voltage conditions in part (b).
  7. Design a complementary inverter logic circuit comprising a p-channel organic phototransistor based on the P3HT transistor shown in Fig. 8.59.
    - (a) Select an n-channel material from Sections 8.6.3 or 8.6.5 to form a reasonable complement to P3HT. Decide on the appropriate  $W/L$  and dielectric, and calculate and plot the resulting drain current characteristics.
    - (b) In combination with the n-channel device, assume that the channel of the p-channel device is illuminated at energies slightly above its energy gap. Determine the logical output function for the light ON and OFF states at the input of the illuminated organic phototransistor.
    - (c) Calculate and plot the transfer characteristics of the circuit as a function of the supply voltage,  $V_{DD}$ , the input bias voltage,  $V_{IN}$ , and the optical intensity illuminating the OPT.
  8. In Chapter 6 we showed that OLEDs need to be driven at  $10 \text{ mA/cm}^2$  to achieve very high brightness often required in displays and lighting. The question is whether or not OTFTs can serve as backplane pixel address transistors in displays. We will simplify this consideration by assuming only a single OTFT is required to address each pixel, although in fact it takes more than one transistor per pixel in practical applications to fully control the OLED brightness over the period of its useful life in a display.
    - (a) Assuming that the pixel dimensions are  $(50 \mu\text{m})^2$  and that the OLED occupies as much area as the OTFT (e.g. it is layered onto the transistor surface), what is the current that can be delivered to an OLED in a common source configuration with  $\mu_{FEp} = 1 \text{ cm}^2/\text{V s}$  assuming a power supply voltage of  $V_{DD} = -10 \text{ V}$  and  $V_{GS} = -5 \text{ V}$ ? The  $\text{SiO}_2$  gate dielectric has thickness,  $t_i = 100 \text{ nm}$  and  $L = 10 \mu\text{m}$ .
    - (b) Plot the drain current density vs. gate capacitance per area for the supply voltage in (a). What is the highest practical drain current density that can be achieved using OTFTs? Is it adequate for driving the OLEDs? Is there another thin film technology that would be more practical?
  9. Figure 8.109b shows a polymer OTFT with hysteresis in its drain current characteristics. Assume that these characteristics are obtained at a voltage sweep rate of  $500 \text{ mV/s}$ . The dielectric thickness is  $300 \text{ nm}$  and the S and D contact thicknesses are also  $300 \text{ nm}$ .
    - (a) Calculate the total trapped charge observed in these characteristics.
    - (b) If the positive voltage sweep results in larger  $I_D$  than for the negative voltage sweep, what is the sign of the trapped charge?
    - (c) What is the approximate electric field near the S and D contacts at  $V_G = -40 \text{ V}$ ? What does this imply about the position of the trap level in the organic energy gap (i.e. are they hole or electron traps)?
  10. A detector with a quantum efficiency at low optical input powers ( $P_{in} \approx 0$ ) of  $\eta_{EQE0}$ , and dark current density of  $I_{dark}$ , is connected to the input of the OTFT in Fig. 8.98, option B.
    - (a) What is the total rms noise current vs. input voltage of a common source single stage amplifier for this circuit?
    - (b) For an output conductance of the input OTFT of  $g_D$  and a diode series resistance of  $R_{ser}$ , what is the maximum linear input optical power range, assuming that the maximum linear power corresponds to a reduction in response to  $\Delta\eta_{EQE}(P_{in})/\eta_{EQE0}$  of  $-1 \text{ dB}$ ?
    - (c) What is the dynamic range of this circuit, assuming that the minimum detectable signal requires  $\text{SNR} = 2$ ?
    - (d) Assuming the device values in Table P8.10, what is the DR? How many bits of grey scale of an incident light beam can be obtained from this circuit?

**Table P8.10** Circuit parameter values

Parameter	Value
$I_{dark}$	1 nA
$g_D$	1 $\mu\text{S}$
$R_{ser}$	100 $\Omega$
$\Delta\eta_{EQE}$	1 dB

11. (a) Calculate the expected gate leakage for the transistor in Fig. 8.98, option B assuming Frenkel-Poole emission is its dominant source for an  $3.6 \text{ nm}$  thick  $\text{AlO}_x$  gate insulator coated by a  $2.1 \text{ nm}$  thick SAM (cf. Fig. 8.96).
- (b) How closely does this agree with the data shown from the complementary inverter pair, assuming both the drive and load transistors have the same  $W$  and  $L$ ?

12. Figure 8.53b shows the transfer characteristics of n- and p-channel OTFTs used in a complementary inverter. The transistor dimensions are  $W/L = 25$ ,  $L = 40 \mu\text{m}$ ,  $t_i = 5.7 \text{ nm}$  SAM/ $\text{AlO}_x$  gate insulator, and a unit-area capacitance of  $700 \text{ nF/cm}^2$ .
- Calculate  $f_T$  for both transistors at  $V_{GS} = \pm 0.5 \text{ V}$ .
  - Calculate  $f_T$  for both transistors at  $V_{GS} = \pm 1 \text{ V}$ .
  - How does the calculated  $f_T$  compare with that obtained from the gate delay of 20 ms for a 5 stage ring oscillator? Explain the sources of the difference.
13. Using ambipolar compound **50** in Table 8.6:
- Specify the  $W/L$ ,  $L$ , and  $t_i$  of a complementary transistor inverter comprising a drive and load with  $A_v = 25$ . The gate dielectric is  $\text{Al}_2\text{O}_3$ .
  - Calculate the drain current and transfer characteristics of both the n- and p-channel transistors.
  - Calculate  $g_m$  and  $g_D$  of the transistors in (a) in both the linear and saturation regimes.
  - As in (a), design the physical characteristics of the inverter with a 3 dB roll-off frequency of 5 MHz.
  - Describe the fabrication sequence to make the transistor pair in (a).
14. For a complementary inverter using transistor pair in Fig. 8.53, graphically determine the noise margin by plotting  $V_{out}$  vs.  $V_{in}$  for the load and drive transistors.
15. We have shown in Section 8.9.3 tactile arrays based on transducers whose resistance is varied by the application of pressure. An alternative transducer that can be very sensitive to pressure changes is one based on capacitance.
- Using the transistor whose characteristics are given in Fig. 8.23, design a capacitive pressure transducer pixel based on a PDMS dielectric. The Young's modulus is 2 MPa and the compressive modulus is 130 MPa. Make sure that you specify the pixel footprint (i.e. area) and the a.c. circuit used at each pixel.
  - What is the minimum deflection your pixel can detect at a measurement frequency of 1 MHz and an rms measurement signal amplitude of 10 meV?
  - What is the pressure that corresponds to the deflection in (b)?

## Expect the unexpected: more possibilities for organic electronics

---

*"If you don't know where you are going, you might wind up someplace else."*

**Yogi Berra, Catcher for the New York Yankees from 1946 to 1963.**

The possibilities for organic semiconductors seem limitless. With each year, researchers discover new phenomena, and engineers invent new devices. In Chapter 1 we enumerated many common myths surrounding organic materials and devices. Many of those myths suggested that there were limitations that were later found not to be so at all. Indeed, it seems that every property of inorganic semiconductors has its analog in organics, even though their materials properties are fundamentally different. Yet it is not the similarities between these systems that make organics interesting. Their value lies in the new opportunities for discovery and innovation that they offer. The purpose of this final chapter is to open a window to the many surprises organics have yet to reveal. And perhaps this chapter will give you new ideas and paths to explore that continue to exploit the "organic difference."

Thus far in Part II, we have focused on three broad classes of devices and their applications: light emitters, photodetectors, and transistors. There are several subclasses of devices within each of these categories. For example, photodetectors include photoconductors, photodiodes, phototransistors, solar cells, and many different specialized optical sensors. The emphasis on these three general device classes is justified by their attracting the preponderance of attention by scientists, engineers and industries driven by their commercial potential. But a fascinating aspect of organics that has given impetus for their continued exploration is the unparalleled versatility in their properties compared to other materials systems. The versatility is enabled by a nearly infinite palette of materials. The entire scope of their application space is only limited by our imaginations.

Here, we introduce a few devices and scientific topics that do not fit neatly into those covered in other chapters. Yet they illustrate the breadth of the field, and some of the devices or their descendants may eventually find applications at scales that will become comparable to those for emitters, detectors and transistors. Given the abundance of research on novel devices, this could be a discussion without end. Hence, only a few examples are introduced. The choices of topics are based on their potential for making a substantial impact on the future of the field, or because they reveal a unique property of organics that has not been adequately considered in previous chapters. Even so, very large and important scientific and application domains have been omitted. Perhaps the most significant omission is that of waveguide-based optical devices. Organics are exceptionally well suited for use as waveguides. These are not included since passive waveguides do not employ an active electronic or excitonic property of the materials. Similarly, waveguide devices employing nonlinear optical effects such as optical switching, optical mixing, etc. rarely rely on an active electronic property such as electrical conduction or optical generation. This topic, therefore, falls outside of the boundaries that define organic electronics, where we apply the working definition of applications that require current for activation, or their characteristics are governed by excitonic effects. We

have also chosen to omit this large class of materials and devices in deference to other excellent texts available that specifically treat this subject. Other topics that have been omitted include a vast and ever growing array of electronic sensors such as distance and motion detectors, bioelectronic sensors, and so on. The list is indeed very long. The interested reader is also encouraged to explore these topics that are well represented in the scientific literature. There simply is insufficient space or time to cover everything in this one volume.

The topics selected for inclusion in this chapter are (i) light emitting electrochemical cells, (ii) microcavity exciton polaritons, (iii) thermoelectricity, (iv) organic memories, (v) organic/two-dimensional (2D) junctions, and (vi) single molecule devices. Each of these devices and/or phenomena has features that are peculiar to organic semiconductors. For example, light emitting electrochemical cells exploit the property of ionic conduction in active electronic devices. Exciton polaritons provide an understanding of organic molecules in resonant optical cavities. This leads to phenomena such as ultrastrong optical coupling, room temperature polariton lasing, and Bose–Einstein condensation. Thermoelectricity and electronic memories represent two broad and very promising application areas where organic materials can offer advantages over inorganics. And finally, limited dimensional systems open entirely new possibilities for organics to be productively combined with ultrahigh mobility 2D inorganic films, or in single molecule devices that may enable next generation (i.e. beyond Moore’s law) electronics used in artificial intelligence, quantum computing and information processing, and molecular sensing.

The topics addressed, therefore, provide a limited but nevertheless important window into what this field may have in store for the future. As the title of this chapter suggests, in the field of organics, it is always a good idea to expect the unexpected.

## 9.1 Light emitting electrochemical cells

The conventional organic light emitting device consists of one or more neutral organic species comprising the emission layer (EML). A different approach to achieving electroluminescence is to combine the chromophore with an ionic medium, or salt. The resulting device is known as a *light emitting electrochemical cell* (LEC). The LEC was initially demonstrated using a 1:1 blend of the polymers, MEH-PPV and PEO, doped with the salt,  $\text{CF}_3\text{SO}_3\text{Li}$  (Pei et al., 1995). This is known as a polymer LEC, or pLEC. Soon after, a small molecular weight LEC (SMLEC) was demonstrated based on the ionic ruthenium polypyridyl complex,  $\text{Ru}(\text{phen})_3^{2+}[\text{2Cl}^-]$  (Lee et al., 1996).

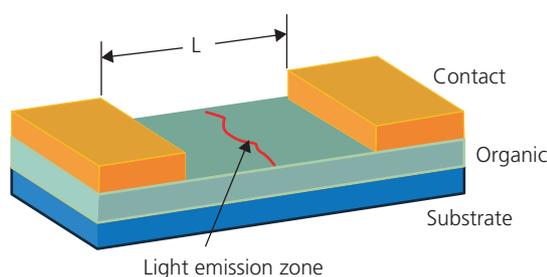

A distinctive feature of the LEC is that it is an ambipolar device: the cathode and anode contacts can be interchanged. Likewise, it consists of only a single layer that is ionically doped via charge injection from the contacts. Another feature is that the energy barriers between the contacts and the active region are reduced by charge injection. This allows for the use of relatively high work function contacts that are resistant to degradation when exposed to the ambient, thus eliminating the need for potentially costly packaging required to protect conventional OLEDs. Another distinguishing attribute is that the devices are oriented within the substrate plane, with anode and cathode positioned laterally as in

a photoconductor. Thus, the devices and their emission zones can be large; on the order of millimeters vs. active regions in OLEDs that are only tens of nanometers thick.

These several advantages are outweighed by several disadvantages that have prevented LECs from becoming a substitute for OLEDs. Chief among the disadvantages is that they take a long time (hundreds of microseconds to tens of minutes) for the light to turn on to full intensity. This eliminates the possibility of their use in conventional information displays, although the faster devices may be suitably fast for lighting. Since the conductivity is based on ionic transport, the device performance (i.e. its conductivity and luminous efficiency) is highly temperature dependent: elevated temperatures result in faster response, higher conductivity and efficiency. Cooling such devices even slightly below room temperature can deactivate almost all of their electronic properties. The light output reaches a peak, and then slowly decreases as the lateral dimension of the light emission zone shrinks with the continued lateral growth of the ionically doped conductive regions where excitons are quenched. Finally, the efficiencies of LECs are well below that of conventional polymer and small molecule OLEDs, even though phosphorescent transition metal complexes have been employed as the active organic material (van Reenen et al., 2013).

A schematic of an LEC is provided in Fig. 9.1. It comprises two metal electrodes of the same composition. One is the anode and the other is the cathode, depending on the polarity of the externally applied voltage. The luminescent polymer mixed with a salt provides ionic conductivity. Typically, the active layer is from 100 nm to 300 nm thick. The simplicity of this structure is one of its attractions; it requires none of the complex layer schemes demanded of high performance OLEDs.

Two explanations have been advanced that describe the properties of LECs: the *electrodynamics* (ED) model, and the *electrochemical doping* (ECD) model. These two mechanisms are illustrated in Fig. 9.2. Apparently both can be active in the same device, depending on the bias voltage and whether the contacts are blocking or non-blocking (Meier et al., 2014).

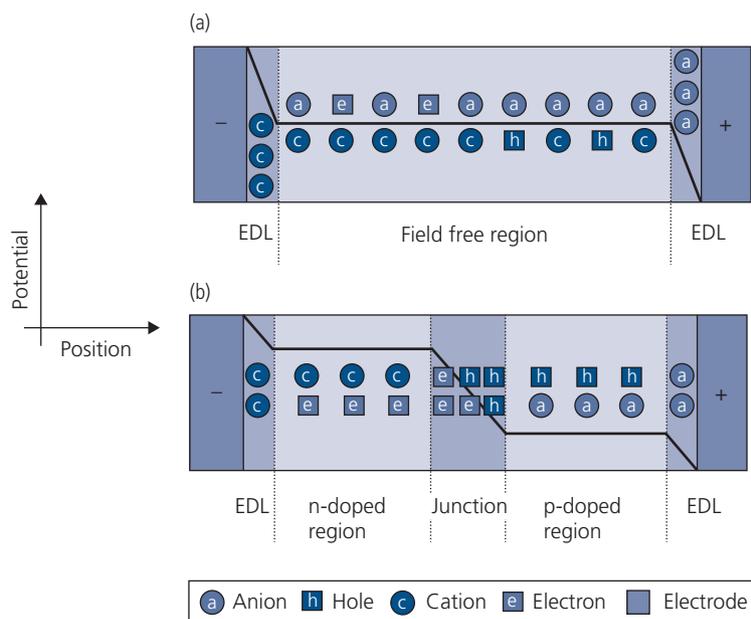

**Figure 9.1** Schematic of a light emitting electrochemical cell of length,  $L$ . Light emission is from an irregular, undoped stripe located between the metal contacts.

In the ED model, nearly all of the potential is dropped across the ionically doped layers (EDLs) at the anode and cathode. These regions contain a high concentration of uncompensated anions (at the anode) and cations (at the cathode) that are attracted to these two regions by the applied voltage. The concentration of ionic species is sufficient to lower the injection barriers, making ohmic contact to the organic layer. Between the contact zones, the ionic species are compensated by injected free charges. This results in an extended charge-neutral region where oppositely charged free polarons combine to form radiative excitons. As soon as a recombination event occurs, additional free charge is drawn in from the contacts to maintain charge neutrality in the central, compensated region of the device.

In the ECD model, electrons are drawn in from the EDL at the cathode to compensate the cations, forming a conductive “n-doped” region. Similarly, oppositely charged ions and polarons injected from the anode generate a “p-doped” region. In either ionically doped region, the potential drop is minimal, resulting in diffusion-limited charge transport. An intrinsic, emissive charge recombination zone forms at the interface between the doped regions. Thus, the EDL model invokes the formation of a p-i-n type diode.

The applied voltage results in a redistribution of the ionic species within the EDL layers that range in thickness from 2 nm to 6 nm. The time to establish the zones, and for the charges to redistribute within

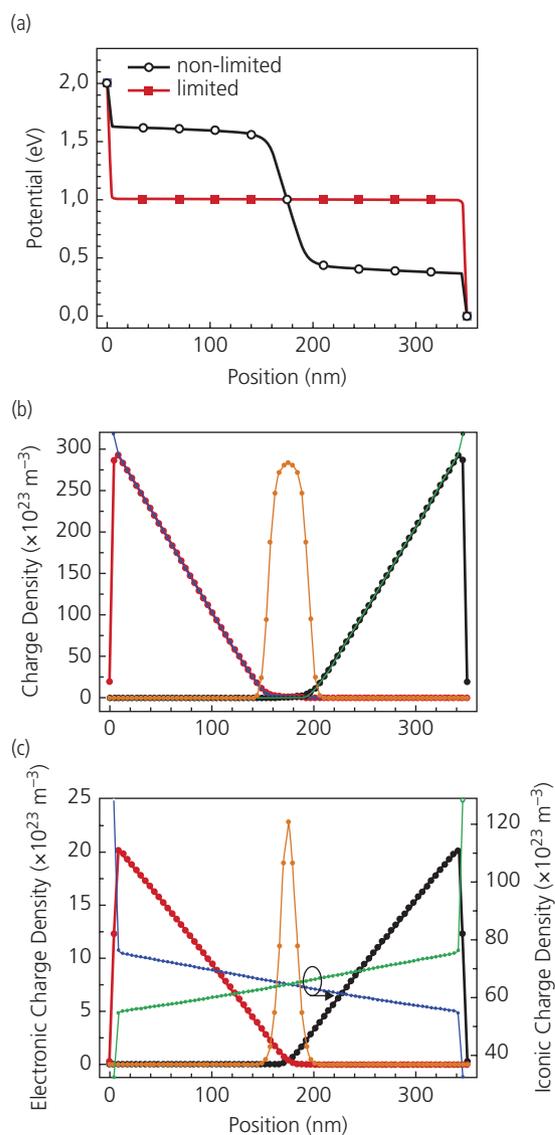

**Figure 9.2** The distribution of free polarons and ions in an LEC according to (a) the electrodynamic (ED) and (b) the electrochemical doping (ECD) models. The black lines show the potential drops across the device active regions (van Reenen et al., 2010).

the bulk of the organic layer, is ultimately a function of the ionic mobility. This results in a slow, temperature-dependent response of both pLEC and SMLEC devices. Once the highly conductive regions are formed, the intervening undoped region consists of uncompensated charges that are able to recombine and emit light. The position of the emission region depends on the ratio of mobilities of the cations and anions. The conductive zone increases in width with the continued injection of free polarons over time. This causes the compensated regions to grow at the expense of the uncompensated region, thus resulting in the shrinkage of the recombination zone, and a concomitant decrease in emission intensity. The rate of advance of the doping fronts is determined by the magnitude of the applied voltage, the ionic mobilities, and the thickness of the organic layer.

The various operating regimes have been modeled to determine the ranges of validity of the ED and EDL pictures, and under which circumstances these models apply (van Reenen et al., 2010, Mills and Lonergan, 2012). The potential distribution for a pLEC comprising an active region, with and without blocking contacts, is shown in Fig. 9.3a. In both cases, there is a large voltage drop across the very narrow EDL near the cathode and anode contacts. For the blocking contact, there is almost no potential drop across the intervening polymer layer. This corresponds to the ED model of Fig. 9.2a where the entire active region has a distribution of cations and anions that are compensated by free polarons of opposite polarity. In contrast, a p-i-n junction forms when Ohmic contacts are used that do not block charge injection. Then, the voltage drop across the heavily doped p and n regions vanishes, and appears only across the junction and at the doped regions near the contacts. This corresponds to the ECD regime of operation in Fig. 9.2b.

The free charge and ion distributions for pLECs with blocking and non-blocking contacts are shown in Fig. 9.3b and c, respectively. For blocking contacts, the ionic and free charge distributions lie directly on top of each other, indicating complete compensation that produces a charge-neutral region across the semiconductor. These distributions change near the contacts where the anion and cation densities are large, but the free charge densities fall toward zero. The recombination zone is relatively large and near the center of the active region between the contacts. It is in this region that the anion and cation densities are small.

The electrochemically doped regime is established by using non-blocking contacts, as shown in Fig. 9.3c. The compensation between ionic and mobile free charge is no longer complete in either the p- or

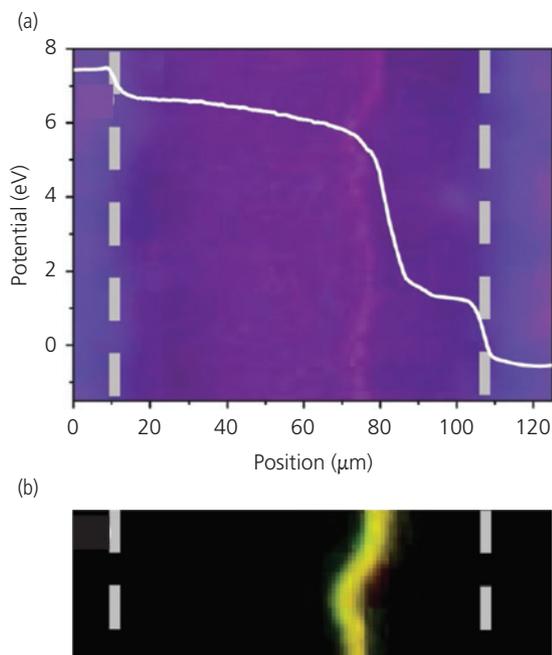

**Figure 9.3** (a) Simulated charge distribution for injection limiting (blocking) vs. non-limiting (i.e. Ohmic) LEC contacts. The charge distribution for (b) limiting and (c) non-limiting contacts. The orange line shows the recombination profile, whereas the red, black, green, and blue lines show the electron, hole, anion, and cation densities, respectively (van Reenen et al., 2010).

Reprinted with permission from van Reenen, S., Matyba, P., Dzwilewski, A., Janssen, R. A., Edman, L. & Kemerink, M., A unifying model for the operation of light-emitting electrochemical cells. *Journal of the American Chemical Society*, 132, 13776-13781. Copyright 2010 American Chemical Society

n-doped regions since the cations and anions are not completely separated, contrary to the case of blocking contacts. This results in a recombination zone that is narrower in the ECD than the ED regime.

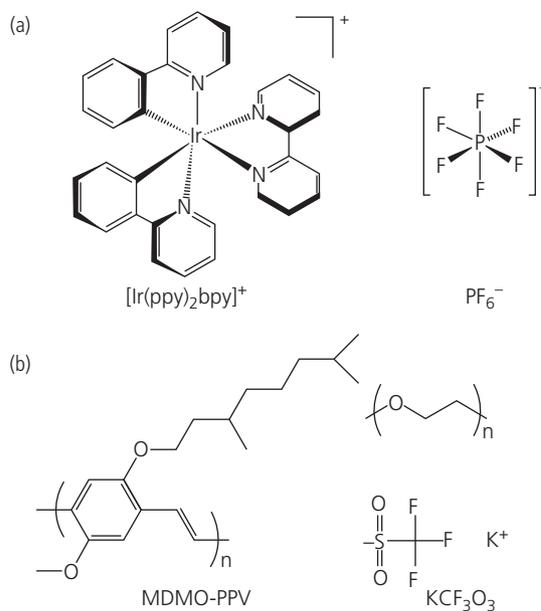

The validity of this analysis has been tested by measuring the potential across the active region of a pLEC with *scanning Kelvin probe microscopy* (SKPM, see

**Figure 9.4** (a) SKPM map of the potential across a pLEC device with non-blocking contacts, at an applied voltage of 8 V. The region between the dashed lines is the polymer, and the contacts are outside of the lines. (b) Electroluminescence image under steady state operation at 8 V (van Reenen et al., 2010).

Section 8.8.1). The device in Fig. 9.4 comprises Au/SY-PPV:PEO:K<sup>+</sup>CF<sub>3</sub>SO<sub>3</sub><sup>-</sup> (1:1.35:0.25)/Au. Here, SY-PPV is a PPV copolymer known as “super yellow,” and potassium triflate, K<sup>+</sup>CF<sub>3</sub>SO<sub>3</sub><sup>-</sup>, is the salt (see Fig. 9.5). The separation between contacts is 100 μm. Since Au forms non-blocking contacts, the SKPM image in Fig. 9.4a corresponds to the ECD regime. Indeed, the potential distribution across the device is consistent with expectations from Fig. 9.2b. There is little or no voltage drop across the doped regions, whereas voltage only drops near the anode and cathode (at the left and right of the SKPM map, respectively) and across the undoped junction region. Likewise, the light emission zone is located in the junction region (Fig. 9.4b), where charges can recombine without quenching. Note the thinness and irregular shape of the recombination zone resulting from local variations in ionic transport within the organic semiconductor. It is not centered between contacts due to differences in the cation and anion mobilities: in this instance the anion mobility is the smaller of the two, resulting in recombination closer to the cathode.

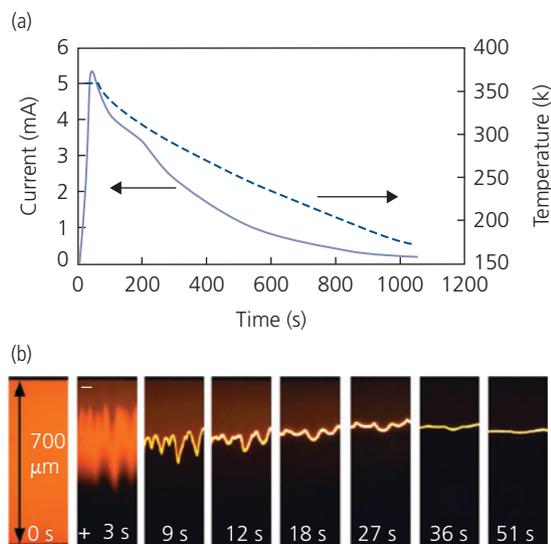

**Figure 9.5** Archetype materials systems used in (a) SMLEC and (b) pLEC devices.

Introducing physically small anion–cation pairs increases their mobilities. Two archetype systems are shown in Fig. 9.5. The small molecule Ir complex in Fig. 9.5a comprises the cation–anion couple [Ir(ppy)<sub>2</sub>bpy]<sup>+</sup>[PF<sub>6</sub>]<sup>-</sup> in a 1:1 blend. The transition metal complex serves both as a phosphorescent emitting molecule as well as a cation. The polymer system comprises an MDMO-PPV fluorophore blended with PEO that improves the ionic mobility. The KCF<sub>3</sub>SO<sub>3</sub> forms a blend with the polymer mixture in the ratio MDMO-PPV:PEO:KCF<sub>3</sub>SO<sub>3</sub> = 1:1.35:0.25.

The transient response at different temperatures of a MEH-PPV:PEO:KCF<sub>3</sub>SO<sub>3</sub> (10:5:0.1.2) pLEC is shown in Fig. 9.6a. The 700 μm long device is imaged using a detector positioned at the opposite end of a scanning, single mode optical pickup fiber whose diameter is sufficiently small to resolve the spatial distribution of the photoluminescence (PL) and electroluminescence (EL) along the length of the channel, as shown in Fig. 9.6b. Heating to 360 K while biased at 20 V activates the electroluminescence. After heating, the device is cooled to 170 K, freezing the emission and doped zones in place. At this temperature, the behavior of these regions can be studied over long periods without change. Note that the current drops by at least one order of magnitude as the sample is cooled due to the decreased electron and hole mobilities, whereas the ionic mobilities nearly vanish.

The PL and EL maps of the active region during the high temperature activation cycle are shown in a series

**Figure 9.6** (a) Dependence of current on time as a MEH-PPV:PEO:KCF<sub>3</sub>SO<sub>3</sub> pLEC is cooled from 360 K to 170 K. (b) The device is “activated” during the first 51 s at 360 K before cooling. The images are of the photoluminescence zone. The line appearing at 9 s is due to electroluminescence from the cell. The cathode is at the top of the images, and the anode at the bottom. After Altal and Gao (2016).

of images in Fig. 9.6b. Initially, there is no electronic doping. Thus, the film is compensated, leading to uniform PL across the sample. Once a voltage is applied, charges are injected from the contacts, and the anions and cations drift toward the oppositely charged contacts. This quenches the luminescence, thereby narrowing the region where PL is observed. After 9 s, fully doped n- and p-regions are established, at which point the PL intensity drops to near zero while a line of intense EL is observed near the cathode. The p-doped region is dark, totally quenching all PL. The offset of the EL emission toward the cathode is due to the higher mobility of cations than anions. As time progresses, the jaggedness of the EL emission line decreases, and its intensity decreases due to narrowing of the i-region as discussed above (Altal and Gao, 2016). The response in Fig. 9.6 shows that changes in the luminescence profile take at least 1 min to stabilize, even at 360 K. Simply cooling the samples to only a few degrees below room temperature can result in response times of hours (van Reenen et al., 2013). Qualitatively similar time-dependent behavior is observed for both pLECs and SMLECs, although the quantitative sensitivities to time and temperature may vary widely due to the different dynamics of the ionic and polaronic species in these different materials systems.

Many advantages to LECs have already been mentioned, the most notable being their reduced sensitivity to environmental exposure. However, their

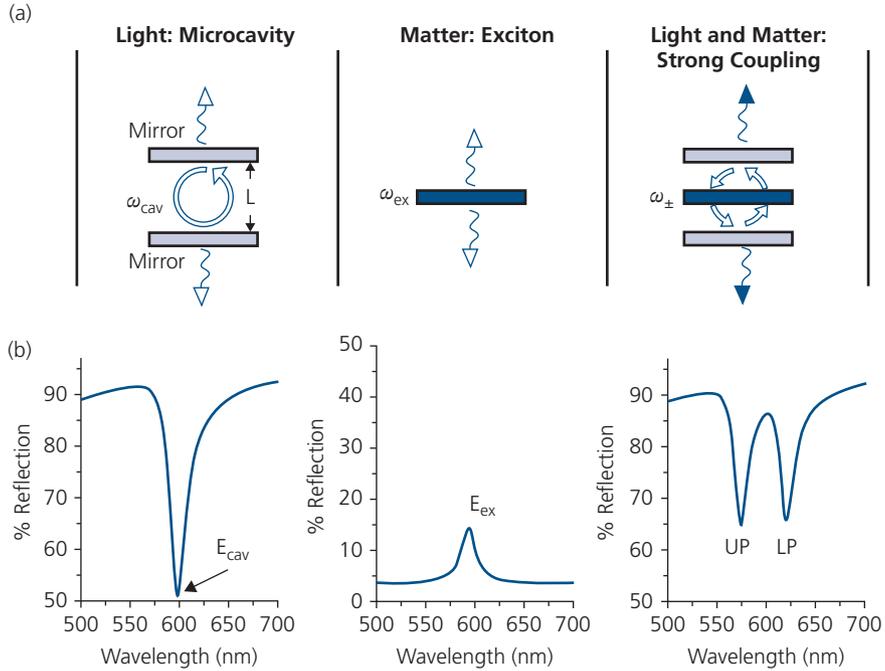

performance is substantially inferior to even modestly performing OLEDs. One of the highest performance LECs uses the oligoether, TMPE-OH as an electron transporter containing the salt, LiCF<sub>3</sub>SO<sub>3</sub>, along with the light emitting SY-PPV. The device turn-on times are ~10–2000 s to reach a luminance of 300 cd/m<sup>2</sup>, depending on details of the composition of the electron transporter. The maximum luminance efficiency is 14 cd/A with an operational lifetime of approximately 350 h (Mindemark et al., 2016).

Electrophosphorescent SMLECs employing the Ir-based cyan emitting molecule-anion pair [Ir(dfppz)<sub>2</sub>(dtb-bpy)]<sup>+</sup>[PF<sub>6</sub>]<sup>-</sup> blended with the near infrared (NIR) emitting cationic charge trapping DOTCI, achieved an external quantum efficiency of 12.8%. A maximum brightness of 16.6 cd/m<sup>2</sup> is obtained after 62 min following application of 3.3 V, although after 45 min the luminescence intensity decayed to half that value. This slow response is also obtained in a device with a vertical (vs. lateral) architecture of ITO/PEDOT:PSS/emissive layer (200 nm)/Ag. While the results are inferior to those of conventional small molecule PHOLEDs using the analogous, neutral Ir complex, the relatively high efficiency reported for the LEC is primarily a result of improved carrier mobility, and hence charge balance from the addition of DOTCI. Note that while the fluorescent emission of DOTCI is in the NIR, it is only doped at 0.01 wt% in the Ir salt complex. This prevents energy transfer, and thus there is no NIR emission from DOTCI at 700 nm (Liao et al., 2011).

## 9.2 Microcavity organic exciton polaritons

A *polariton* is a quantum mechanical quasiparticle that is the superposition of a photon that is *strongly coupled* to a material state (e.g. an exciton) in a resonant optical cavity. The polariton is unique in that it contains attributes of both states of which it is comprised. Thus, like a photon, it is a boson governed by Bose–Einstein statistics. The most immediate outcome of this property is that a population of polaritons can occupy a single state, forming a *Bose–Einstein condensate* (BEC) that exhibits coherent, laser-like emission, superfluidity, vortices, and strong nonlinear optical effects such as all-optical switching. On the other hand, its matter-like properties give the polariton mass, although it is far lighter than the excitons of which it is comprised. Thus, an exciton-polariton can diffuse farther and faster than the bare excitonic state.

Figure 9.7 is an illustration of the polaritonic state. A microcavity with distance,  $L$ , between a pair of mirrors has a resonance at frequency,  $\omega_{cav}$ , given by

**Figure 9.7** Conceptual illustration of the physics of microcavity exciton polaritons (upper panels). A photon cavity mode, combined with an exciton mode, forms a new quasiparticle known as an exciton-polariton in the strong coupling regime. Resonances in the reflectivity for each situation are shown in the lower panels. Here,  $E_{cav} = \hbar\omega_{cav}$  is the energy and frequency of the cavity mode,  $E_{ex} = \hbar\omega_{ex}$  is for the exciton mode, and UP and LP refer to the upper and lower polariton branches, respectively. After Tischler et al. (2007).

the well-known Fabry-Pérot expression  $k_z = N\pi/L_{eff}$ . Here,  $N$  is the integer mode number,  $L_{eff}$  is the effective cavity length which is the sum of the separations between the mirrors and the penetration of the optical field into the mirrors, and  $k_z$  is the out-of-plane wavevector. An example reflection spectrum of the bare cavity is shown in the left-hand lower panel in Fig. 9.7. This cavity has a stop band at 600 nm.

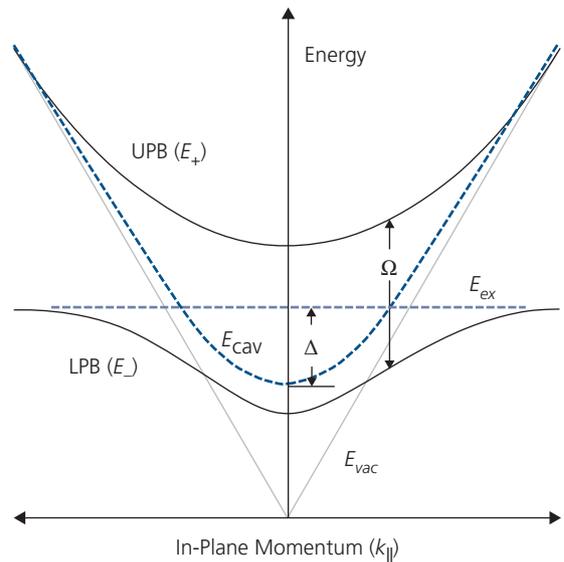

Since the in-plane wavevector,  $k_{||}$ , is unconstrained by energy barriers at the mirrors, the cavity photon dispersion is given by

$$\begin{aligned} E_{cav} &= \hbar\omega_{cav} = \hbar(c/n)\sqrt{k_z^2 + k_{||}^2} \\ &= \hbar(c/n)\sqrt{(N\pi/L)^2 + k_{||}^2}. \end{aligned} \quad (9.1)$$

Here,  $\hbar$  is Planck's constant divided by  $2\pi$ ,  $c$  is the speed of light, and  $n$  is the refractive index within the cavity. The blue dashed line in Fig. 9.8 shows the cavity mode dispersion spectrum. The photon outside of the cavity follows a linear dispersion,  $E_{vac} = \hbar ck$ , shown by the diagonal lines in the figure. Within the cavity at small  $k_{||}$ , the curvature of the cavity mode implies an effective mass for the photon equal to:

$$m_{cav} = \frac{\pi\hbar Nn}{Lc}. \quad (9.2)$$

Typically,  $m_{cav} \approx 10^{-5}m_0$ , where  $m_0$  is the electron rest mass.

**Figure 9.8** Dispersion relation of a polariton showing the upper and lower polariton branches (UPB at  $E_+$  and LPB at  $E_-$ , respectively). Also the various energies are defined including the Rabi splitting energy,  $\Omega$ , and the cavity detuning,  $\Delta < 0$ .

The exciton is a property of the material filling the cavity, with a binding energy of  $E_{ex}$ . The frequency of the exciton is largely unchanged when the material is placed inside the cavity except at large  $k_{||}$ . The reflectivity of an excitonic material is shown in Fig. 9.7,

center lower panel, and its lack of dispersion is shown by the flat dashed line in Fig 9.8.

For the condition where  $\omega_{ex}$  is resonant with  $\omega_{cav}$  a new state is formed that is a superposition of two coupled oscillators (the photon and the exciton, see Fig. 9.7, right panel). The new state, sharing characteristics of both the cavity photon and the exciton, is the polariton. As with all coupled oscillator pairs, the polariton has two normal modes, or resonances that are separated into the more exciton-like *lower polariton branch* (LPB) and the photon-like *upper polariton branch* (UPB). The splitting energy at the anti-crossing between the LPB and UPB is known as the *Rabi energy*,  $\Omega$  (see Fig. 9.8). This is linearly proportional to the exciton–photon dipole interaction strength,  $g_0$ . The coupling is divided between the two normal modes, and hence is equal to half of the splitting between branches.

The plot in Fig. 9.8 shows negative detuning,  $\Delta$ , between the cavity mode and the exciton, that is,

$$\Delta = E_{cav}(k_{\parallel} = 0) - E_{ex}(k_{\parallel} = 0) < 0. \quad (9.3)$$

The Rabi splitting is found at the value of  $k_{\parallel}$  where the cavity and exciton energies are equal. The exciton effective mass is also significantly reduced due to its admixture with the photon mode. The mass is obtained starting with (Deng et al., 2010)

$$\alpha = \frac{1}{2} \left( 1 + \frac{\Delta E(k_{\parallel})}{\sqrt{\Delta E(k_{\parallel})^2 + \Omega^2}} \right) \quad (9.4a)$$

and

$$\beta = \frac{1}{2} \left( 1 - \frac{\Delta E(k_{\parallel})}{\sqrt{\Delta E(k_{\parallel})^2 + \Omega^2}} \right), \quad (9.4b)$$

where  $\Delta E(k_{\parallel}) = E_{ex}(k_{\parallel}) - E_{cav}(k_{\parallel})$ . For  $\Delta E=0$  (e.g. at  $k_{\parallel} = 0$  when  $\Delta E(0) = \Delta = 0$ ), then  $\alpha = \beta = \frac{1}{2}$ , and the polariton consists of half photon and half exciton content in both the lower and upper polariton branches. The variables,  $\alpha$  and  $\beta$  are the absolute squares of the so-called *Hopfield coefficients*. The effective mass of the polariton in both the lower and upper branches are related to these coefficients by

$$\frac{1}{m_{LPB}} = \frac{\alpha}{m_{ex}} + \frac{\beta}{m_{cav}} \quad (9.5a)$$

and

$$\frac{1}{m_{UPB}} = \frac{\beta}{m_{ex}} + \frac{\alpha}{m_{cav}}. \quad (9.5b)$$

With  $m_{cav} \approx 10^{-5}m_0$ , and the reduced mass of the exciton in organic compounds of  $m_{ex} \geq m_0$ , we see

that the polariton effective mass is nearly equal to the cavity photon mass in both branches. This results in a longer exciton lifetime due to a reduced interaction between electron and hole owing to the larger exciton radius (see Eq. 3.142), and a much larger exciton diffusivity. This suggests that exciton polaritons based on organic thin films can have vastly different properties than a free exciton, at least near  $k_{\parallel} = 0$ . At higher in-plane momenta, however, the LPB flattens and takes on principally excitonic character, in which case  $\beta \rightarrow 0$ ,  $\alpha \rightarrow 1$ , and  $m_{LPB} \rightarrow m_{ex}$ . Similarly, the upper branch becomes purely photon-like.

The energies of two coupled harmonic oscillators are found from solutions to the eigenvalue equation:

$$\begin{aligned} H\Psi_{p,k} &= \begin{pmatrix} E_{cav} - i\gamma_{cav}(k_{\parallel}) & \Omega/2 \\ \Omega/2 & E_{ex} - i\gamma_{ex}(k_{\parallel}) \end{pmatrix} \Psi_{p,k} \\ &= E_{LPB,UPB} \Psi_{p,k}, \end{aligned} \quad (9.6)$$

which yields the following solutions for the upper and lower branches:

$$\begin{aligned} E_{LPB,UPB}(k_{\parallel}) &= \frac{1}{2} \left\{ E_{ex} + E_{cav} + i(\gamma_{cav} + \gamma_{ex}) \right. \\ &\quad \left. \pm \left[ \Omega^2 + (E_{ex} + E_{cav} + i(\gamma_{cav} - \gamma_{ex}))^2 \right]^{1/2} \right\}. \end{aligned} \quad (9.7)$$

Equation 9.7 is the general solution to the dispersion relationship comprising the two branches in Fig. 9.8. This solution only applies to a coupled binary oscillator system. However, excitonic states in organics show strong vibronic character, often exhibiting 0–0, 0–1, 0–2, etc. modes that, if contained within the stop band of a microcavity, can also couple to the polariton state, generating additional branches in the dispersion relationship. Then, depending on the number of coupled modes, the  $2 \times 2$  matrix of Eq. 9.6 needs to be expanded accordingly (Kéna-Cohen and Forrest, 2008).

### 9.2.1 Cavity designs

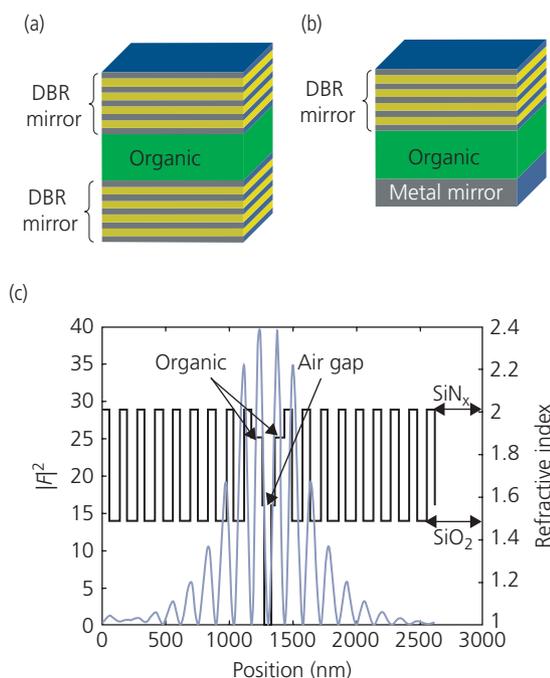

In Eq. 9.7,  $\gamma_{cav}$  and  $\gamma_{ex}$  are damping terms that add to the homogeneously broadened cavity and exciton linewidths, respectively. Cavities with mirrors whose reflectivities are less than unity leak photons, thus decreasing the photon lifetime. Escaping photons couple to the external vacuum field where they can be observed, and thus provide information about the polariton population. The *quality factor* of a cavity comprising two *distributed Bragg reflectors* (DBRs) with reflectivities of  $R_1$  and  $R_2$  is

$$Q = \frac{E_{cav}}{\gamma_{cav}} \approx \frac{\pi(R_1 R_2)^{1/4}}{1 - (R_1 R_2)^{1/2}}. \quad (9.8)$$

A cavity with a high  $Q$  has highly reflective mirrors ( $R_1, R_2 \rightarrow 1$ ), allowing for hundreds to thousands of photon cycles within the cavity before escape. The high  $Q$  results in a narrow linewidth, and hence a concomitantly longer photon lifetime of  $\tau_{cav} \approx \hbar/\gamma_{cav}$ .

Two types of cavities that are most commonly used in organic polaritonic devices are shown in Fig. 9.9. Two DBRs can form a symmetric cavity that sandwiches the organic at the central antinode of the electric field (Fig. 9.9a). Alternatively, one DBR is replaced with a metal mirror in an asymmetric arrangement (Fig. 9.9b). This structure generally has a much lower  $Q \sim 50$ – $100$ , while the double DBR cavity can have  $Q \sim 500$ – $5000$ . If both mirrors are replaced by metals, with one being ultrathin and hence semi-transparent, the  $Q$  is reduced to  $\sim 10$ . Such cavities are known to result in ultrastrong coupling where  $\Omega$  is an appreciable fraction of the exciton energy. This is considered further in Section 9.2.5.

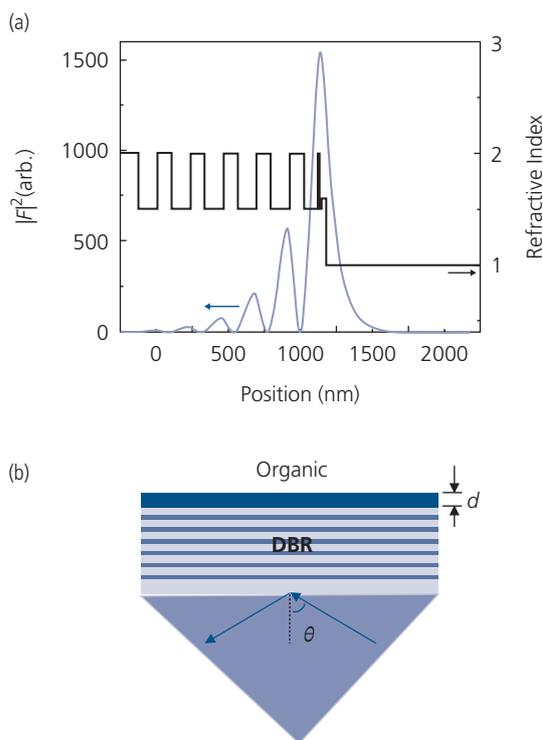

Finally, it is notable that one of the mirrors can be eliminated completely in a one-sided, or “open”

**Figure 9.9** Two example cavities for observing polaritons. (a) A high  $Q$  cavity with two DBR mirrors, and (b) a lower  $Q$  cavity with one metal and one DBR mirror. (c) Optical field intensity ( $|F|^2$ ) and index profiles in an archetype double DBR structure. The organic layer is split into two sections with an air gap in between. The optical field has antinodes in the organic and within the gap.

dielectric structure shown in Fig. 9.10a. The optical mode is trapped in the relatively high index DBR and the organic film on its surface, penetrating into air with an evanescent traveling wave, known as a Bloch surface wave (BSW) (Lerario et al., 2017). The BSW is excited by resonant coupling to the optical pump using a prism attached to the glass substrate (known as the *Kretschmann configuration*). This all-dielectric cavity can have a very high  $Q$ -factor due to the use of a lossless, low index dielectric (air) on one surface.

A compilation of cavity types, their  $Q$ -factors, cavity volumes, polariton velocities, and propagation lengths is found in Table 9.1. The table points to the important characteristics of polaritons compared with bare organic materials. Excitations in high  $Q$  cavities result in a dramatic reduction in exciton effective mass that consequently leads to extraordinarily long diffusion lengths ( $\sim 100 \mu\text{m}$ ). We have seen in previous chapters that a long diffusion length can be utilized to great advantage in many photonic devices including OLEDs, OPDs, and OPVs.

**Figure 9.10** (a) Calculated optical field intensity distribution in a one-sided optical structure whose index profile is shown to the right. The DBR consists of six pairs of alternating layers of 135 nm thick SiO<sub>2</sub> and 101 nm thick SiN<sub>x</sub> on glass. It is capped by an organic film of thickness,  $d$ . (b) Experimental configuration for exciting Bloch surface waves as shown in (a).

The optical field intensity profile for a symmetric DBR cavity is shown in Fig. 9.9c, superimposed on the index of refraction profile of the SiO<sub>2</sub>/SiN<sub>x</sub> mirror stacks. The organic film itself is divided into two sections, each attached to a different mirror surface, with a gap between them. This arrangement results in field antinodes within the organics as well as in the gap, maximizing interactions between the field and the excitonic material layers. Note that very little field leakage beyond the DBR results in a long  $\tau_{cav}$ , and hence a high  $Q$ .

The radiative width of the exciton line is a materials property that depends on the exciton oscillator strength,  $f_{ex}$  (see Section 3.6.1). Thus,

$$\gamma_{ex} = \frac{\pi}{n} \frac{q^2}{4\pi\epsilon_0 m_{ex}c} f_{ex}, \quad (9.9)$$

where  $\epsilon_0$  is the permittivity of free space and  $q$  is the electron charge. The interaction between photon and exciton is determined by the magnitude of  $f_{ex}$ . The linewidth increases linearly with the oscillator strength, which is much larger for organic Frenkel

excitons compared with dielectrically screened, and therefore weakly bound Wannier–Mott (W-M) states in inorganic semiconductors.

Taking line broadening into consideration, the Rabi splitting energy is given by (Zhu et al., 1990)

$$\Omega = \sqrt{[aL\mathcal{F}\gamma_{ex}\gamma_{cav}/\pi] - [(\gamma_{ex} - \gamma_{cav})^2/4]}. \quad (9.10)$$

Here,  $\mathcal{F}$  is the cavity finesse and  $a$  is the absorption coefficient of the organic, which like  $\gamma_{ex}$ , is proportional to the oscillator strength. Thus the Rabi splitting increases with  $\gamma_{ex}$  and  $\gamma_{cav}$ , and thus  $f_{ex}$  and  $Q$ , up to the point where the linewidth becomes so large that the second term in Eq. 9.10 is dominated by cavity losses. Thus, the strong coupling regime corresponds to the condition where  $\Omega$  is greater than the combined widths of the cavity and exciton modes.

A comparison of semiconductors commonly used for studying polaritons is provided in Table 9.2. The benefit of using organics is primarily due to their large exciton binding energy. Thus, organic polaritons

**Table 9.1** Comparison of cavity types and the resulting organic polariton characteristics

Cavity type	Q	Vol. <sup>a</sup> ( $\mu\text{m}^3$ )	$\Omega$ (meV)	$\tau_{cav}$ (ps)	Velocity ( $\mu\text{m}/\text{ps}$ )	Prop. length ( $\mu\text{m}$ )	Ref. <sup>b</sup>

are stable at room temperature. Combined with their large oscillator strengths, unique polariton phenomena such as Bose–Einstein condensation and polariton lasing can be observed in ambient laboratory conditions. These physical properties are also reflected in the large Rabi splitting energies of organics compared to either high or low dielectric constant inorganic semiconductors. Thus, organic semiconductors offer a realistic route to the exploitation of polariton phenomena in devices that are operated at, or even well above room temperature.

### 9.2.2 Optically pumped organic polaritons

Optical pumping of the microcavity is generally done at high  $k_{\parallel}$ , as shown in Fig. 9.11. This creates an exciton reservoir that continually replenishes polaritons that are lost due to photon leakage from the cavity. At high pump intensities, a BEC may form at  $k_{\parallel} = 0$ . The density at the LPB minimum however, is reduced by the exciton bottleneck at the inflection in the dispersion of the LPB. The large phonon energies characteristic of intramolecular vibrations partially avoids the formation of the bottleneck. This is in contrast to inorganic semiconductors where the phonon energies are at least an order of magnitude smaller, inhibiting transfer to  $k_{\parallel} = 0$  of the LPB. Thus, strong exciton–exciton and exciton–phonon scattering in organics reduces the in-plane momentum, allowing the condensate to form.

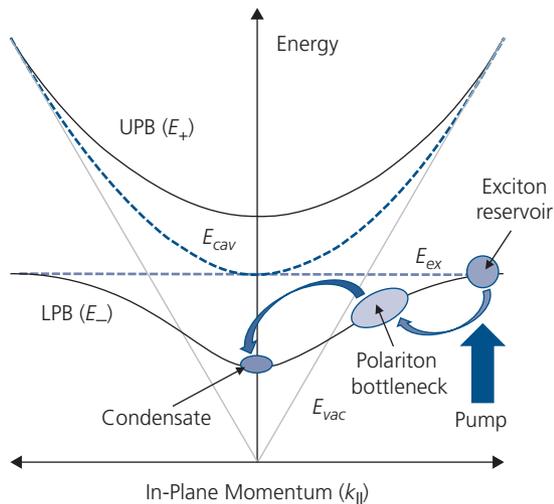

The exciton–exciton scattering rate in a microcavity is (Tassone and Yamamoto, 1999)

$$\Gamma_{ex-ex} = \frac{\pi^2}{2} (n_{ex} m_{ex} a_0^4) \frac{E_B^2}{\hbar^3}, \quad (9.11)$$

where  $a_0$  is the excitonic Bohr radius,  $E_B$  is the exciton binding energy, and  $n_{ex}$  is the exciton density per unit area in the microcavity. We have shown that  $a_0$  for Frenkel excitons is  $\sim 10\%$  of the radius for W-M states in inorganics (Eq. 3.142), but  $E_B$  and  $m_{ex}$  are 10–100 times that for inorganics. Also,  $n_{ex}$  can be 100 times larger for organics due to the large density of states (DOS). Taking this into consideration,  $\Gamma_{ex-ex} \sim 10^2\text{--}10^4$  times higher for organics than for inorganic semiconductors, thereby reducing the bottleneck to condensation by an approximately equivalent amount.

The foregoing analysis suggests that narrow, homogeneously broadened exciton linewidths are necessary to observe strong coupling, which would perhaps rule out the possibility of such an observation in organics whose vibronically broadened states result in a linewidth greater than  $\Omega$ . However, the first report of strong coupling in an organic employed the porphyrin, 4TBPPZn (Lidzey et al., 1998). Porphyrins are characterized by their narrow Q-band absorption in the visible and high luminescence efficiency. The room temperature Rabi splitting showed  $\Omega = 160$  meV due to the  $\sim 10^3$  times higher  $f_{ex}$  for the organic compared with inorganic InGaAs quantum wells, where strong coupling is observed only at very low temperatures. Another approach to achieving comparatively narrow linewidths is to use ordered organic layers known as *J-aggregates*. Comprised of cyanine dyes, these ultrathin films feature sharp absorption bands suitable for strong coupling. The molecules are precipitated from solution onto a substrate to form an ordered morphology. When sandwiched between a dielectric DBR and a Ag mirror, Rabi splittings as large as 180 meV are observed (Lidzey et al., 1999).

Not long after these demonstrations, strong coupling was also observed in vacuum-deposited thin films with structural order extending possibly to only nanocrystalline dimensions. The demonstration employed a 60 nm thick layer of NTCDA sandwiched between DBR and metal mirrors. It was striking that both the 0–0 and 0–1 vibronic modes were hybridized within the cavity stop band, resulting in two exciton–phonon coupled states that effectively transferred energy between the LPB, the middle polariton branch (MPB), and the UPB. The Rabi splittings observed were exceptionally large:  $\Omega_{0-0} = 280$  meV for the 0–0 exciton–polariton, and  $\Omega_{0-1} = 120$  meV for the 0–1 state (Holmes and Forrest, 2004). Even though the absorption lines of amorphous NTCDA films are broad, polaritons can be observed when the vibronic relaxation time is longer than the Rabi lifetime,  $\Omega/\hbar$ .

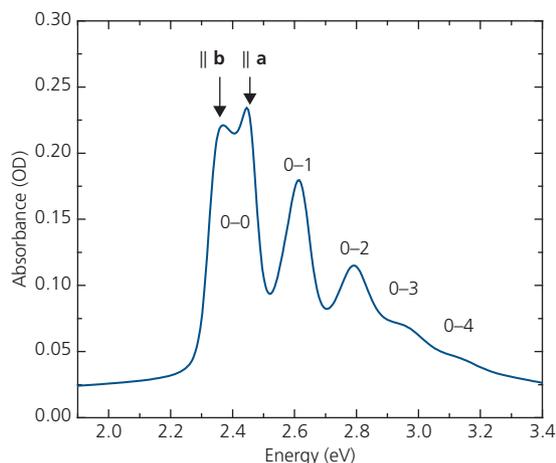

**Figure 9.11** Optical pumping of an organic in a microcavity results in the generation of a high  $k_{\parallel}$  exciton reservoir that relaxes toward the minimum of the LPB where a condensate is formed. The inflection in the dispersion relation creates a bottleneck where polaritons are slowly scattered to both higher and lower  $k_{\parallel}$ . This dispersion relation corresponds to a detuning of  $\Delta = 0$ .

This is equivalent to the condition that the Rabi splitting should be on the order of, or greater than the homogeneously broadened exciton linewidth (Skolnick et al., 1998, Holmes and Forrest, 2004).

An example of hybridization of the multiple vibronics of polycrystalline tetracene illustrates how strong coupling is quantified and analyzed, and illustrates the robustness of organic exciton-polariton states. Figure 9.12 shows the absorption spectrum of a vacuum deposited tetracene film. It features an extended progression of vibrational modes from 0–0 to 0–4, with the higher modes becoming less distinct due to a combination of decreasing intensity and line broadening. Interestingly, the Davydov components of the 0–0 mode (p-band) along the **a** and **b** crystalline axes are resolved using light that is selectively polarized along these axes. Recall from Section 3.6.4 that Davydov splitting results from Coulomb interactions between the two tetracene molecules within each unit cell. Although the domains with diameters ranging from 1–10  $\mu\text{m}$  are axially symmetric in the substrate plane, the observation of Davydov modes is due to ordered stacking in the out-of-plane direction typical of many planar aromatic hydrocarbons.

To observe strong coupling, tetracene films were deposited onto an Al back surface mirror, and then capped by a semitransparent, 35 nm thick Ag top mirror through which the cavity is illuminated. The use of two metal mirrors results in  $Q \sim 26$ . Reflectivity spectra taken in  $5^\circ$  increments are provided in Fig. 9.13a. The spectra show a series of minima corresponding to the LPBs of both Davydov components. Two branches that are hybrids between the

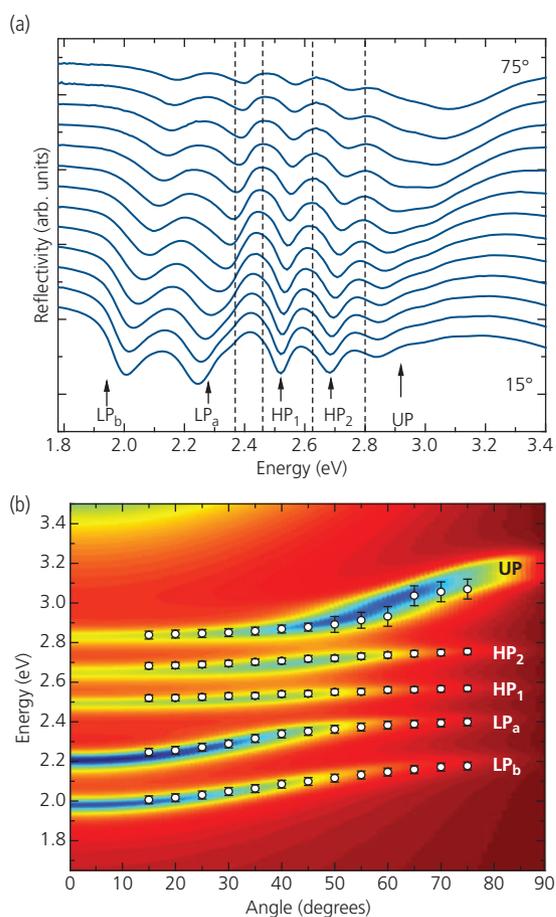

**Figure 9.12** Absorption spectrum of a 140 nm thick, vacuum deposited polycrystalline tetracene film showing its vibronic progression. The 0–0 peak is split into its Davydov components parallel to the **a** and **b** crystalline axes.

LPBs and the higher order vibronics are also visible. The UPB, with its photon-like behavior, is clearly resolved at approximately 2.8–3.0 eV.

Simulations of the dispersion data require that the crystalline anisotropy be taken into account. This is done using the dielectric tensor of tetracene, viz.

$$\epsilon_{ij}(\omega) = \begin{pmatrix} \epsilon_a(\omega)\cos^2\varphi & \cos\varphi\sin\varphi(\epsilon_a(\omega) & 0 \\ +\epsilon_b(\omega)\sin^2\varphi & -\epsilon_b(\omega)) & \\ \cos\varphi\sin\varphi(\epsilon_a(\omega) & \epsilon_a(\omega)\sin^2\varphi & 0 \\ -\epsilon_b(\omega)) & +\epsilon_b(\omega)\cos^2\varphi & \\ 0 & 0 & \epsilon_c \end{pmatrix}. \quad (9.12)$$

**Figure 9.13** (a) Angle-dependent reflectivity spectra of a microcavity containing a 160 nm thick tetracene film. The spectra are taken in  $5^\circ$  increments. The dotted lines indicate the energies of the bare resonances observed in the absence of a cavity. Positions of the two lower polariton branches (LPBs) from the Davydov splitting of the 0–0 exciton, hybrid branches (HP) and upper branch (UP) are indicated. Here,  $\varphi$  is the angle of the principal crystalline axis relative to the laboratory frame  $x$ -axis,  $\omega$  is the light frequency, and  $\varepsilon_a$ ,  $\varepsilon_b$ , and  $\varepsilon_c$  are the relative dielectric constants along  $\mathbf{a}$ ,  $\mathbf{b}$ , and  $\mathbf{c}$  directions of the triclinic tetracene unit cell. Also, the in-plane momentum is obtained from a projection of the angle of the incident light to the sample,  $\theta$ . Equation 9.1 gives the cavity photon energy, from which we obtain the dispersion relation:

$$E(k) = E_0 \sqrt{1 + \hbar^2 c^2 k_{\parallel}^2 / n_{\text{eff}}^2 E_0^2}, \quad (9.13)$$

where  $E_0 = \hbar c / n_{\text{eff}} L$  is the energy at  $k_{\parallel} = 0$ , and  $n_{\text{eff}}$  is the effective index of refraction of the uncoupled, non-absorbing cavity taking into account field penetration into the mirrors. Now (Skolnick et al., 1998),

$$k_{\parallel} = \frac{E(k)}{\hbar c} \sin \theta. \quad (9.14)$$

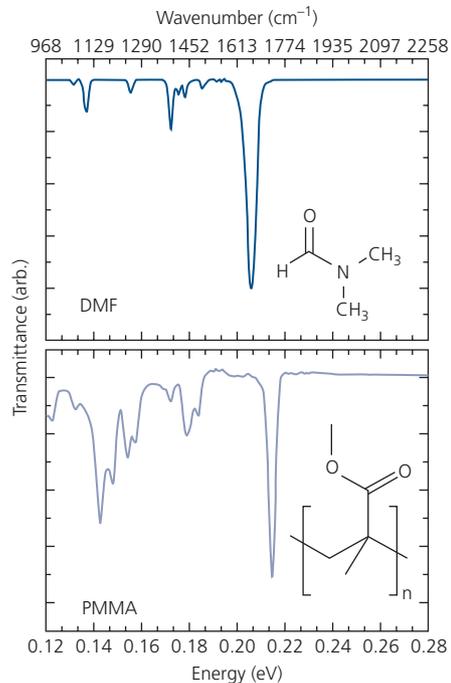

Substituting Eq. 9.14 into Eq. 9.13 gives the dependence of energy on the light incident angle:

$$E(\theta) = E_0 \left( 1 - \frac{\sin^2 \theta}{n_{\text{eff}}^2} \right)^{-1/2}. \quad (9.15)$$

Solutions to the  $5 \times 5$  eigenvalue equation (cf. Eq. 9.6) are solved for a five-level (see Fig. 9.12) coupled oscillator. The results are provided in the color map in Fig. 9.13b for the two LPBs, the hybrid branches coupled to the 0–1 and 0–2 vibronics, and the UPB. The data (points) are accurately fit by this theory, yielding the Rabi splittings between each pair of bands of nearly 400 meV in some cases. The branches and anticrossing features of polariton modes in the reflection spectra are also found in the PL spectrum of many materials.

Energy exchange between polariton branches is due to hybridization of cavity and exciton modes. Or, as we have seen, it can also result in hybridization of multiple vibronics from the same molecules. Likewise, if more than one excitonic species (e.g. two organics) with near resonant excited states are blended into a cavity, energy exchange between these materials also becomes possible. This leads to many new possibilities for devices, and for exploiting emergent energy transport phenomena.

An example of the utility of strong coupling can be found in the use of hybridized vibrational modes of different molecules to catalyze reactions between them. Strong coupling between carbonyl, C=O stretching modes of PMMA and DMF in Fig. 9.14 is possible due to their very narrow transmission spectral linewidths and near resonance at  $1729 \text{ cm}^{-1}$  and

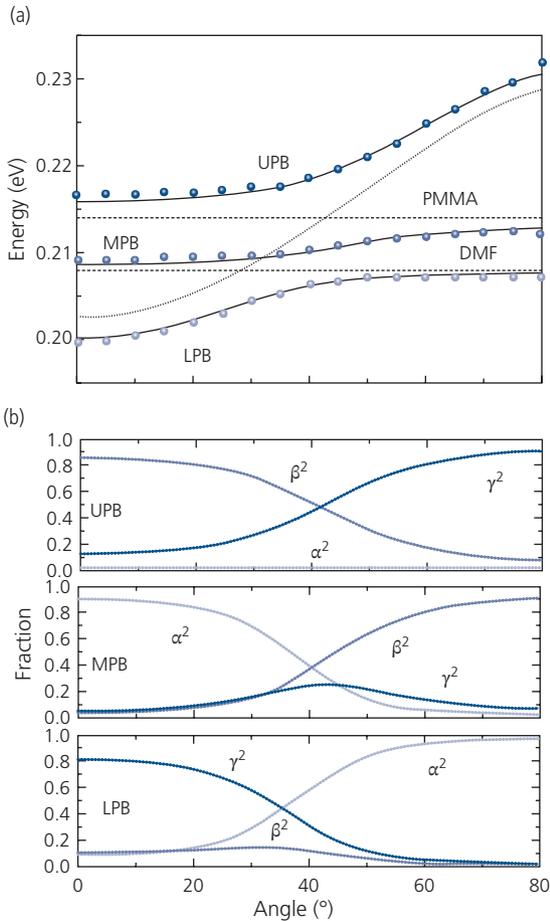

**Figure 9.14** Infrared transmission spectra of DMF and PMMA. Molecular formulae of the molecules are shown in the insets (Muallem et al., 2016).

$1662 \text{ cm}^{-1}$ . The IR states exhibit strong coupling by sandwiching a blend of PMMA and DMF between two DBRs consisting of Ge ( $n = 4.01$ ) and ZnS ( $n = 2.24$ ), with a cavity resonance at  $E_{\text{cav}} = 0.21 \text{ eV}$  that couples to both states. The DBR materials are chosen for their transparency in the near IR, and the ease of film growth by vacuum thermal evaporation. The appropriate thickness of each layer in the DBR is  $\lambda/4n$ . The transmission spectra of the blend result in three polariton branches corresponding to hybridization of the photon and the two IR modes of PMMA and DMF.

The measured dispersion relationships are shown in Fig. 9.15a. The simulated dispersion curves are shown by solid lines. These curves are obtained by solutions to the  $3 \times 3$  secular matrix of Eq. 9.6 assuming  $\gamma = 0$ . The polariton state mixing coefficients,  $\alpha$ ,  $\beta$ , and  $\gamma$ , are the new eigenvectors of the strongly coupled system, and give the relative contributions from the DMF, and PMMA vibronic states, and the cavity mode, respectively, in each of the three branches. Thus  $\alpha$ ,  $\beta$ , and  $\gamma$ , are found from solutions to

$$\begin{bmatrix} E_{\text{cav}} & V_{\text{DMF}} & V_{\text{PMMA}} \\ V_{\text{DMF}} & E_{\text{DMF}} & 0 \\ V_{\text{PMMA}} & 0 & E_{\text{PMMA}} \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \\ \gamma \end{bmatrix} = E \begin{bmatrix} \alpha \\ \beta \\ \gamma \end{bmatrix}. \quad (9.16)$$

**Figure 9.15** (a) Measured (points) and calculated (solid lines) infrared dispersion curves of a PMMA:DMF microcavity showing the upper, middle, and lower (UPB, MPB, and LPB, respectively) polariton branches, giving evidence for strong coupling of carbonyl modes in the two materials. Dashed lines correspond to the empty cavity mode, and the PMMA and DMF vibrational states. (b) Solutions to the energy eigenvalue equation give the Hopfield coefficients that show the relative contributions from the DMF, PMMA, and photon modes ( $\alpha^2$ ,  $\beta^2$ ,  $\gamma^2$ , respectively) in the various branches (Muallem et al., 2016).

Here, the two interaction potentials are ( $V_{DMF}$ ,  $V_{PMMA}$ ), and the uncoupled exciton energies are ( $E_F$ ,  $E_{W-M}$ ). The potentials are related to the Rabi frequencies by  $V = \Omega/2$ . The calculated mixing coefficients for each branch are shown in Fig. 9.15b.

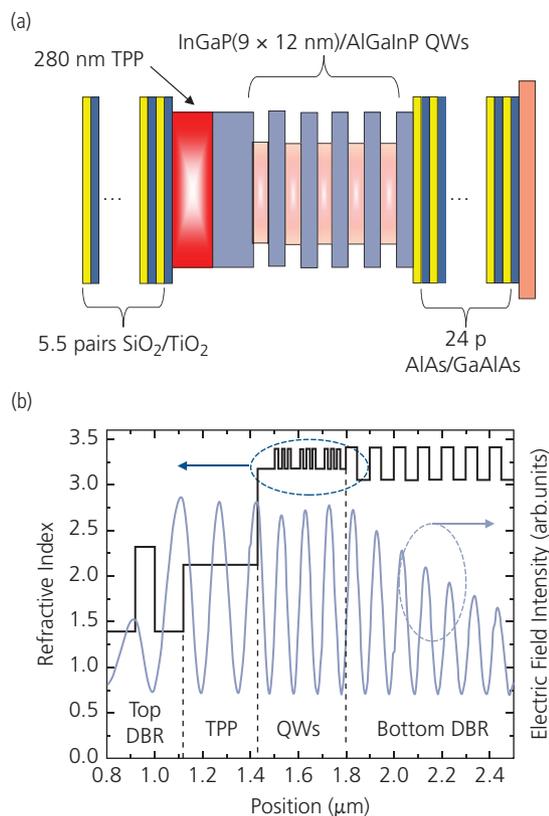

The UPB is principally photon-like ( $\gamma$ ) at high angles, whereas the PMMA contribution ( $\beta$ ) is strongest at low angles. There is almost no contribution from DMF ( $\alpha$ ) in the upper branch. The situation is reversed for the LPB, where near  $k_{\parallel} = 0$ , the contribution from DMF is small compared to that of the photon mode. At high angles, the relative contributions are reversed, and the branch becomes almost completely excitonic. The MPB is most interesting, since it consists of

contributions from both molecular states, with only a minor contribution from both cavity mode. However, at approximately  $40^\circ$ ,  $\alpha^2 = \beta^2$  indicating complete mixing and energy transfer between PMMA and DMF. The PMMA content is highest at large  $k_{\parallel}$ , and the DMF contribution is dominant as  $k_{\parallel} \rightarrow 0$ . The cavity mode contribution is substantial in the transition region where there is complete mixing between the DMF, PMMA and photon modes (Muallem et al., 2016). One anticipates that chemical interactions can be enhanced from this mixing within the MPB. Indeed, the control of the kinetic coupling between spiropyran and merocyanine derivatives by coupling to cavity modes has been reported, opening the path to using quantum electrodynamic effects to tune the rate of chemical reactions between species whose vibronic states lie within the cavity resonance (Hutchison et al., 2012).

### 9.2.3 Hybrid organic/inorganic semiconductor polaritons

Energy transfer from excitonic to conventional semiconductors is achieved by hybridization of Frenkel and W-M excitons in the same resonant cavity. The first observation of this hybridization was achieved by combining W-M excitons in red emitting InGaP multiple quantum wells (QWs) that are resonant with the Soret band of TPP, using the structure in Fig. 9.16a. The bottom mirror is a DBR composed of 24 pairs of undoped  $\text{Al}_{0.46}\text{Ga}_{0.54}\text{As}$  ( $n = 3.45$ ) and AlAs ( $n = 3.04$ ), grown by gas source molecular beam epitaxy on a GaAs substrate. The nine, 12 nm thick  $\text{In}_{0.52}\text{Ga}_{0.48}\text{P}$  QWs between 12.5 nm thick  $\text{Al}_{0.4}\text{Ga}_{0.6}\text{In}_{0.5}\text{P}$  barriers are similarly grown to form the inorganic active region. A 320 nm thick TPP layer is deposited onto the 75 nm thick AlGaInP spacer by VTE to produce a nanocrystalline film. Finally, the TPP is capped with a 5.5 pair DBR consisting of sputter-deposited  $\text{TiO}_2$  ( $n = 2.30$ ) and  $\text{SiO}_2$  ( $n = 1.46$ ).

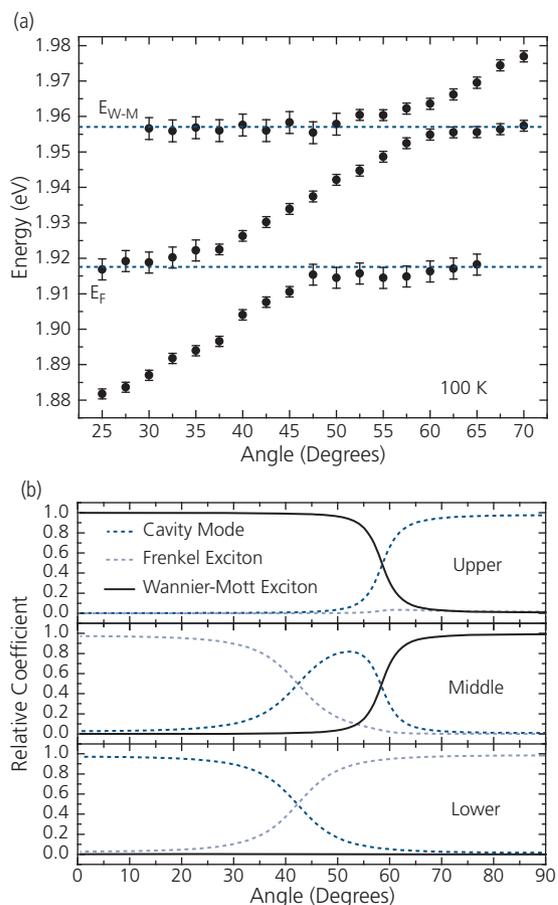

The index of refraction profile and the resulting electric field within the cavity is shown in Fig. 9.16b. Several field antinodes coincide with the strategically placed, three QW groups spaced by AlGaInP. Also, the TPP is sufficiently thick to contain several field maxima, ensuring strong coupling to both the inorganic and organic regions of the cavity. Strong coupling is observed at both 100 K and 4 K (Holmes et al., 2006). The reduced temperature is necessary to ensure the stability of the lower binding energy, W-M state. The dispersion relationships shown in Fig. 9.17a taken from the reflectivity spectra at  $T = 100$  K show hybridization of the W-M and Frenkel excitons in the

**Figure 9.16** (a) Hybrid organic/inorganic polariton cavity comprising a 24-period AlAs/GaAlAs DBR, 9-period InGaP/AlGalnP quantum wells/AlGalnP spacer/TPP/5.5-period SiO<sub>2</sub>/TiO<sub>2</sub> DBR. (b) Index of refraction and electric field profiles across the cavity.

MPB, with mixing coefficients in Fig. 9.17b confirming the extent of the hybridization. Due to the energetic separation of the uncoupled excitonic states, there is only approximately 20% Frenkel and W-M character at 55°. Pronounced and rapid energy transfer between these two very different excitonic states is promoted by strong microcavity coupling analogous to the formation of a hybrid charge transfer exciton (HCTE) at an organic/inorganic heterojunction (cf. Section 4.7.3).

Room temperature W-M/Frenkel hybridization has been achieved between ZnO and NTCDA. ZnO has a strongly bound (and hence thermally stable) W-M state with  $E_B = 60$  meV. The cavity structure is shown in Fig. 9.18, inset, with the dispersion relation obtained from its reflectivity spectra shown in the figure. An interesting feature of this cavity is that the NTCDA 0–1 vibronic is in near perfect resonance with the ZnO exciton. Fits to the data using an approach similar to Eq. 9.16 yield a Rabi splitting energy of  $\Omega_2 = 320$  meV between the middle and upper branches.

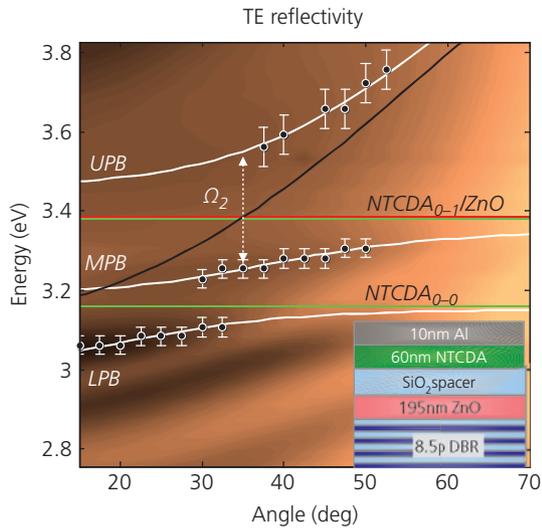

**Figure 9.17** (a) Measured (points) and calculated (lines) dispersion relations showing strong coupling between the Frenkel (F) and Wannier-Mott (W-M) states of the structure in Fig. 9.16. Also shown are the respective uncoupled exciton energies,  $E_F$  and  $E_{W-M}$ . (b) Mixing coefficients for the various modes in the three polariton branches. After Holmes et al. (2006).

The lower branch splitting is roughly half that value. The resonance between the ZnO and NTCDA 0–1 state leads to strong mixing, with  $\alpha^2 = \beta^2 = 0.4$  at an angle of 30°, suggesting strong energy transfer even at room temperature (Slootsky et al., 2014).

## 9.2.4 Polariton lasers and Bose–Einstein condensation

A particularly attractive feature of polaritons is their ability to form a BEC in the LPB. Emission from the condensate is coherent, and unlike a laser, there is no requirement for population inversion. Hence, while it shares many of the characteristics of conventional lasers, emission from the equilibrium condensate does not require a threshold pump intensity as long

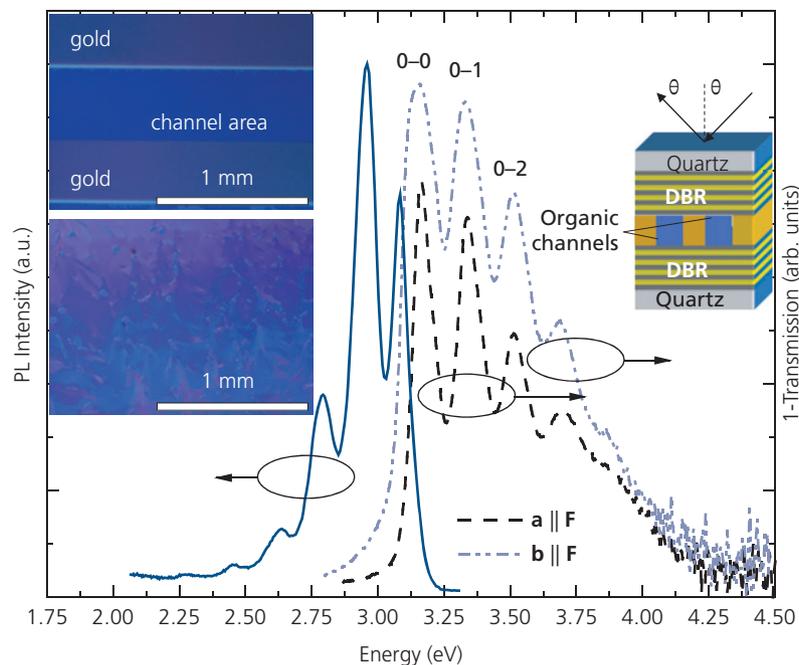

as the LPB population can be supplied from the exciton reservoir at a rate that is greater than or equal to the polariton decay rate itself. Formation of a

**Figure 9.18** TE reflectivity spectra (points) and fits to the dispersion relations of a ZnO/NTCDA W-M/Frenkel hybridized polariton cavity (white lines). The uncoupled exciton states are shown by the horizontal dashed lines. The NTCDA 0–1 vibronic is resonant with the ZnO W-M state. The cavity mode is shown by the curved black line. Inset: Structure used in the measurements (Slootsky et al., 2014).

condensate at the polariton ground state energy is inhibited by a strong polariton bottleneck, shown in Fig. 9.11. However, we have already noted that the bottleneck is considerably reduced in organics compared with inorganics due to their high phonon energies and strong exciton–exciton scattering.

Room temperature polariton lasing in anthracene (Kéna-Cohen and Forrest, 2010) contrasts with lasing in inorganics at low temperature needed to stabilize the W-M exciton (Deng et al., 2003). Anthracene single crystals have narrow linewidths that are suitable for both strong coupling and polariton lasing. (Kéna-Cohen et al., 2008) The cavity structure is shown in the inset of Fig. 9.19. Two DBRs are deposited onto separate quartz substrates. Gold strips are then deposited on the DBRs whose combined thickness is equal to the cavity length,  $L$ . The substrates are brought into contact, and the Au strips cold-weld bond by applying pressure (Section 5.6.4) to form the empty cavity. An open end of the cavity is immersed into a molten solution of anthracene that is drawn into the gaps between Au strips by capillary action (Section 5.4.1). Nucleation at the strip edges results in the growth of continuous, single crystals, as shown in the upper micrograph in the left inset of Fig. 9.19. In contrast, a film of anthracene grown on the substrate without the

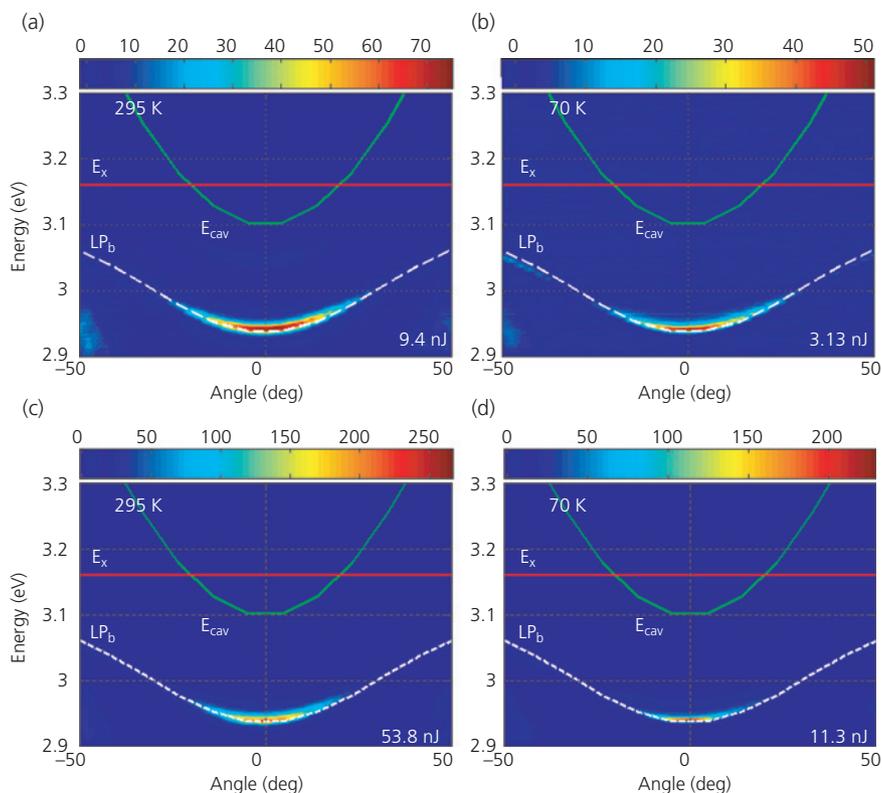

**Figure 9.19** Right: Inverse transmission ( $1-T$ ) spectrum of a 120 nm thick anthracene single crystal channel for electric field polarizations along the **a** and **b** crystal axes. Left: Photoluminescence spectrum of the anthracene single crystal. The vibronic spectra mirror the absorption spectrum, with the highest emission energy peak narrowed by self-absorption. Right inset: Schematic of the microcavity. Left insets: Phase contrast micrographs of the channel area within the cavity (top) and a thicker area far away from the gold channels where multiple domains are observed (bottom) (Kéna-Cohen et al., 2008).

constrained dimensions of the cavity forms a rough, polycrystalline film, as shown in the lower micrograph. The spectra of the crystalline films shows Davydov splitting between light polarized along the **a** and **b** crystal axes, similar to that found for tetracene in Fig. 9.12. The narrow linewidths are suitable for demonstrating strong coupling. Thus, the growth of single crystals within a precisely fabricated high- $Q$  ( $\approx 600$ ) cavity are essential steps to realizing polariton lasing at thresholds well below that assumed for conventional anthracene lasers (Kéna-Cohen and Forrest, 2010).

The dispersion relations for cavity luminescence at room temperature and 77 K are shown for the lower polariton **b** polarized branch ( $LP_b$ ) in Fig. 9.20. A signature of condensation is the abrupt and significant narrowing of the angular dispersion near the ground polariton state as the pump power is increased above threshold. Furthermore, the luminescence stays within the  $LP_b$  branch rather than moving into the cavity mode, as would be expected for conventional lasing.

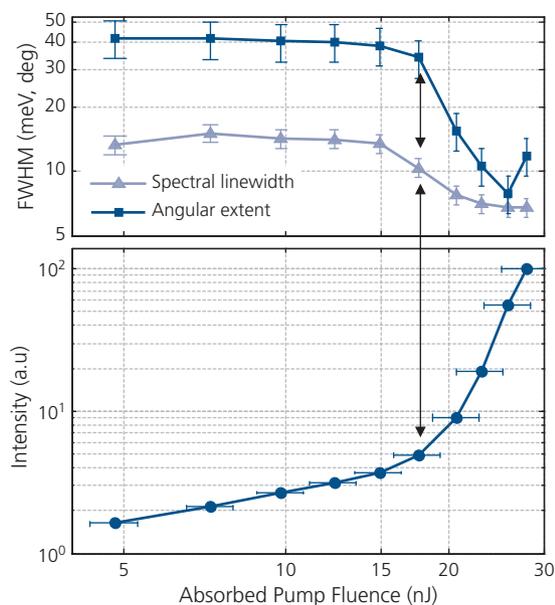

The transition to polariton lasing is accompanied by a rapid increase in the slope of the output intensity vs. pump fluence, as well as a narrowing of the output emission spectrum. The trends in output intensity, spectral linewidth and angular extent of emission with pump fluence from the lower branch at  $\sim 120$  K are plotted in Fig. 9.21. The lasing threshold is at a fluence of 17 nJ, at which point the spectral linewidth decreases by a factor of 2 and the angular extent of the lower branch luminescence decreases from  $40^\circ$  to  $7^\circ$ . The intensity dispersion in Fig. 9.20 approximately follows a Bose-Einstein distribution with a characteristic temperature of 326 K when plotted vs.  $E(k_{\parallel}) - E_0$ , suggesting that the condensate is near equilibrium. Also, the PL lifetime dramatically decreases from 1 ns below threshold, to  $< 30$  ps above threshold (Kéna-Cohen and Forrest, 2010).

Unlike a conventional laser, the polariton laser characteristics are strongly temperature dependent. This is illustrated in Fig. 9.22 where threshold vs. temperature of a polariton laser is compared with a

**Figure 9.20** Angle-resolved polariton photoluminescence showing dispersion in  $LP_b$  below (a) and (b), and above (c) and (d) the lasing threshold at room temperature and 70 K. The dispersion fit to a coupled-oscillator model (dashed line) remains unchanged, indicating strong coupling both below and above threshold. The cavity photon (green line) and the lowest anthracene exciton absorption (red line) are detuned by  $\Delta = -60$  meV. Also, the pump fluences at  $\lambda = 360$  nm are indicated (Slootsky et al., 2012).

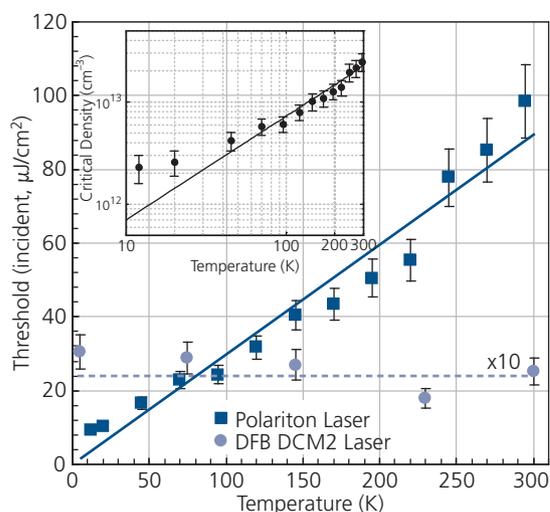

**Figure 9.21** Integrated intensity (circles), spectral linewidth (triangles), and angular extent of polariton emission (squares) at 120 K as functions of absorbed pump fluence. All three parameters exhibit a transition at the lasing threshold at 17 nJ (Slootsky et al., 2012).

conventional, low threshold laser employing an Alq<sub>3</sub> host doped at 2 wt% with the red-emitting fluorophore, DCM2, described in Section 6.8. The conventional laser has a threshold that is approximately ten times lower than the polariton laser. Furthermore, its threshold and other lasing characteristics are temperature independent owing to the “quantum dot” nature of isolated fluorescent molecules in a wide energy gap host matrix that contribute to the laser emission.

There are numerous possible explanations for the higher threshold of polariton lasers, including the much lower PL efficiency of neat anthracene (~0.6) compared to DCM2 doped in a host matrix (~0.9), and temperature-independent losses in the anthracene cavity. Note that the increase in polariton lasing threshold with temperature is opposite to that expected for condensation limited by a bottleneck between the ground state and the exciton reservoir, where lack of thermally-assisted scattering results in an increase in threshold as temperature is decreased.

The critical density for BEC is calculated by assuming a finite two-dimensional system approximately equal to the pump spot of radius,  $R$ , using the Bose-Einstein distribution function:

$$N_c = \frac{1}{\pi R^2} \sum_{k_{||} \geq 2\pi/R} \left\{ \exp\left[\frac{E(k_{||}) - E(0) - \mu}{k_B T}\right] - 1 \right\}^{-1}. \quad (9.17)$$

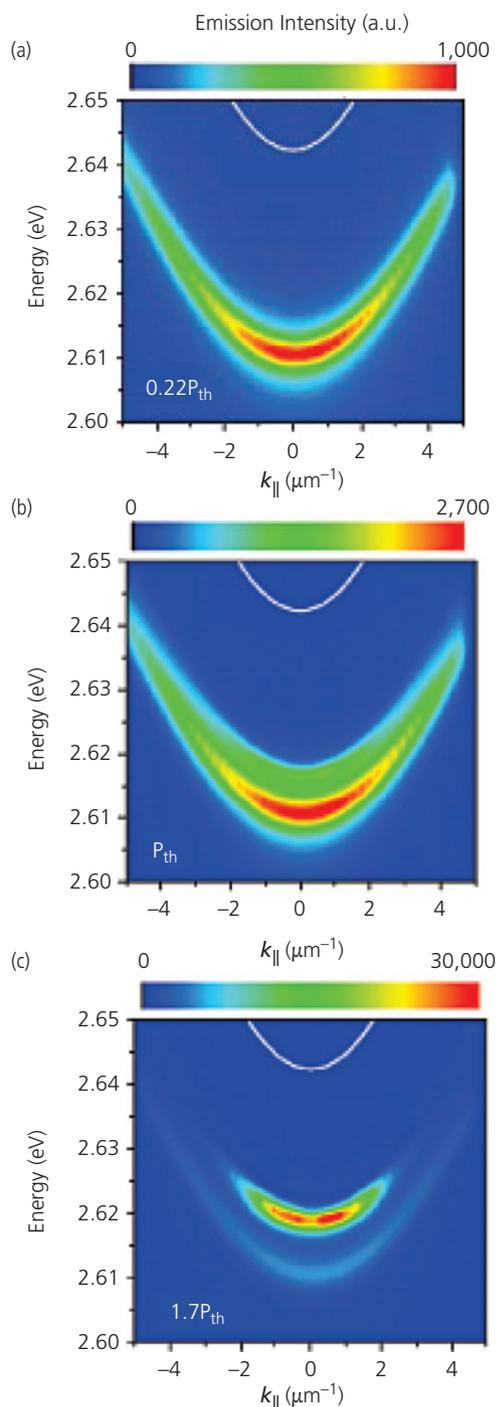

**Figure 9.22** Temperature-dependent threshold for the anthracene polariton laser (squares) and a conventional organic distributed feedback laser (circles). The conventional laser threshold is temperature independent, in marked contrast to the polariton laser. Lines are a guide to the eye. Inset: Calculated polariton population assuming 50% absorption of incident light and a polariton quantum efficiency of  $10^{-6}$  (circles), and the critical density for condensation in the thermodynamic limit (line) as functions of temperature (Slootsky et al., 2012).

The chemical potential,  $\mu$ , approaches 0, allowing for an unlimited number of bosons in excess of the critical density,  $N_c$ , to populate the ground state. Substituting the LP<sub>b</sub> dispersion and evaluating the sum in Eq. 9.17 gives the critical density as a function of temperature, as shown by the line in the inset in Fig. 9.22. The calculated linear regime for anthracene extends above room temperature to nearly 400 K due to strong light-matter interactions compared to that of analogous inorganic systems.

The polariton density is  $N = 0.5 \times \eta \times N_{inc}/V$  for a PL quantum efficiency,  $\eta$ , and an estimated 50% absorption of incident light by the active medium of volume,  $V$ . Also,  $N_{inc}$  is the number of incident photons. Comparing the experimental threshold pump fluence with the critical BEC density in the thermodynamic limit in Eq. 9.17 yields a quantum efficiency of only  $\eta \approx 10^{-6}$ . The discrepancy between  $N_c$  (which assumes an infinite particle lifetime) and the pump power required for lasing arises from the existence of loss pathways for the relaxation of excitons from the reservoir to the bottom of the polariton branch.

The strength of exciton-photon interactions in organics has led to observations of BEC in the disordered polymer, MeLPPP, sandwiched between two Ta<sub>2</sub>O<sub>3</sub>/SiO<sub>2</sub> DBRs. This ladder-type polymer has a relatively narrow emission spectrum with a peak at 2.68 eV (Plumhof et al., 2014). The device

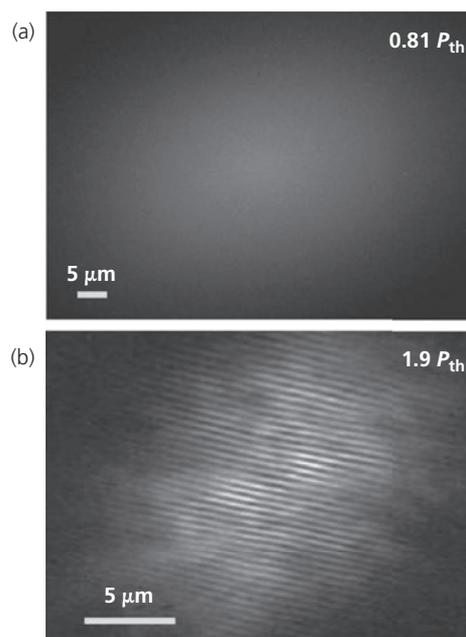

exhibits another interesting feature of polariton lasers: spectral blue shifts with pump fluence shown in Fig. 9.23a–c. There are several notable characteristics of these data. The pronounced decrease in the extent

**Figure 9.23** LPB emission from MeLPPP polaritons at different pump intensities. (a)  $0.22P_{th}$ , (b)  $P_{th}$ , and (c)  $1.7P_{th}$ . Note the mode splitting above threshold in (c) indicative of a non-equilibrium condensate limited by the polariton bottleneck. The uncoupled cavity mode is shown by the white line (Plumhof et al., 2014).

of in-plane momentum above threshold is accompanied by symmetric lasing intensity maxima about  $k_{\parallel} = 0$ . This is due to incomplete thermalization from the polariton bottleneck between the exciton reservoir and the LPB ground state. This, in turn, results in an increase in threshold as temperature is decreased, opposite to that of the crystalline anthracene laser. Furthermore, laser emission (not shown) is blue-shifted from the polariton emission by approximately 10 meV, although it remains  $>20$  meV below the cavity mode energy. Note that a second population of non-lasing polaritons is also apparent in Fig. 9.23c at lower energies, possibly due to the second higher vibronic state of the polymer that also is coupled to the cavity. The blue shift with pump fluence is due to repulsive polaron interactions, and is opposite to the red shift experienced by conventional lasers that are pulled toward regions of higher gain as the transparency increases above threshold. It is notable that neither the disordered polymer nor crystalline anthracene polariton lasers make a transition to conventional lasing. This differs from inorganic lasers, possibly since the conventional lasing threshold may exceed the damage limit of the organics.

An additional feature of a polariton laser is spatial beam coherence, illustrated by the interferograms in Fig. 9.24 for a thermally evaporated, amorphous TDAF layer sandwiched between six-period,  $\text{Ta}_2\text{O}_3/\text{SiO}_2$  DBRs. The cavity  $Q \sim 600$  leads to Rabi splitting energies of 580 meV for a detuning of  $\Delta \sim 400$  meV.

**Figure 9.24** Interferograms (a) below and (b) above threshold for a TDAF polariton laser (Daskalakis et al., 2014).

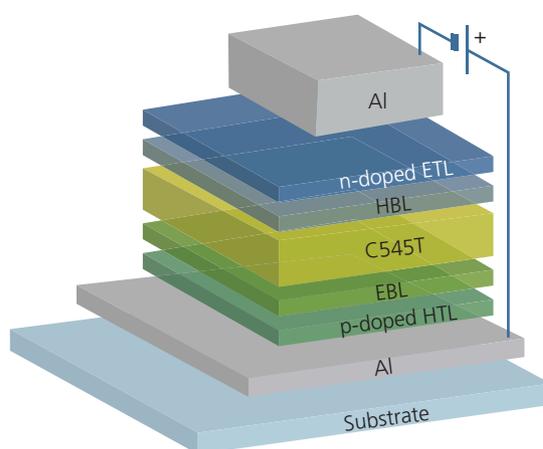

Below threshold, no fringes appear (Fig. 9.24a), indicating a total absence of spatial coherence. At  $1.9P_{thr}$  ordered interference fringes are visible across the entire emitting area of the laser, indicative of coherent emission. Also, the emission is TM polarized, independent of the pump beam polarization (Daskalakis et al., 2014). The presence of fringes and polarized emission both point to spatial and temporal coherence.

We can draw several conclusions from the foregoing observations of polariton lasing. The first is that it can be observed for both crystalline and amorphous films as long as strong coupling is present. As noted above, this is possible when the exciton and cavity linewidths are less than the Rabi splitting that, unlike conventional semiconductors, can be very large. Further, polariton lasing exhibits features that distinguish it from conventional lasing, such as a blue shift in emission above threshold, and in some cases an increase in threshold as temperature is decreased. Polariton lasing has a threshold far below that of its conventional lasing threshold. The existence of a low threshold is a consequence of the reduced polariton bottleneck whereby supply of polaritons from the exciton reservoir exceeds losses due to a combination of non-radiative and radiative processes. To date, the thresholds remain too high to enable electrically pumped organic polariton lasing at room temperature. Cooling is not expected to improve this situation. Finally, like a conventional laser, the emission from a polariton laser is polarized, and has both temporal and spatial coherence.

### 9.2.5 Ultrastrong coupling and polaritonic OLEDs and OPDs

In spite of the high thresholds for BEC formation, a step toward realizing electrically pumped polaritonic lasers has been made by the demonstration of a polaritonic OLEDs and organic photodetectors. Both device types employ a pair of metal mirrors, resulting in *ultrastrong coupling* between the exciton and photon modes. Here, ultrastrong coupling is defined as the condition where the Rabi splitting is an appreciable fraction of the exciton energy, that is, when the nominal condition that  $\Omega \geq 0.1E_{ex}$  is met. The simple dipolar interactions employed in analyzing strongly coupled polariton dynamics must be modified to include nonlinear effects such as antiresonant couplings in the ultrastrong coupling regime (Ciuti et al., 2005, Kéna-Cohen et al., 2013).

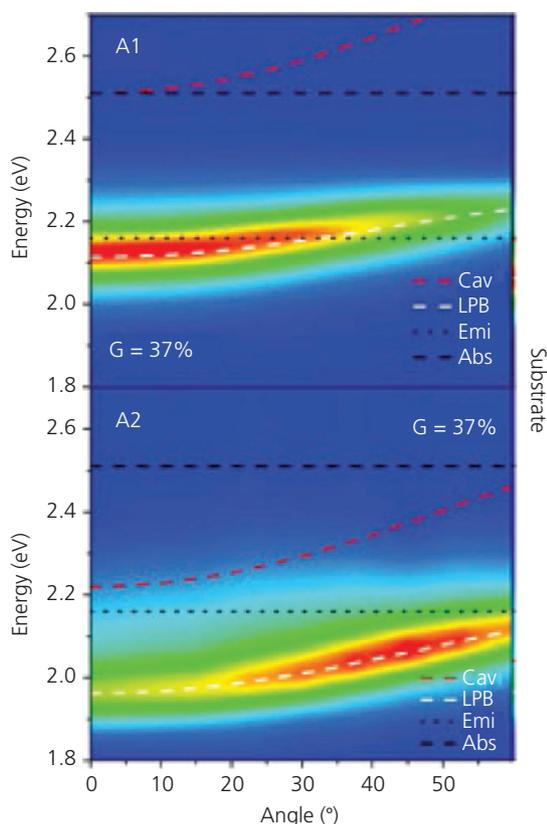

Small molecule based OLEDs whose spectra are modified by ultrastrong coupling have been reported (Tischler et al., 2005, Gubbin et al., 2014, Genco et al., 2018). Ultrastrong coupling has resulted in a large

**Figure 9.25** Polaritonic OLED structure exhibiting ultrastrong coupling via both electrical and optical pumping. The cavity is formed by the two Al mirrors, and the EML comprises a 55 nm thick neat C545T fluorescent layer (Genco et al., 2018).

exciton to polariton conversion efficiency approaching 25% in the device structure in Fig. 9.25. This device comprises a 55 nm thick C545T green fluorescent emitting layer (EML). The amount of detuning is adjusted by varying the thickness of the EML as well as the surrounding charge injecting layers from a total thickness of from 110–130 nm. Ultrastrong coupling is achieved by sandwiching this conventional OLED structure between two Al electrodes, with emission emerging from the bottom, 25 nm thick semitransparent anode.

Ultrastrong coupling was verified by measuring the reflectance due to optical pumping. There the ratio of the Rabi splitting energy to that of the bare exciton was a remarkable  $G = 0.92 \text{ eV}/2.5 \text{ eV} = 0.37$ , which is well beyond the nominal threshold of 0.1 for ultrastrong coupling. Emission intensity vs. angle from OLEDs with cavity detunings of 26 meV (A1) and  $-283 \text{ meV}$  (A2) are shown in Fig. 9.26. The emission follows the expected dispersion curve of the LPB, since the polaritons relax into the lowest available energy state more rapidly than their recombination rate. Also, this dispersion shows that the emission is due to coupling to the electrically generated excitons. Note that the emission from cavity A2 with the large detuning is not centered at the LP branch minimum, but rather has the highest intensity at approximately  $40^\circ$  from normal. This is due to the polariton bottleneck, preventing polaritons that are pumped at high angles from relaxing into the minimum energy state at  $0^\circ$ . The external quantum efficiency of polariton emission is 0.2%, which corresponds to an approximately 25% coupling of exciton to polariton state emission. Also, the OLEDs exhibit a maximum intensity of  $700 \text{ cd/m}^2$ .

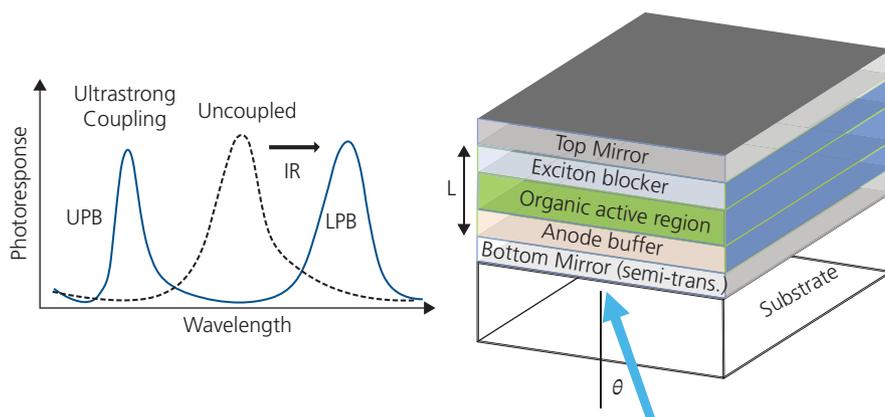

**Figure 9.26** Polariton OLED emission from the LP branch for two different cavity detunings: A1 = 26 meV, and A2 = -283 meV. The bare exciton absorption (black dashed line), the photon dispersion (red dashed line), the exciton emission (black dotted line), and the LP branch dispersion (white dashed line) energies are also shown. The color map spans from highest (red) to lowest (blue) emission intensity (Genco et al., 2018).

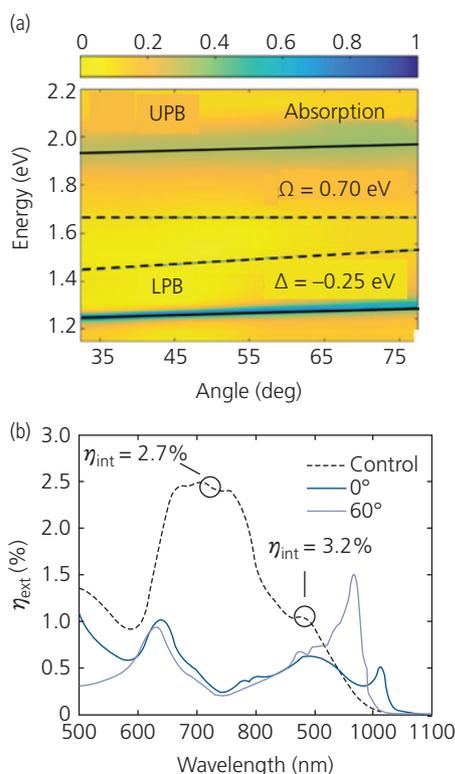

© 2018 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim

Ultrastrong coupling has been exploited in a polaritonic organic photodiode (OPD), where splitting between the branches results in a large red shift of the LPB. This permits photodetection at much longer wavelengths than for the same materials used in an uncoupled detector. Conceptually, this can be understood by the illustration in Fig. 9.27. Like the polaritonic OLED, the active region is sandwiched between metal mirrors to create a strong coupling environment. The organic active region consists of a donor–acceptor junction that can dissociate the polaritonic state, thereby generating photocurrent. Ultrastrong coupling splits the uncoupled excitonic absorption spectrum into widely separated upper and lower branches. The LPB is significantly red-shifted, with a nearly equal blue shift of the UPB. This, in principle can result in absorption deep into the IR that is typically poorly accessed by the bare organic films due to rapid recombination of IR excitons as limited by the energy gap law (see Section 3.6.1).

A NIR absorbing OPD employed a structure analogous to that in Fig. 9.27. The structure is a planar-mixed HJ (see Section 7.1.2): Ag anode (75 nm)/HATCN (15 nm)/CuPc (15 nm)/SnPc:C<sub>60</sub> (0.73:0.27 by vol., 110 nm)/C<sub>60</sub> (30 nm)/Bphen (15 nm)/LiF (1 nm)/Ag cathode (25 nm). The absorption of the SnPc donor has a peak at 850 nm, with a tail extending to 1  $\mu$ m. The absorption and external quantum efficiency ( $\eta_{\text{ext}}$ ) spectra of the device are provided by the color maps in Fig. 9.28a and b, respectively. Remarkably, a very large Rabi splitting of  $\Omega = 0.70$  eV is 42% of the uncoupled exciton wavelength. The wavelength shift of the LPB is as large as 0.44 eV, and the blue shift of the UPB is 0.36 eV. The  $\eta_{\text{ext}}$  spectrum follows that of

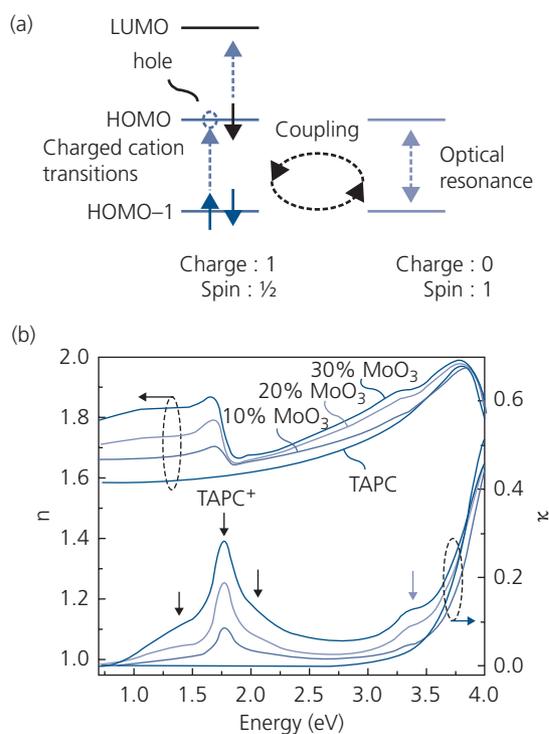

**Figure 9.27** (right) Schematic of a strongly coupled OPD in a cavity comprising two metal mirrors. The thin lower mirror is semi-transparent. (left) The spectrum of an uncoupled exciton is split by a significant fraction of the exciton energy by ultrastrong coupling. The lower branch is shifted into the infrared (IR).

**Figure 9.28** (a) Absorption dispersion for an ultrastrong coupled SnPc:C<sub>60</sub> OPD. Solid lines are fits to coupled oscillator theory assuming a Rabi splitting of 0.70 eV and a detuning of -0.25 eV. The dashed lines are the bare exciton (horizontal) and cavity modes (diagonal). (b) OPDs with weak coupling (control, dashed line) and strong coupling at two different incident angles (Eizner et al., 2018).

the absorption in Fig. 9.28a. Additional spectral details are resolved in the internal ( $\eta_{int}$ ) and external quantum efficiency plots in Fig. 9.28b. The strongly coupled spectra at 0° and 60° reveal the two peaks at short and long wavelengths. The external efficiency at long wavelength is considerably higher than for an analogous, uncoupled device (dashed line), employing a non-reflective ITO anode. In particular, the peaks at 970 nm and 1  $\mu$ m for incident angles of 60° and 0°, respectively, are considerably more intense than for the conventional OPD. The peak external quantum efficiencies at both short and long wavelengths of the strongly coupled devices, however, fall short of those for conventional excitonic OPDs (Eizner et al., 2018).

Finally, strong coupling between photons and charges can generate a polaron-polariton that is qualitatively different from exciton-polaritons. The former couples a spin- $\frac{1}{2}$  particle (a polaron) with a spin-1 photon, resulting in a quasiparticle that follows Fermi statistics. This is in contrast to the exciton-polaron

**Figure 9.29** (a) Energy scheme for a hole polaron-polariton on a cationic molecule. The hole in the HOMO level is coupled to the electron in HOMO-1 via resonance with the cavity field. (b) Index of refraction and extinction coefficient of neutral (blue vertical arrow) and cationic (black arrows) TAPC as a function of MoO<sub>3</sub> doping concentration (Cheng et al., 2018).

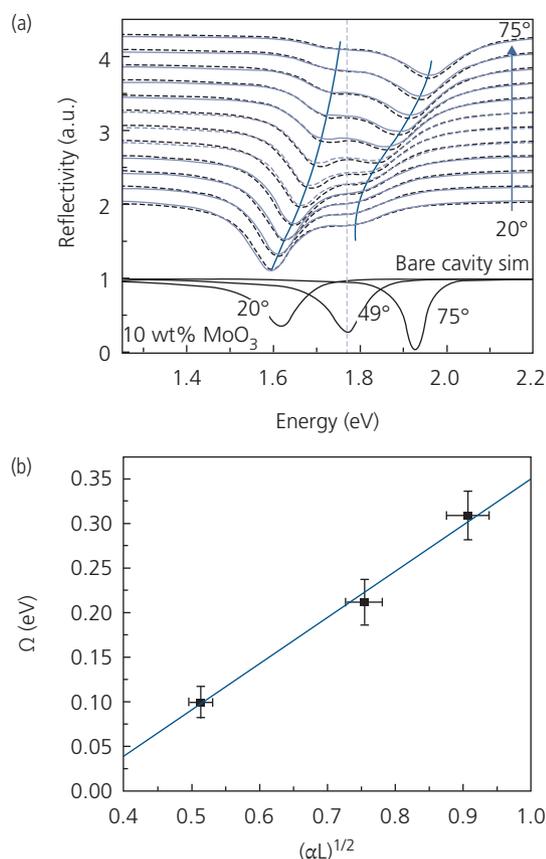

which is a boson. The charged polaron-polariton can respond to an external electric field, and is similar to a *trion*, which is a weakly bound charge-exciton state found in inorganic semiconductors at low temperatures. The large Rabi splitting of the polaron-polariton is a consequence of the intense, narrow spectral linewidths of anionic and cationic radical organic species, making them stable even at room temperature.

An energy level diagram of a cationic polaron-polariton is shown in Fig. 9.29a. A missing electron in the HOMO (i.e. a hole) is bound to an electron in the HOMO-1 state, and is coupled to a resonant cavity photon to form the quasiparticle. Analogously, a molecular anion radical with an unpaired electron in the LUMO couples to the LUMO+1 or other higher LUMO states. To prepare the cationic states, the hole conducting TAPC is doped with MoO<sub>3</sub> whose large LUMO energy serves as an electron acceptor. Electrons are transferred from the HOMO of TAPC to MoO<sub>3</sub>. Increasing the dopant concentration increases the density of TAPC<sup>+</sup> cations.

Evidence for charge transfer is inferred from the spectra in Fig. 9.29b. The extinction peak (with

attenuation coefficient,  $\kappa$ ) at 1.77 eV and its sidebands only exists in the presence of the dopant. Therefore, these features are assigned to a singly charged radical cation species. The neutral exciton is found at approximately 3.5 eV. The increase in  $\kappa$  is accompanied by a drop in the real part of the index of refraction,  $n$ . This is confirmed by direct optical measurements of the cationic species in solution (Cheng et al., 2018).

Films of 10 wt% MoO<sub>3</sub>:TAPC were sandwiched between a reflective, 100 nm thick Ag mirror and a semitransparent, 17 nm Ag mirror that form a strongly coupled cavity. Reflectivity spectra are shown in Fig. 9.30a along with the calculated spectra assuming a coupled oscillator pair. The TAPC<sup>+</sup> reflectivity peak at 1.77 eV is split, resolving the anticrossing between the two polaron branches with a Rabi energy of

**Figure 9.30** (a) Measured reflectivity spectra (blue lines) of a 10 wt% MoO<sub>3</sub>:TAPC film in an optical microcavity. Fits to the data using a coupled oscillator model are shown by the dashed lines that highlight the anticrossing of the LPB and UPB. The lower spectra show the calculated uncoupled exciton spectra at several angles. (b) Rabi splitting energy vs. optical absorbance (Cheng et al., 2018).

320 meV. The magnitude of the splitting is indicative of ultrastrong coupling found in cavities bound by metal mirrors.

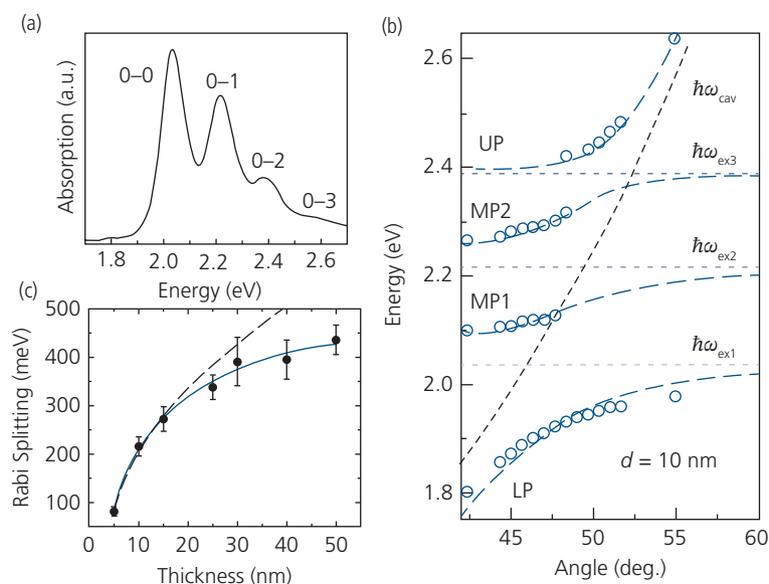

Interestingly, it is found that the splitting is related to the film absorbance via  $\Omega \propto (\alpha L)^{1/2}$  (see Fig. 9.30b), consistent with Eq. 9.10. That is, the TAPC<sup>+</sup> density, and hence its absorption increases linearly with MoO<sub>3</sub> concentration. This, in turn, increases the coupling of the TAPC<sup>+</sup> to the cavity mode.

Since the polariton carries charge, it can be electrostatically manipulated. Thus, the transport of polarons from source to drain in a resonant cavity transistor can be influenced by charge injection and the gate potential. A remarkable aspect of polaron-polaritons lies in their room temperature stability that apparently is unique to organic materials with their low dielectric constants, and consequently large binding energies of the molecular excited states.

The foregoing devices experience ultrastrong coupling using cavities comprising two metal mirrors. However, ultrastrong coupling can be observed for any cavity that provides sufficient optical feedback. An all-dielectric structure that supports BSWs has demonstrated this degree of coupling in DBP thin films on the surface of a DBR pre-deposited on a fused silica substrate, see Fig. 9.10. The DBP absorption spectrum in Fig. 9.31a shows four well-resolved peaks corresponding to the 0–0, 0–1, 0–2, and 0–3 vibronics in the S<sub>1</sub> manifold. Fits to the coupled oscillator formalism for a  $d = 10$  nm thick film are shown in Fig. 9.31b. All three of the dominant vibronics are coupled to the BSWs, yielding a Rabi splitting of 215 meV, which is at the lower edge of the ultrastrong coupling regime.

The coupling increases with organic film thickness. This is anticipated since the evanescent field that leaks out of the DBR overlaps more of the organic film as its thickness increases. However, the effect saturates due to the exponential decay of the field intensity with distance from the DBR surface. In the constant field approximation, the Rabi splitting energy is given by  $\Omega(d) = A\sqrt{d - d_0}$ , where  $A$  is a constant and  $d_0$  is a distance that scales with the line broadening parameter,  $\gamma$ . This expression results in the dashed line fit in Fig. 9.31c, clearly overestimating the coupling strength at  $d > 15$  nm. To correct for reduced field interactions, the exponentially decreasing field amplitude over characteristic length,  $l$ , must be integrated across the film thickness. Then, the Rabi splitting follows (Hou et al., 2019)

$$\Omega(d) \propto \mu\sqrt{N}\bar{F} = \mu\sqrt{N} \int_0^d \frac{e^{-x/l}}{d} dx, \quad (9.18)$$

**Figure 9.31** (a) DBP absorption spectrum. (b) Reflectivity spectrum of a 10 nm thick DBP film in an all-dielectric cavity, showing coupling of the three lowest vibronics in the strong coupling regime. The exciton energies of  $\omega_{ex1}$ ,  $\omega_{ex2}$ , and  $\omega_{ex3}$  correspond to the 0–0, 0–1, and 0–2 transitions, respectively. The cavity mode is also shown. (c) Rabi splitting vs. DBP thickness,  $d$ . The onset of ultrastrong coupling occurs when  $\Omega \approx 0.1E_{ex} \approx 215$  meV corresponding to  $d \gtrsim 10$  nm. The dashed and solid lines are discussed in text (Hou et al., 2019).

where  $\bar{F}$  is the mean electric field,  $N$  is the number of oscillators that is proportional to  $d$ , and  $\mu$  is molecular transition dipole moment. As shown by the solid line in Fig. 9.31c, this expression no longer overestimates the degree of coupling. Although the effect saturates with film thickness, significant coupling is achieved with the all-dielectric cavity, reaching  $\Omega > 0.2E_{ex}$  at film thicknesses of 50 nm.

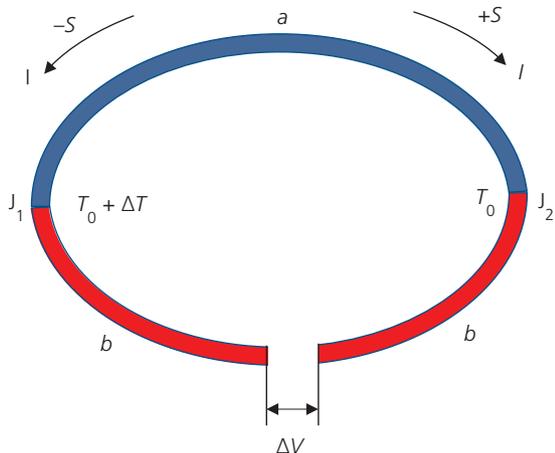

While the results of the active polaritonic OLEDs and OPDs are promising, their performances still fall short compared with conventional devices. Nevertheless, as noted above, the stable room temperature polariton phenomena in organic semiconductors open doors to many new potential nonlinear optical applications, ranging from electrically pumped polariton lasers, to all-optical logic gates and IR detectors (Sanvitto and Kéna-Cohen, 2016, Snoke and Keeling, 2017). The list of properties accessed via strong coupling, and of their concomitant optical phenomena yet to be discovered, is long and growing. For example, early demonstrations of using polaritons for the control of chemical reactions may eventually lead to new chemistries based on the interaction of light and matter. The insights that polaritonic phenomena provide into the understanding, and ultimately the control of energy transfer between both homogeneous (organic/organic) and heterogeneous (organic/inorganic) materials systems provides compelling reasons to continue their investigation and exploitation.

### 9.3 Organic thermoelectricity

Thermoelectric materials provide a simple and potentially low cost route to temperature control, measurement, and thermal energy conversion to electricity. However, many inorganic materials used in efficient thermoelectric devices are often difficult or costly to synthesize, are comprised of difficult to obtain materials, and may be brittle, preventing their being shaped into desired form factors. The need for efficient thermoelectrics useful in a wide range of thermal generating and harvesting applications has therefore focused attention on the use of organic thin films that can be made from earth-abundant materials at low cost, while having adaptable form factors via fabrication on large area, flexible substrates.

The processes of thermal generation (i.e. heating and refrigeration) and energy harvesting are complementary, and hence can be understood from a single analytical perspective. The *Seebeck effect* is when a temperature difference across a semiconductor results in a voltage difference that can deliver power to a load (energy harvesting). The converse, *Peltier effect*, is when current across a semiconductor develops a temperature difference, enabling heating or cooling, depending on the direction of current flow.

These two effects are conveniently understood with reference to the thermocouple in Fig. 9.32, where two different materials (a and b) form a pair of parallel

**Figure 9.32** Schematic of two dissimilar materials, **a**, **b**, forming a thermocouple. The thermocouple comprises a pair of junctions,  $J_1$ ,  $J_2$ , at different temperatures. This induces a voltage drop,  $\Delta V$ , and hence a current flow,  $I$ , in an external load. A clockwise current flow results from a material with a positive Seebeck coefficient,  $S$ . Otherwise  $S$  is negative.

junctions,  $J_1$  and  $J_2$ . If the two junctions are at different temperatures,  $T_0$  and  $T_0 + \Delta T$ , a voltage is developed across the gap in material **b**, whose magnitude is given by the *Seebeck coefficient*:

$$S_{ab} = \Delta V / \Delta T. \quad (9.19)$$

In this discussion, we use  $S_{ab}$  for the Seebeck coefficient, although  $\alpha_{ab}$  is also used. If the current flows from the hot to the cold junction ( $\Delta T > 0$ ), then  $S > 0$ , whereas if it flows in the reverse direction,  $S < 0$ . The direction of current flow depends on whether the majority carriers are electrons or holes. The Seebeck effect is thus also useful for determining the majority carrier type of a semiconductor.

The converse phenomenon of heating or refrigeration of a junction via the passage of current,  $I$ , is characterized by the *Peltier coefficient*:

$$\pi_{ab} = I / \dot{Q}_{th}, \quad (9.20)$$

where  $\dot{Q}_{th}$  is the rate of cooling or heating. That is, one of the junctions is heated at rate  $\dot{Q}_{th} > 0$ , while the other is cooled at rate  $\dot{Q}_{th} < 0$ . The Peltier effect is most frequently used for thermoelectric heaters and coolers. The Seebeck and Peltier coefficients are related via the *Kelvin relationship*:

$$S_{ab} = \pi_{ab} / \Delta T. \quad (9.21)$$

The magnitude of the thermoelectric effect of a particular material is characterized by the dimensionless figure of merit,  $z$ :

$$zT = \frac{S^2 \sigma T}{\kappa}, \quad (9.22)$$

where  $\sigma$  is the electrical conductivity and  $\kappa$  is its thermal conductivity. Here,  $z$  is an intensive parameter that is defined by the material characteristics alone. However, to characterize a thermoelectric device with resistance,  $R$ , and thermal conductance  $K$ , use of the extensive parameter:

$$ZT = \frac{S^2 T}{RK} \quad (9.23)$$

is more appropriate.

Finally, the *power factor* of the material is

$$PF = S^2 \sigma. \quad (9.24)$$

Equation 9.22 shows that a high  $zT$  is achieved for materials with a high electrical and a low thermal conductivity. High electrical conductivity is required to reduce internal power loss,  $I^2 R$ . On the other hand,  $\kappa$  must be small such that the device can support a large thermal gradient across a small distance so as not to thermally short the hot to the cold end. Shorting results in a decreased  $\Delta T$  across the thermocouple.

The thermal conductivity is due to the sum of the conductivity from the lattice,  $\kappa_{lat}$ , and the electron population,  $\kappa_{el}$ . Heat transport by phonons is expressed using

$$\kappa_{lat} = \frac{1}{3} C_v v \lambda_{ph}, \quad (9.25)$$

where  $C_v$  is the heat capacity per volume,  $v$  is the velocity of sound, and  $\lambda_{ph}$  is the phonon mean free path. For conducting polymers, the lattice contribution to the thermal conductivity is 0.1–1 W m<sup>-1</sup> K<sup>-1</sup>. The electronic contribution is related to the electrical conductivity via the *Weidemann–Franz law*, viz.

$$\kappa_{el} = L \sigma T, \quad (9.26)$$

where  $L = (\pi^2/3)(k_B/q)$  is the *Lorenz factor*. Thus,  $\kappa_{el}$  is proportional to the electrical conductivity, leading to a tradeoff in finding  $\sigma$  that maximizes  $zT$ . In organic semiconductors,  $\kappa_{el} \ll \kappa_{lat}$ , and often can be neglected.

The Seebeck coefficient for a material is ultimately determined by the DOS,  $g(E)$ , available for conduction by electrons and/or holes. Recall from Section 4.3.2 that the HOMO and LUMO densities of states can be approximated by Gaussian distributions about the frontier energy levels,  $E_{HOMO}$  and  $E_{LUMO}$ , respectively. We have shown that conduction is affected by both static and dynamic disorder, which are characteristics of both polymers and small molecules. Thus, the picture is made more complete by inclusion of a separate Gaussian DOS centered at energy  $E_T$  near the Fermi energy. An example DOS for an archetype p-type material is shown in Fig. 9.33. A similar trap state distribution can also exist at the LUMO edge, and in

fact this most likely is the case in most organics. The conductivity of carriers via either conduction or valence states then can be written

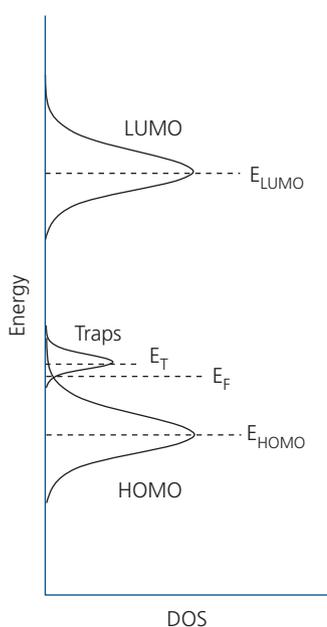

$$\sigma = \int \sigma(E) dE = q \int g(E) \mu(E) f(E) [1 - f(E)] dE, \quad (9.27)$$

where  $\mu(E)$  is the energy-dependent mobility, and the terms including the Fermi function,  $f(E)$ , account for the probability that a charge can move from an occupied to an unoccupied state. This analysis suggests that the fraction of electrons between  $E$  and  $E + dE$  contributing to conduction is given by  $\sigma(E)dE/\sigma$ , in which case we can calculate the Seebeck coefficient for metallic materials (where  $\kappa_{lat} < \kappa_{el} \propto \sigma$ ) as follows (Fritzsche, 1971, Mott and Davis, 1979):

$$S = -\frac{k_B}{q} \int \left( \frac{E - E_F}{k_B T} \right) \frac{\sigma(E)}{\sigma} dE. \quad (9.28)$$

This relationship is valid for materials where the conduction takes place at or near the Fermi energy,  $E_F$ , and  $\sigma$  is a slowly varying function about  $E_F$ . Note that in p- and n-type materials, the conduction level energies,  $E$ , are less than or greater than  $E_F$ . Hence, the sign of the integrand, and consequently,  $S$ , changes for the different materials types. By convention,  $S < 0$  for n-type, and  $S > 0$  for p-type semiconductors.

In n- or p-type organics, the charges are primarily transported within either the HOMO or the LUMO level state distributions where  $E$  may significantly differ from  $E_F$ , making Eq. 9.28 incomplete (Kaiser, 1989). In disordered organic materials, electron-phonon interactions must be considered, but are

**Figure 9.33** Density of states (DOS) at the HOMO and LUMO energies, along with a trap density centered at  $E_T$ .

absent in this expression. It is likely that organics are single energy band conductors, that is, either holes or electrons dominate the conductive properties of a particular material. If transport occurs by three-dimensional (3D) *variable range hopping*, then  $\sigma = \sigma_0 \exp[-(T_0/T)^{1/4}]$  where  $\sigma_0$  and  $T_0$  are constants. In this case, Eq. 9.28 becomes (Mott and Davis, 1979)

$$S = \frac{k_B^2}{2q} (T_0 T)^{1/2} \frac{d \ln D(E)}{dE} \Big|_{E=E_F}, \quad (9.29)$$

leading to the more realistic approximation used for degenerate semiconductors (Cutler et al., 1964):

$$S = \left( \frac{2k_B m^* T}{3\hbar^2} \right) \left( \frac{\pi}{3n} \right)^{2/3} \left( \frac{k_B}{q} \right). \quad (9.30)$$

This is known as the *Mott formula*. From the foregoing, a thermoelectric device must balance the electrical and thermal conduction properties to maximize its efficiency. The tradeoffs are qualitatively illustrated for insulators, semiconductors, and metals in Fig. 9.34. In the lower panel, we show that the electron contribution to the thermal conductivity is important only in metals, and in very highly doped (i.e. degenerate) semiconductors, whereas for most semiconductors and insulators,  $\kappa_{lat}$  is dominant. The decrease in  $S$  due to an increasing  $\sigma$  is counteracted by the low  $\kappa$  of insulators. Taking these factors into consideration, the power factor peaks for highly doped semiconductors. However, this applies only to materials systems where  $\sigma$  and  $\kappa$  are linked. One advantage of organic materials is the ease with which doping and thermal conductivity can be independently controlled. We will find below that composites consisting of carbon nanotubes (CNTs) dispersed in polymer matrices, or ionic doping of PEDOT are two strategies used to optimize this tradeoff.

An additional figure of merit for a *thermoelectric generator* (TEG) is its maximum efficiency,  $\eta_{TEG}$ , which is equal to the ratio of the energy supplied to the load to the heat absorbed at the hot junction. The thermodynamic limit of  $\eta_{TEG}$  is the *Carnot efficiency*,  $\eta_C = \Delta T/T_H = (T_H - T_C)/T_H < 1$ , where  $T_H$  ( $T_C$ ) is the temperature of the hot (cold) junction. Then, it can be shown for a generator with figure of merit,  $Z$  (Rowe, 2005),

$$\eta_{TEG} = \eta_C \frac{\sqrt{1 + Z\bar{T}} - 1}{\sqrt{1 + Z\bar{T}} + T_C/T_H}, \quad (9.31)$$

where  $\bar{T} = (T_H + T_C)/2$  is the average temperature.

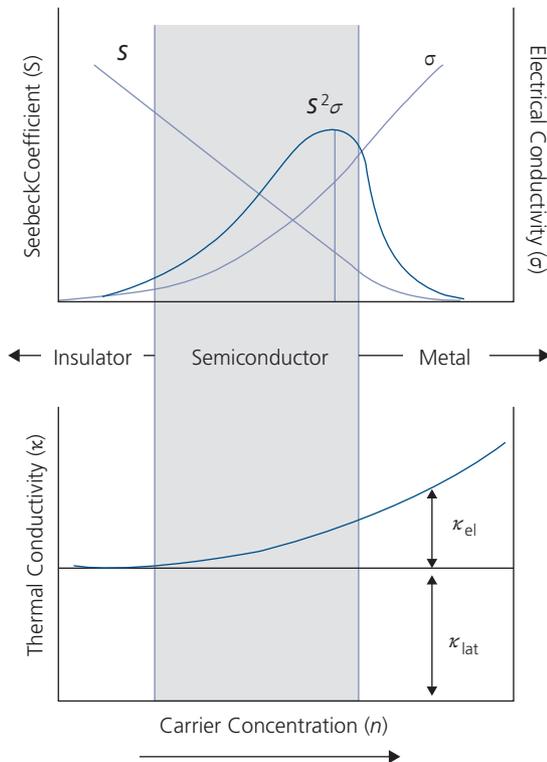

Organic semiconductors are useful for thermal power generation at temperatures that are tolerable for these materials, that is, at  $T \leq 150^\circ\text{C}$ . Fortunately this range represents the largest fraction of waste heat

generated in common household and building environments. Inorganics, however, can be used where more extreme temperatures are produced, such as scavenging heat from automobile exhausts, incinerators, and in the production of materials such as Si, steel, etc. Taking  $T_C = 300$  K and  $T_H = 450$  K as reference temperatures, the Carnot efficiency is  $\eta_C = 0.33$ . Of course,  $\eta_C$  increases with  $T_H$ , ultimately limiting the maximum  $\eta_{TEG}$  that can be reached at the lower end of the temperature range accessible to organics. Figure 9.35 shows the dependence of  $\eta_{TEG}$  and  $\eta_C$  on  $T_H$  for several values of  $Z$  in the temperature range typically accessed by organic TEGs. The highest  $ZT \sim 1\text{--}2$  is achieved with inorganic alloys such as  $\text{Bi}_2\text{Te}_3$  and  $\text{SiGe}$  (Snyder and Toberer, 2011), which is at least a factor of four higher than reported for organic TEGs (Russ et al., 2016). Also,  $Z$  is roughly 50% that of  $z$  in the most efficient, practical thermoelectric appliances. Thus, for an organic TEG operating at 450 K, we find an upper practical value of  $Z \sim 0.8 \times 10^{-3} \text{ K}^{-1}$ , giving  $\eta_{TEG} \sim 2.2\%$  at  $T_C = 300$  K.

Analogously, the maximum efficiency for cooling is

$$\eta_{COP} = \frac{T_C}{\eta_C T_H} \frac{\sqrt{1 + ZT} - T_H/T_C}{\sqrt{1 + ZT} + 1}, \quad (9.32)$$

which is also known as the maximum *coefficient of performance*. This corresponds to a maximum

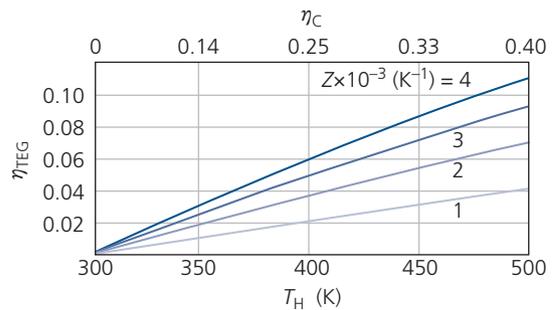

**Figure 9.34** Tradeoffs between the Seebeck coefficient, electrical conductivity, thermal conductivity, and power factor vs. carrier concentration in thermoelectric materials, ranging from insulators to metals.

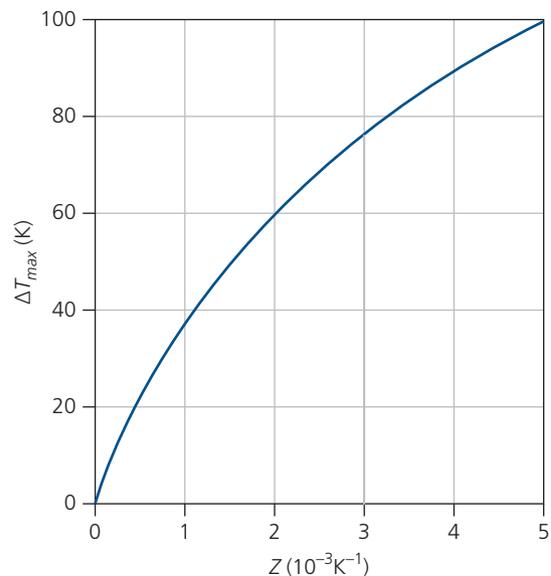

temperature difference of  $\Delta T_{max} = \frac{1}{2} Z T_C^2$ . A plot of the theoretical maximum temperature for a generator with figure of merit  $Z$ , and with  $T_H = 298$  K is shown in Fig. 9.36. Using the performance values given above, a refrigeration module employing organic thin films is expected to have  $\Delta T_{max} \sim 50$  K.

### 9.3.1 Organic thermoelectric module architectures

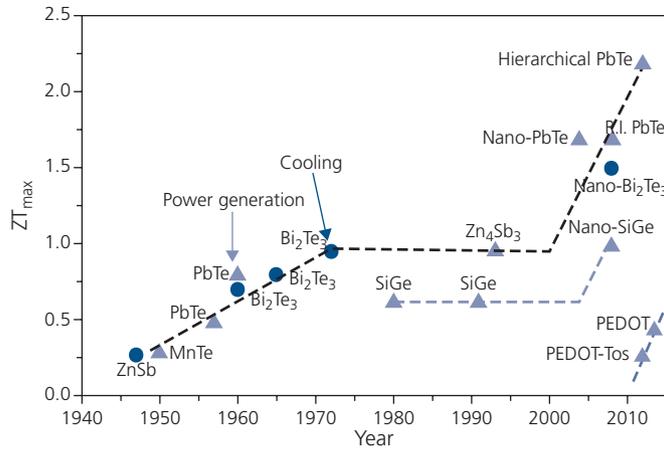

Figure 9.37 provides a compilation of representative  $ZT_{max}$  values versus the year of their demonstration for several inorganic and organic thermoelectric materials. The inorganic materials undergo a significant increase in  $ZT_{max}$  when nanostructured such as with quantum wells or nanowires, to break the strict dependence between the electrical and thermal conductivities of the materials (Hicks and Dresselhaus, 1993). The highest values are obtained for Pb-based

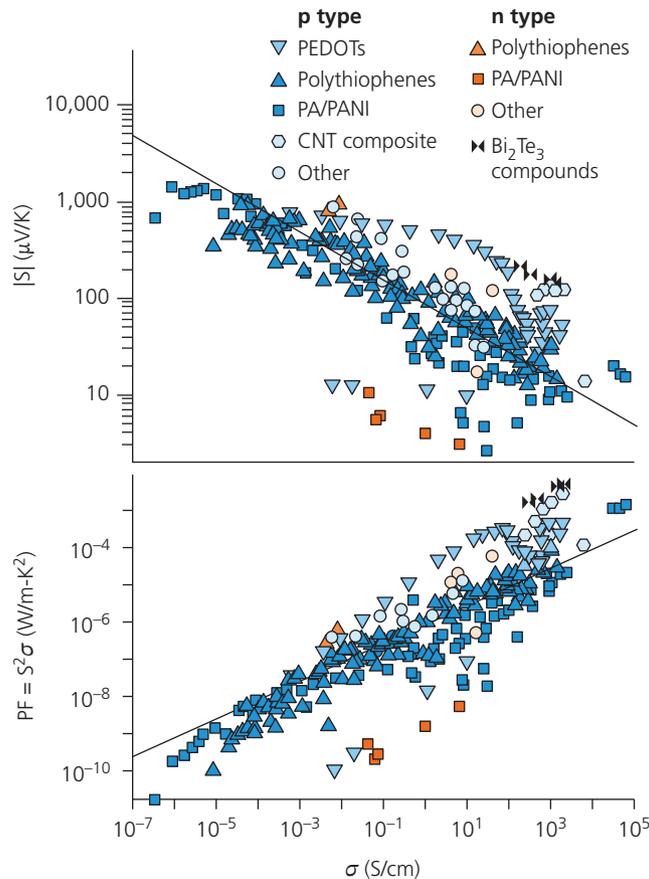

**Figure 9.35** Thermoelectric generation efficiency ( $\eta_{TEG}$ ) vs. hot junction temperature ( $T_H$ ) for several  $Z$  values. Also shown is the Carnot efficiency ( $\eta_C$ ) for  $T_C = 300$  K.

**Figure 9.36** Maximum temperature difference of a thermoelectric refrigerator vs.  $Z$  at  $T_H = 298$  K.

**Figure 9.37**  $ZT_{max}$  of representative thermoelectric materials vs. the year of their demonstration used in power generation (triangles) and refrigeration (circles) applications. The inflection in  $ZT_{max}$  around the year 2000 separates values obtained for inorganic bulk and nanostructured materials. The best organic values are obtained for PEDOT with a tosylate anion (PEDOT-Tos) (Bubnova et al., 2011) and PEDOT itself (Kim et al., 2013b). Adapted from Heremans et al. (2013).

**Figure 9.38** Seebeck coefficients and power factors for a variety of organic thermoelectric materials. Included for comparison is the high performance inorganic alloy,  $\text{Bi}_2\text{Te}_3$ . Solid lines correspond to the empirical relationships:  $S \propto \sigma^{-1/2}$  and  $PF \propto \sigma^{1/2}$ . References for each material are found in Russ et al. (2016). Reprinted by permission from Springer Nature, Nature Reviews Materials, 1, 16050, Russ, B., Glaudell, A., Urban, J. J., Chabiny, M. L. & Segalman, R. A., Organic thermoelectric materials for energy harvesting and temperature control. Copyright 2016.

II–VI semiconductors, with  $ZT_{max} > 2$ . Nanostructuring of organic materials has also led to higher thermoelectric figures of merit, as discussed below. To date, the highest  $ZT_{max}$  for organics hovers at just less than 0.5, with the best results obtained for

PEDOT and related polymers (Bubnova et al., 2011, Kim et al., 2013b).

Selected values of  $S$  and  $PF$  for a population of both n- and p-type organic thermoelectric materials are shown in Fig. 9.38. The various points correspond to

data taken from the literature, with specific references provided in Russ et al. (2016). The data roughly follow the empirical relationships  $S \propto \sigma^{-1/4}$  and  $PF = S^2 \sigma \propto \sigma^{1/2}$  shown by the lines. While there is considerable scatter of the data about the trend lines, it is nevertheless remarkable that the data follow these trends over approximately 11 decades in conductivity, and are independent of whether the material is n- or p-type. The origin of these empirical relationships is as yet unclear, and does not appear to be well fit by variable range hopping (cf. Eq. 9.29) or conduction along the mobility edge. It has been suggested that this trend may be coincidental, in that it may exist for high conductivity (and hence degenerately doped) organics that blends smoothly into a similar functionality for low doped, semiconducting-to-insulating materials (Glaudell et al., 2015, Russ et al., 2016). In any case, it is clear that the relationship between conductivity and the thermoelectric properties of organics is robust, and hence can be a useful predictive tool for selecting materials for specific applications.

The performance of the inorganic bismuth chalcogenide,  $\text{Bi}_2\text{Te}_3$ , is shown for comparison (black, opposing triangles). While this material has the highest  $PF$ , CNT composites, polyanilenes (PANI), polyacetylenes (PA), and PEDOT-based compounds are competitive, reaching a maximum  $PF \sim 3 \times 10^{-3} \text{ W m}^{-1} \text{ K}^{-2}$ . Also, due to the generally higher hole compared to electron mobilities in organics, the thermoelectric properties of p-type organic thin films (blue data points) also tend to be superior to n-type materials (orange points).

To scavenge a meaningful amount of energy, or to cool or heat a load with a significant thermal mass, the thermoelectric elements must be arranged in a module comprising a parallel array of individual

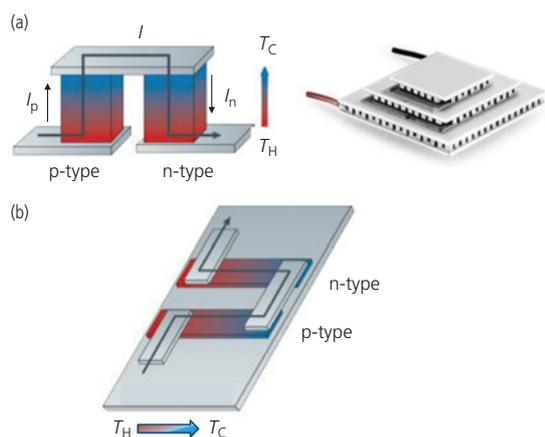

thermocouples or heaters, as shown in Fig. 9.39. The two types of elements employ either bulk or thin film architectures (Fig. 9.39a and b, respectively). The hot, heat-rejecting side is isolated from the heat-absorbing (cold) side by thermoelectric materials that have a low thermal but high electrical conductivity.

A module such as shown on the right in Fig. 9.39a consists of an electrical series connection of individual elements, with each element absorbing and rejecting heat in parallel. Since n- and p-type materials have Seebeck coefficients of opposite sign, using a combination of materials with opposite majority carrier types results in effective thermal isolation of the hot and cold surfaces while producing equal electron and hole currents ( $I_n$  and  $I_p$ ). If the values of  $\sigma$  and  $\kappa$  are identical for materials of both carrier types (which is almost never the case), then  $z = Z$ .

Stacking multiple thermoelectric coolers (TEC) or heat generators (TEG), with each subsequent cooler module smaller than the one beneath it, results in an increased  $\Delta T$  between the top and bottom surfaces. The stack should be mounted on an efficient heat sink to dispose of waste heat when used as a TEC, or to increase the highest possible temperature of a TEG. The diminishing area for each module compensates for the less than unity efficiency of the Peltier effect.

While bulk elements are readily achieved using inorganics, organic materials are more adaptable to a thin film form factor, making the geometry in Fig. 9.39b preferable. The thin film TEC or TEG can be mounted on a flexible and/or conformable sheet. This allows for roll-to-roll manufacturing of large area modules, which can lower cost and increase production throughput. A disadvantage of thin film TE devices is that thermal conduction through the substrate can thermally short-circuit the device. Using low thermal conductivity substrates is, therefore, imperative.

The thin film architecture also places constraints on its orientation to achieve intimate contact with the thermal load. As in the case of bulk elements, using a combination of n- and p-type legs connected in series increases the total current generated per device area, while providing thermal isolation of the cold and hot regions of the load. Matching hole and electron currents is accomplished in the in-plane configuration by adjusting the leg widths ( $w$ ) via printing. For example, if  $I_n = xI_p$  in a cooler whose legs are of equal width, then the currents are balanced when  $x = w_p/w_n$ , where  $w_p$  and  $w_n$  are the widths of the p- and n-type legs, respectively. Note too, that the thermal properties of the n- and p-type regions must be matched to achieve the highest performance. Thermal and electrical matching conditions may not

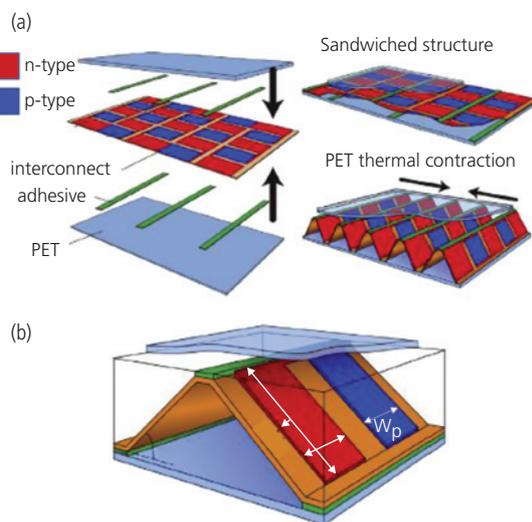

**Figure 9.39** (a) Bulk thermoelectric cooling (TEC) element comprising a p- and an n-type leg. On the right is a multistage TEC using arrays of bulk elements. (b) Thin film TEC element.

always result in the same leg geometries, in which case tradeoffs are inevitable.

An example configuration for thin film thermoelectrics uses a corrugated structure as shown in Fig. 9.40a, originally demonstrated for Ag/Ni TEG modules. The p- and n-type organic materials along with their series/parallel electrical connections are printed onto a thermoformable (e.g. PET) base film. The array is attached only to the bottom substrate and the top lid (also PET) along the interconnect lines. Heating the package results in shrinkage of the lid and base, causing the TEG array to buckle into the third dimension. This allows for contact between the hot and cold surfaces that are separated only by the thin films themselves and the resulting air gaps. The detail in Fig. 9.40b shows that the n- and p-type stripe widths can be independently adjusted to match the currents generated in each material. This is one of many possible configurations. Depending on the application (e.g. for thermometry on an irregular skin surface), the 2D planar configuration may in fact be preferable to 3D arrangements.

### 9.3.2 Example devices

The thermoelectric performance, including relevant materials parameters for many organic thin films and composites optimized for their thermoelectric properties, can be found elsewhere (Chen et al., 2015b, Toshima, 2017). Among the various materials used as thermoelectrics, PEDOT has shown the highest performance (Bubnova et al., 2013, Kim et al., 2013b). As

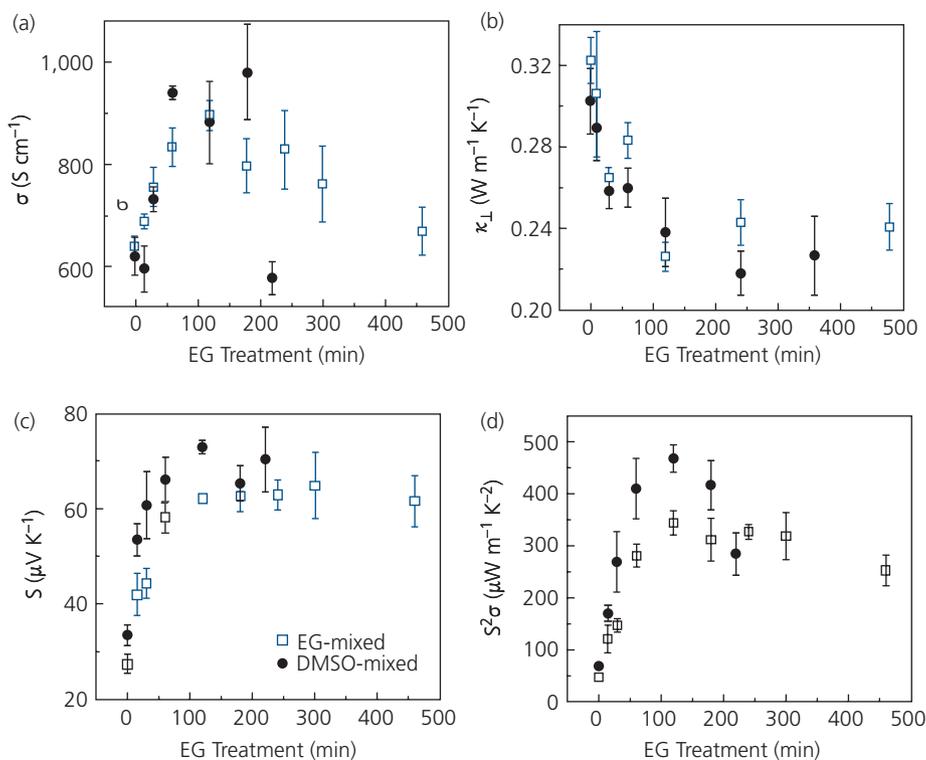

**Figure 9.40** (a) Fabrication of a 3D, corrugated TEG module using a 2D thin film architecture. (b) Detail of a single element of the module. Adapted from Sun et al. (2015).

we have shown in the preceding discussion, organics have strong electron–phonon interactions that decouple the electrical from the thermal conductivity. The challenge for organics, then, is to achieve a sufficiently high electrical conductivity in both p- and n-type materials to avoid dissipative  $I^2R$  losses. In this regard, the conductivity of PEDOT can be controlled over several orders of magnitude by changing its ratio with an ionic species such as PSS. Since PSS is hydrophilic and PEDOT is hydrophobic, they can be readily separated using organic solvents.

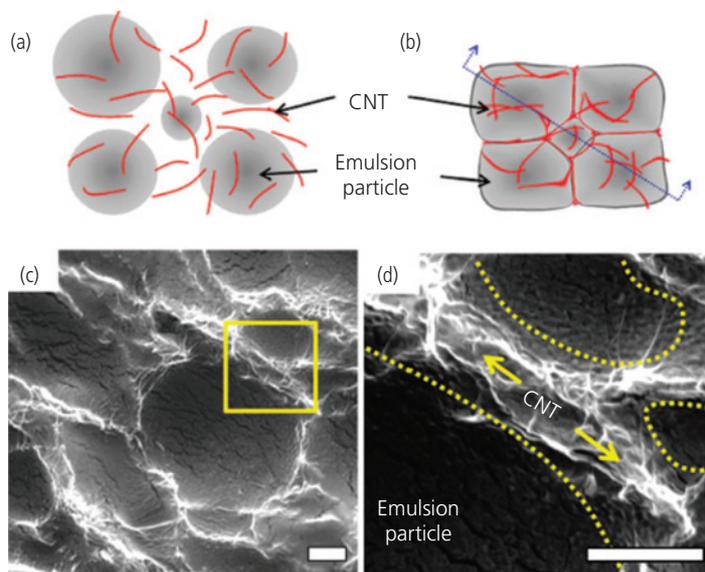

Dedoping, which increases the electrical resistance, has been achieved by thermal annealing films of PEDOT:PSS spun onto glass from solutions mixed in either ethylene glycol (EG) or DMSO. Figure 9.41 shows the electrical and thermal properties of the cast films that are dedoped by subsequent immersion in an EG solution for extended periods; the doping is decreased with the duration that the mixture spends in solution. The electrical conductivity in Fig. 9.41a increases with time until approximately 100 min, at which point it reaches a peak value close to 1000 S/cm. After 200–300 min, the change in conductivity decreases due to completion of the dedoping process. Concurrently, the thermal conductivity measured perpendicular to the film plane ( $\kappa_{\perp}$ ), which is  $\sim 60\%$  of the in-plane conductivity ( $\kappa_{\parallel}$ ), decreases monotonically with time, as shown in Fig. 9.41b. The similarity of the dependence of  $\sigma$  and  $\kappa$  on annealing time indicates that the electrons in PEDOT:PSS partially contribute to the film thermal conductivity.

The Seebeck coefficient,  $S$ , is found by measuring the change in voltage due to a temperature difference across the sample after accounting for the substrate thermal conductivity (Fig. 9.41c). Combining measurements of  $S$  and  $\sigma$  gives the thermal power in Fig. 9.41d, and the figure of merit,  $ZT$ . It is observed that  $PF$  is maximized for the film with maximum  $\sigma$ , achieving  $S^2\sigma = 500 \mu\text{W m}^{-1} \text{K}^{-2}$ , with a corresponding  $ZT = 0.42$ . As shown in Fig. 9.37, this value is less than the best inorganic alloy thermoelectric materials, although it has the advantages of using earth-abundant source materials to produce flexible thin films.

An approach to segregating the thermal and electrical properties is to create a nanostructured composite that has regions of high electrical conductivity percolating through a thermally insulating, dielectric matrix. Such composites are achieved by blending conductive materials such as metal nanoparticles (NPs) with a conducting organic or CNTs in an insulating polymer. Figure 9.42a illustrates the random

**Figure 9.41** Characteristics of thermally annealed PEDOT:PSS films mixed in either EG or DMSO vs. exposure time in an EG solution. (a) Electrical conductivity, (b) thermal conductivity perpendicular to the film plane, (c) Seebeck coefficient, and (d) power factor (Kim et al., 2013b).

distribution of CNTs in a solution containing a polymer emulsion. An *emulsion* is a stable suspension of particles or liquid in a solution of different composition (e.g. water). When the emulsion is dried, a film is

formed that excludes the CNTs from the particle volumes, forming conducting paths within the interstices along the boundaries between the particles (see Fig. 9.42b). In this way, narrow, electrically

conducting paths are formed along the CNTs that are separated by regions that inhibit thermal transport.

This film morphology is produced by blending 1–20 wt% of a distribution of single, double, and triple-walled CNTs into a PVA homopolymer emulsion that comprised 55 wt% solids in water. The PVA particle diameter distribution varies from 0.14  $\mu\text{m}$  to 3.5  $\mu\text{m}$ . The CNTs are dispersed in the matrix by first adding gum arabic before blending into the PVA. The solid composites are then dried in ambient for 2 days, followed by vacuum for 24 h to generate the 3D network in Fig. 9.42b. A microscope image of the resulting network is shown in Fig. 9.42c. The CNT clusters lie within the excluded volumes between PVA particles, forming what is apparently a continuous network. Indeed, the detail image in Fig. 9.42d shows a high density of tubes that forms electrically conducting paths that percolate throughout the film volume.

The thermoelectric performance of the composite is shown in Fig. 9.43. The electrical conductivity of the networks increases over several decades as the CNT concentration increases from 1 wt% to 20 wt%, indicating that the density of percolating pathways increases with the volume of nanotubes. It reaches a maximum of 50 S/cm at 20 wt% CNT, which is considerably less than for PEDOT:PSS, possibly due to resistance between the nanotubes within the conducting paths. We showed in Section 7.4.2 that casting CNTs from polymer suspensions can result in resistive contacts between overlapping nanotubes. In contrast to the electrical

**Figure 9.43** Electrical conductivity and Seebeck coefficient vs. CNT concentration in the PVA emulsions in Fig. 9.42. Inset: Thermal conductivity vs. CNT concentration. Adapted from Yu et al. (2008).

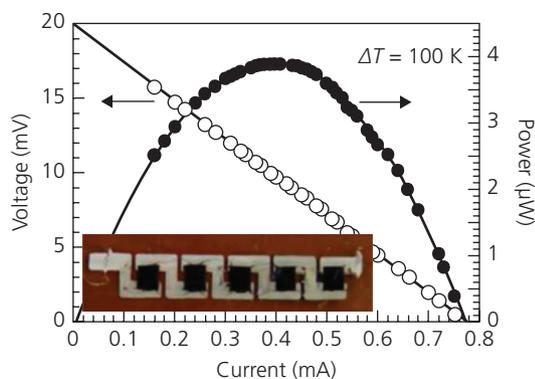

conductivity, the thermal conductivity (Fig. 9.43, inset) is largely unaffected by the presence of the nanotubes. The Seebeck coefficient, too, is relatively constant with CNT concentration even up to 20 wt%. At 20 wt%, a maximum  $zT = 0.006$  is obtained at 300 K, limited primarily by the low conductivity of the CNT regions (Yu et al., 2008).

The conductivity of CNTs is improved by including an ionic species within the film bulk. Table 9.3 shows results obtained by including the cationic polymer, *n*-PETT, into a mixture of the insulating PVC and a dispersion of CNTs. The *n*-PETT forms 10–50 nm diameter NPs that are dispersed with CNTs to form an electrically conducting but thermally insulating three-component network. The *n*-PETT is an *n*-type material, and thus leads to a negative Seebeck coefficient even when dispersed by itself in PVC. However, the conductivity of this material is quite low compared to the CNT and CNT/PVC films. Notably, the high hole conductivity of CNTs leads to a positive *S*. The benefit of using *n*-PETT to electrically interconnect the CNTs is apparent from the *n*-PETT:CNT:PVC (10:8:3) composite that shows an electrical conductivity of 630 S/cm, which is almost equal to that of a sheet of pure CNTs. The thermal conductivity of this three component film is only 0.07  $\text{W m}^{-1} \text{K}^{-1}$ , which is approximately the same as that of CNTs diluted in PVC. As a result, a peak  $zT = 0.31$  at 340 K is achieved, which is nearly that of dedoped PEDOT:PSS.

A five-leg thermocouple comprising composite *n*-PETT:CNT:PVC films printed on a polyimide substrate is shown in the inset of Fig. 9.44. This represents one of the few device-scale demonstrations of a thermoelectric device based entirely on organic semiconductors. The  $t = 5.7 \mu\text{m}$  thick by  $w = 4 \text{ mm}$  legs are series-connected by Ag electrodes in a module comprising five,  $L = 5 \text{ mm}$  long elements. A temperature difference of  $\Delta T = 100 \text{ K}$  perpendicular to the module results in the voltage and power-

**Table 9.3** Thermoelectric characteristics of mixed films at 340 K (Toshima et al., 2015)

The height of a semiconductor element is 5 mm (Toshima et al., 2015).

current characteristics obtained under a varying load of 0–100  $\Omega$  shown in Fig. 9.44. The temperature difference, and hence the module efficiency is ultimately limited by the thermal conductivity of the Ag interconnects and the polyimide substrate. Extrapolation of the voltage to  $I = 0$  gives an open circuit voltage of 19.9 mV. The internal series resistance obtained from the slope is  $R_{ser} = 25.6 \Omega$ . The peak power, which is equal to  $P_{max} = (\frac{1}{2}V_O)^2/R_{ser} = (NS\Delta T)^2/4[NL/(\sigma wt)]$ , is 3.88  $\mu W$ , where  $N = 5$  is the number of thermoelectric elements.

The foregoing discussion suggests that organic thermoelectric properties can approach those of inorganic alloys. The highest performances are achieved using high conductivity PEDOT derivatives, as well as with polymer composites with CNTs, metallic (Yoshida and Toshima, 2014), and even thermoelectric alloys such as  $\text{Bi}_2\text{Te}_3$  and related compounds (Toshima and Ichikawa, 2015). While the substantial benefits of organics include ease of processing using low cost, flexible, earth-abundant source materials, several challenges remain to be solved before they find widespread application. For many organic TEG and TEC configurations, substrate thermal conductivity remains a limitation. Also, the lack of thermal stability of organic materials, particularly at temperatures  $>200^\circ\text{C}$ , limits their use at high temperatures where the Carnot efficiency is large. One further issue that needs attention is the inherent anisotropy of organic materials. For example, the in-plane thermal conductivity,  $\kappa_{\parallel}$ , can differ from the out-of-plane value,  $\kappa_{\perp}$ , by at least a factor of 2 (Kim et al., 2013b). Similar anisotropies in the electrical conductivity are also common. Hence, it is not always clear that the high  $zT$  values reported will be experienced in devices assuming a perhaps unfavorable

orientation, leading to a much smaller  $ZT$  than anticipated. And finally, while the highest performance is obtained from p-type organic materials, there are very few, if any high performance *n*-type materials (see Fig. 9.38). Ultimately, this may require modules with metal interconnects between elements, or a significant asymmetry in device dimensions for the *n*- and *p*-type legs. Hence, materials development merits further attention before such devices find practical deployment.

## 9.4 Memories

Organic materials offer the possibility of delivering very inexpensive memory devices on flexible substrates. Applications where this may be an attractive form factor include RFIDs, and buffers for data acquisition from sensors used in medicine, robotics, and imaging. Several generic types of organic memories including *static* and *dynamic random access memories* (SRAM and DRAM) and *read-only memories* (ROM) have been demonstrated. A RAM is where the access to all memory elements (i.e. bits) is rapid and independent of the position of the bit in the memory. This is in contrast to time-accessed or serially addressed memories such as magnetic tapes. A *dynamic memory* is one where the contents can be changed on demand, whereas in a ROM, the contents are permanently written to contain vital information that does not change with time, such as the basic input-output system (BIOS) used to launch a computer operating system. A ROM is a *non-volatile memory* that preserves its contents even in the absence of power. Similarly, RAMs can be either volatile or non-volatile, depending on the character of the memory element. While a ROM is essential for all computation applications, non-volatile RAM is the most versatile and ubiquitous. It is the basis of NAND flash memories that pervade modern computational systems. Retention times of 10 years and read-write cycle reliability into the thousands are desirable for conventional memories, although this is dependent on the specific demands of a given application. The state of the memory should be retained over operating temperatures from  $-40^\circ\text{C}$  to  $+85^\circ\text{C}$ .

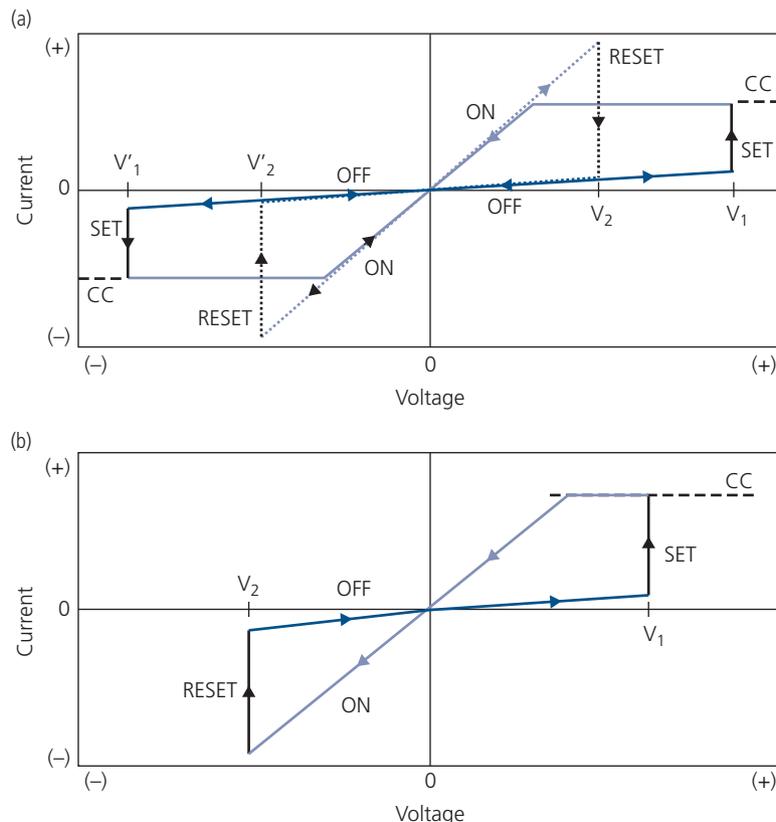

Organic memories are arranged in an array of metallic column and row interconnects separated by the memory material that changes its conductive state when a bit is written or erased. This so-called *cross-point array* minimizes the area occupied by each active memory element. Packing of arrays in a 3D configuration is the predominant form of high density NAND flash, since its bit density per circuit area is multiplied by the number of 2D array layers.

The most common and simple mechanism for storing information is using an organic material or device whose resistance (i.e. its memory state) is changed by several decades on application of a voltage during the write, or “set” cycle. The memory location is then read by measuring the magnitude of the current (and thus the resistance) through the device at a voltage much lower than that needed to write the bit. The resistance change can be permanent (i.e. where the memory element is a *fuse* that is blown once it is written), or it can be reversible by application of a second write pulse.

The read and write cycles of a volatile resistive memory are shown in Figs. 9.45a and b for unipolar and bipolar switching, respectively. Initially, the memory device is highly resistive and is in the OFF state (which may represent either a logical “1” or “0”). When queried by a small read voltage, the current is small due to the high resistance of the element. When the voltage is driven to the set voltage,  $V_1$ , the resistance is reduced, giving a constant current (CC in Fig. 9.45) equivalent to the ON state. To reset the device, the current in the ON state is increased until its value at “reset” is reached, corresponding to voltage  $V_2$ . This returns the element to its high resistance, OFF state. To non-

destructively read the state of the memory, the voltage swing is maintained in the range  $0 < V < V_2$ . The *memory window*,  $\Delta V$ , is the voltage difference needed to switch between logic states, that is,  $\Delta V = |V_1 - V_2|$ . The operation is unipolar since the voltage swings for SET and RESET are either both positive or negative. A bipolar device undergoes the same sequence of steps for reading and writing, except that the voltage polarities used for set and reset are opposite to each other, as shown in Fig. 9.45b. The choice of unipolar or bipolar switching depends on the circuit architecture and availability of the appropriate voltages.

Figure 9.45 points to a common feature of all memory elements. There must be hysteresis in the  $I$ - $V$  characteristics, leading to an open loop that clearly distinguishes between the ON and OFF states (with corresponding currents of  $I_{on}$  and  $I_{off}$ , respectively). The magnitude of  $I_{on}/I_{off}$  ultimately limits the size of a practical memory array. To achieve a moderate to large memory size,  $I_{on}/I_{off} = 10^5$ – $10^6$  is required (Prime and Paul, 2009). Also, the read cycle must be non-destructive of the memory contents, otherwise the contents must be refreshed by delivering a second set or reset signal after the memory is queried for a certain number of cycles. Read and write times limit

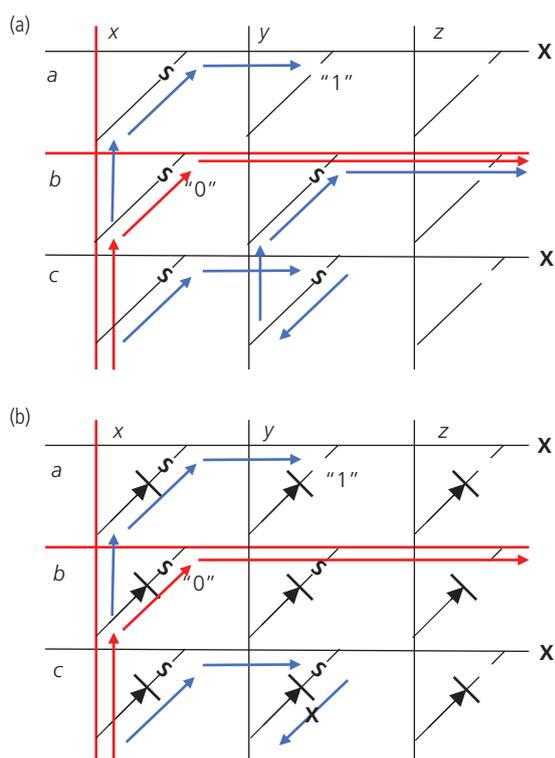

**Figure 9.45** (a) Unipolar resistive memory switching. CC = constant current used in the read cycle. (b) Bipolar memory switching (Heremans et al., 2011).

the memory access rate, and are typically on the order of several microseconds for high speed NAND flash.

### 9.4.1 Memory arrays

All digital memories comprise arrays of elements. Leakage currents from neighboring, unaddressed memory cells can lead to errors in identifying whether the contents of the target element is a 0 or a 1. Similarly, leakage can result in errors in writing data to the desired location. The source of this failure is the accumulation of *sneak currents*, which were discussed in the context of photodiode arrays in Section 7.2.2. This is illustrated in the fuse memory array in Fig. 9.46a. A logical 0 for this device is contained in a low resistance memory element, whereas a 1 is stored by an open element, or “blown fuse.” Matrix memories are read row by row. The logic state of each memory cell is determined by scanning through the several

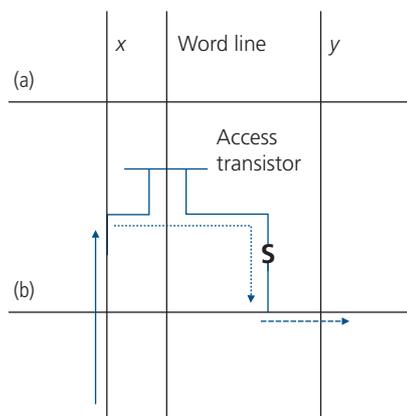

**Figure 9.46** (a) A cross-point memory array comprising fuses (S) that represent a logical 0 in the low resistance mode, and a 1 when open (i.e. a blown fuse). The circuit reading the memory connects the column on the far left with the second row (highlighted in red). Unconnected rows are marked X. Red arrows connect rows and columns through the addressed fuse at  $(b,x)$ . In this example, a parasitic current (blue arrows) through the unblown fuses at  $(b,y)$ ,  $(c,x)$  and  $(c,y)$  contribute parasitic current through  $(b,x)$  in the 0 state. (b) The same array except where a nonlinear circuit element (a diode) accompanies each fuse. The sneak current through  $(c,y)$  is significantly reduced through the reverse-biased diode at  $(c,y)$ .

columns. To address the target element at  $(b,x)$  in Fig. 9.46a, a voltage is applied between row  $b$  and column  $x$ , and the current  $I_{on}$  is read at the row output. However, unblown fuses at  $(b,y)$ ,  $(c,x)$ , and  $(c,y)$  provide a secondary path, adding to the total current. Thus, if element  $(b,x)$  is in the 0 state, a current will still be read out at row  $b$  due to the sneak currents through this secondary path, mistaking the logic state of  $(b,x)$  for a 0. Any number of paths on a large scale array thus makes the error-free readout of memory unlikely. Similar ambiguities exist in writing the memory. In spite of its shortcomings, a three stage, 3D stacked organic resistive array has been reported in an architecture that is presumably inspired by 3D NAND flash memories based on Si (Song et al., 2010). No data were provided on the array performance other than that of individual memory elements. This makes it impossible to evaluate the contrast between the 1 and 0 states, although according to Fig. 9.46a, this limits its practicality as a memory circuit.

Sneak currents are eliminated, or at least significantly reduced by including a non-linear circuit element such as a diode or an access transistor at each cross-point, as shown in Fig. 9.46b. The sneak current at point  $(c,y)$  encounters a reverse-biased diode, thus breaking its path to readout line  $b$ . However, reverse leakage currents in the diode, or parasitic source-drain currents in the access transistor add from each column and row, potentially resulting in a current that is sufficient to be mistaken for a logical 1, even if such a state is in error. The accumulation of leakage currents, therefore, also limits the size of the array.

An alternative nonlinear element is the access transistor in Fig. 9.47. This configuration employs an additional interconnect, called the “word line,” that switches an access transistor channel between the conducting and non-conducting states, thereby isolating

**Figure 9.47** One cell of a memory array employing an access transistor with a resistive memory element, S.

the desired pixel. Here, the channel leakage sets a limit to the array size that gives an acceptable on/off current ratio for error-free read and write operations. A common means to increase the memory size in either diode or transistor arrays without incurring readout errors, while simultaneously decreasing the memory element access time is to divide the array into blocks, and then using multiple read/write electronics in parallel to address the various memory sectors.

Organic memory elements are configured into several different classes, depending on the phenomenon that is exploited to store data. The bit can be stored by a change in resistance as discussed above, or in capacitance. The resistance changes are induced by application of a switching voltage that results in a chemical change (e.g. reduction or oxidation) of the organic molecules comprising the element, charge transfer to trapping sites that change the potential between electrodes, or electromigration of metal filaments that short the electrodes. Alternatively, an organic ferroelectric material has two stable dipolar polarization states that can either point along, or opposite to the direction of the applied field. The dielectric properties of the ferroelectric can be switched by an applied voltage, inducing a change in the device capacitance.

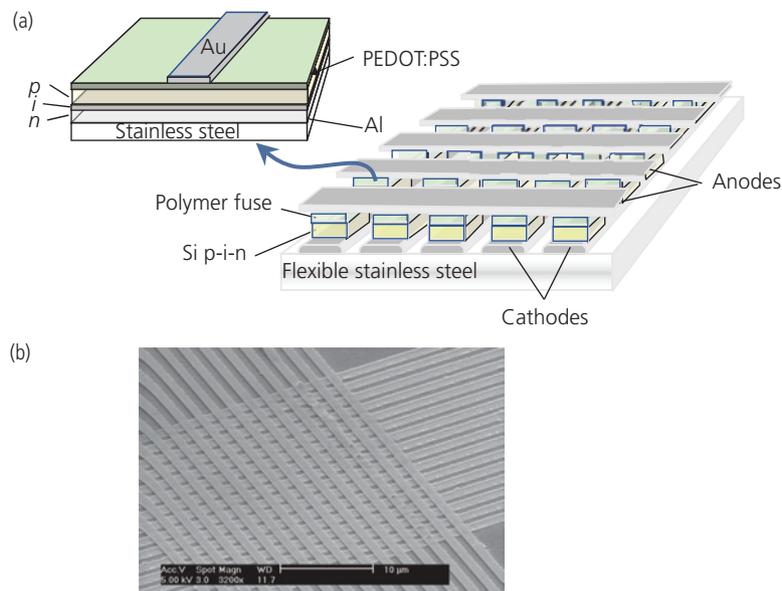

### 9.4.2 WORM memories

A resistive *write once, read many times* (WORM) memory array based on PEDOT:PSS fuses that are integrated in series with an amorphous Si p-i-n junctions

is shown in Fig. 9.48. The device consists of an array of thin film diodes pre-deposited onto a flexible, stainless steel substrate. The Al diode cathodes are arranged in columns. The p-Si regions form one contact of a  $\sim 50$  nm thick film of PEDOT:PSS (1:2.5) spun onto the diode, and then cured at elevated temperature. The Au row contacts are vacuum deposited through a shadow mask to form  $17 \mu\text{m}^2$  row and column overlaps that define each memory cell. The  $16 \times 16$  array in Fig. 9.48b is fabricated using cold-welded rows and columns applied with a PDMS stamp (see Section 5.6.4).

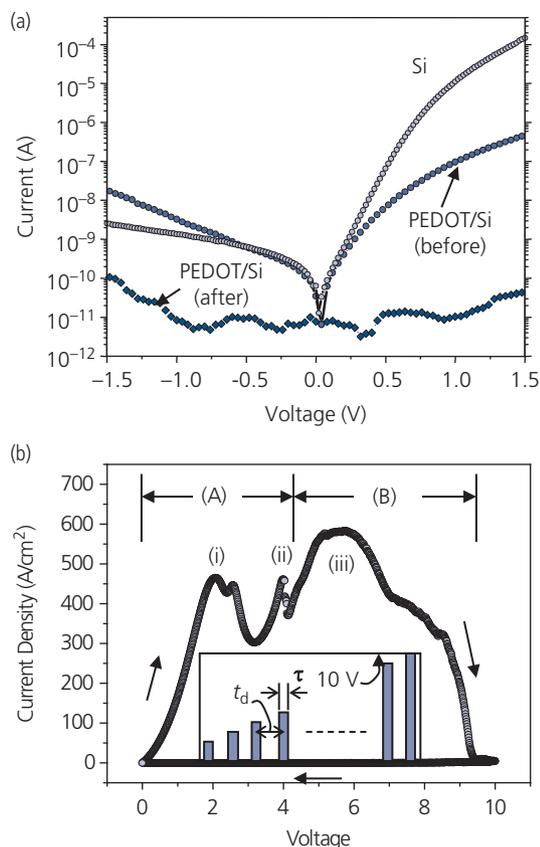

The asymmetric  $I$ - $V$  characteristics of one element are shown in Fig. 9.49a, along with the switching cycle in Fig. 9.49b. The forward current of the Si diode (open circles) reaches  $100 \mu\text{A}$  at a voltage of  $1.5 \text{ V}$ , whereas under reverse bias, the leakage is only  $2.3 \text{ nA}$  at  $-1.5 \text{ V}$ , yielding a rectifying ratio of  $\sim 10^5$ . Due to the series resistance of the thin organic film, the forward current is reduced to  $400 \text{ nA}$  for the memory element. To switch the fuse state from “closed” to “open,” the voltage is ramped at  $1.0 \text{ V/s}$  from  $0 \text{ V} \rightarrow 10 \text{ V} \rightarrow 0 \text{ V}$ . During each voltage step of duration  $t_d = 10 \text{ ms}$ , the voltage is applied for  $\tau = 4 \text{ ms}$  (a 40% duty cycle); see inset, Fig. 9.49b. Ramping the voltage to  $8 \text{ V}$  opens the fuse, reducing the current to a background leakage of  $\leq 10 \text{ pA}$  at all voltages applied. Hence, the contrast between a **1** and **0** is  $I_{\text{on}}/I_{\text{off}} \sim 10^4$  at a forward bias of  $1.5 \text{ V}$ . The memory elements irreversibly and reproducibly switch on the application of the voltage.

The film undergoes a transition to its high resistivity state by traversing two distinct regions: **A** from  $V = 0$

**Figure 9.48** (a) PEDOT:PSS fuse/Si p-i-n diode WORM memory array with a detail of a single memory element at the upper left. (b) SEM image of a WORM memory with only PEDOT:PSS fuses between row and column array electrodes fabricated by cold-weld electrode stamp transfer. The scale bar is  $10 \mu\text{m}$ . First publication in Nature, 2003.

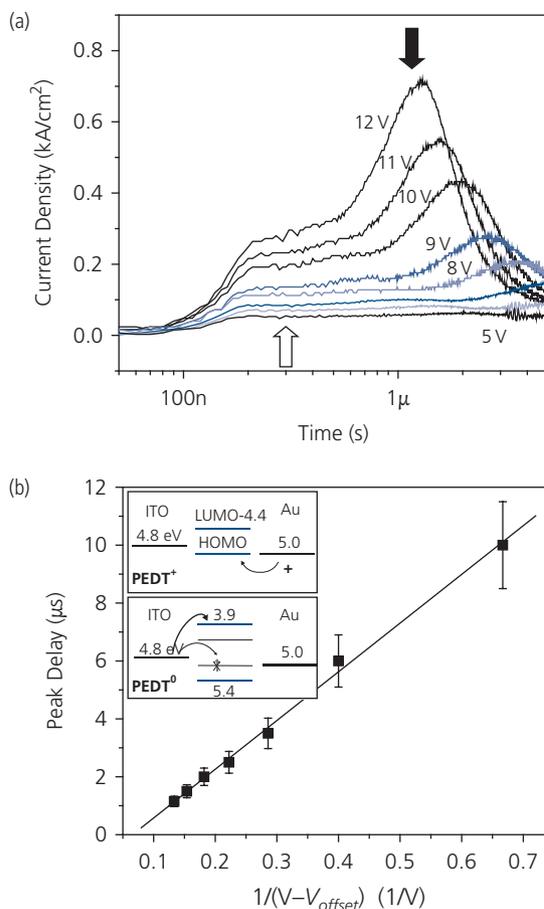

**Figure 9.49** (a) Current–voltage characteristics of the PEDOT:PSS/Si p-i-n diode before and after switching. (b) The switching process of the memory element. Two regions are observed during application of a ramp of switching voltage pulses. Region **A** results in small, semi-reversible increases in resistance, whereas **B** results in an irreversible,  $10^4$  increase in resistance. Features of note are labeled (i), (ii), and (iii). Inset: Switching pulse sequence (Möller et al., 2003).

First publication in Nature, 2003.

to 4 V and **B** at  $V \geq 4$  V. At the lowest voltages (0–2 V), the current density is reversible over the time scales of the experiment (minutes). At higher voltages, the current reaches a first (i), and then a second peak (ii). The permanent conductivity changes induced by sweeps of up to 4 V are small. The magnitude of the change depends on the pulse duration,  $\tau$ . The second, sharp peak (ii) that appears for lower voltage sweeps, is reduced in magnitude and broadens as  $\tau$  is increased from 0.5 ms to 4 ms. However, once the film is biased into region **B**, a qualitatively different process is initiated, resulting in a dramatic and permanent decrease in conductivity. Indeed, once the last broad peak (iii) appears, there is a precipitous decrease in conductivity by several orders of magnitude, and the fuse is permanently opened (Möller et al., 2003).

Figure 9.50a shows the transient response of a 55 nm thick PEDOT film sandwiched between Au and ITO

**Figure 9.50** (a) Transient response of the current density across a 55 nm thick PEDOT:PSS film vs. voltage during a  $>10 \mu\text{s}$  voltage pulse with a rise time of 100 ns. The hollow arrow shows the region where no changes in conductivity are observed. The solid arrow indicates the current peak at which there is a permanent drop in conductivity, as apparent from the decrease in current density following the peak. (b) Peak transient delay vs.  $1/(V - V_{\text{offset}})$ , where  $V_{\text{offset}} = 4.5$  V is required for electron injection. The straight line fit to the data yields an electron mobility of  $\mu_n = (1.7 \pm 0.4) \times 10^{-6} \text{ cm}^2/\text{V s}$ . Inset: Energy level diagrams of PEDOT in the oxidized (upper panel) and neutral (lower panel) states, along with the electrode arrangement (Möller et al., 2003).

electrodes at several different voltages. The response at  $>5$  V is separated into two regions: a plateau (hollow arrow), followed by a current peak (solid arrow). The delay between the pulse onset and the peak decreases with increasing voltage, reaching a current density of  $700 \text{ A/cm}^2$  after  $1 \mu\text{s}$  for a pulse height of 12 V. The current peak corresponds to initiation of the permanent change in film conductivity in region **B**. The peak delay from the leading edge of the voltage pulse is linearly dependent on  $1/(V - V_{\text{offset}})$ , where  $V_{\text{offset}} = 4.5$  V is the voltage drop across the Au contact necessary to inject an appreciable concentration of electrons.

The transient response is due to of double carrier injection (Hack and Street, 1992). In PEDOT, the

current is primarily carried by holes (Johansson et al., 2002). However, at  $V > V_{offset}$ , electrons are injected, thereby neutralizing some of the hole space charge. This, in turn, increases the internal electric field within the polymer, leading to a further increase in hole current. This phenomenon of “double injection gain” is similar to current gain in a photoconductor (see Section 7.1.1), and leads to the current peak observed. At higher pulse voltages, the peak delay decreases due to the larger density of injected electrons. Although the current is controlled by the presence of electrons, they do not contribute appreciably to the film conductivity.

Since PSS is electrically insulating, conduction occurs by hole transport along low resistivity percolation pathways formed by PEDOT<sup>+</sup> chains throughout the film. The energy levels of PEDOT<sup>+</sup> responsible for charge transport are shown in the top inset, Fig. 9.50b (Xing et al., 1997, Greczynski et al., 2001, Heuer et al., 2002). Holes are injected from both Au and ITO into the HOMO of PEDOT<sup>+</sup> at 5.0 eV. The LUMO is 0.6 eV above the HOMO, presenting a barrier to electron injection. To promote electron injection, PEDOT<sup>+</sup> is electrochemically reduced to PEDOT<sup>0</sup>, and the energy level scheme changes to that in Fig. 9.50b, lower inset. In neutral PEDOT<sup>0</sup>, electrons can only occupy the LUMO at 3.9 eV. Hence, there is rapid, sequential oxidation and reduction by the successive transfer of holes and electrons into the polymer.

The reduction of PEDOT<sup>+</sup> continues with increasing current until a maximum number of chains in the neutral PEDOT<sup>0</sup> state are achieved at voltages  $>2$  V but still within region **A**. At  $V_{offset} > 4.5$  V, electron injection leads to process **B** where a permanent decrease in film conductivity by up to a factor of  $10^3$  occurs. The temperature rise of  $\sim 200^\circ\text{C}$  at current densities of  $\sim 1\text{kA}/\text{cm}^2$  dedopes the PEDOT<sup>+</sup> (Pei et al., 1994). Thermal effects can lead to segregation of the PEDOT and PSS components, creating additional and permanent energy barriers at the contacts that can greatly decrease the conductance between electrodes (Xu et al., 2006).

An  $N \times N$  resistive matrix memory is addressed row-by-row by measuring the current flowing from  $N$  columns to the selected row. Hence, the maximum number of pixels in a row that can be accommodated without leading to read errors (i.e. detecting that a pixel is written when in fact it is not) is  $N = \text{mod} |I_{F1}/I_{F0}| / S_B \sim 10^3$ , assuming the signal-to-background current ratio required to reliably distinguish a **1** from a **0** is  $S_B = 10$ . Here,  $I_{F1}$  and  $I_{F0}$  are the forward biased currents for the two logical states shown in Fig. 9.49a. Assuming that the current of a written

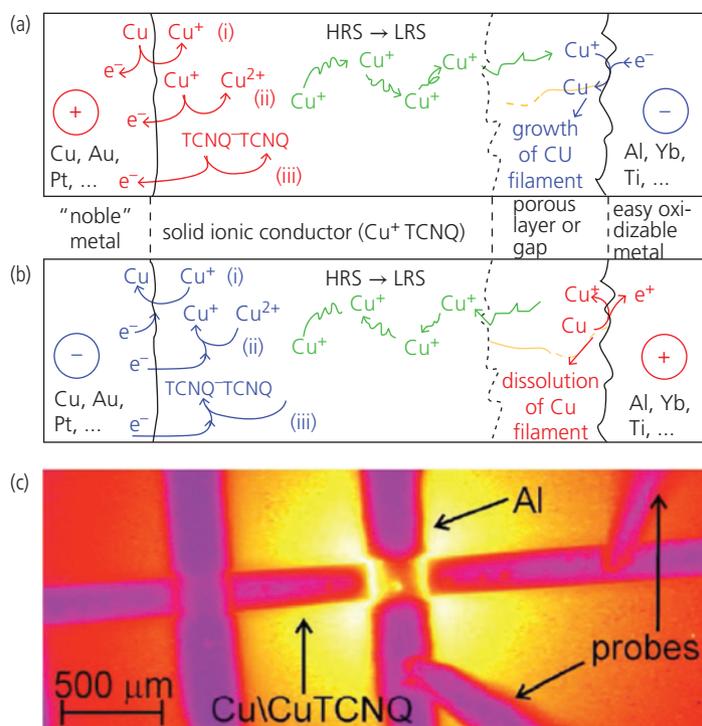

pixel is  $<10^{-4}$  of the forward-biased current of a single element, this suggests that a 1 Mb memory is achievable with these devices.

### 9.4.3 Reversible resistive memories

Conductive filament growth has been used for achieving non-volatile, reversible memory elements. Analogous to the WORM, the formation of conducting metallic filaments is thermally activated. Switching between the conducting and insulating states has been attributed to the formation of conductive salts between a metal electrode and an organic film. For example, the conducting  $\text{Cu}^+\text{TCNQ}^-$  salt can be neutralized into a non-conducting  $\text{Cu} + \text{TCNQ}$  state by reversing the polarity between Cu contacts to the TCNQ thin film. Alternatively, the non-conducting state is associated with the formation of a thin, insulating oxide at the counter electrode to the Cu (Billen et al., 2007). The conductivity of a Cu/CuTCNQ/Al memory cross point unexposed to air is in its conducting, or *low resistance state* (LRS) that cannot be switched to a *high resistance state* (HRS) by applying a voltage. When exposed to air, the HRS is the native state, which switches to a LRS by applying either positive or negative 5–10 V.

The model proposed for filamentary conduction is illustrated in Fig. 9.51a, with the reverse process of filament dissolution in Fig. 9.51b. Switching from HRS to LRS occurs via the reduction of Cu from the anode to  $\text{Cu}^+$ , or  $\text{Cu}^{2+}$  from  $\text{Cu}^+$ , with  $\text{TCNQ}^-$  in the film bulk (processes i, ii, and iii in Fig. 9.51a, respectively). The Cu cations migrate toward the oxidized cathode where they penetrate the imperfect, very thin insulating coating. Oxidation of the  $\text{Cu}^+$  at the cathode surface produces a metallic Cu filament that, over time and under sufficient bias, shorts the oxide, dramatically decreasing the resistance. Reversing the contact polarity results in the opposite reaction, whereby neutral Cu in the filaments is reduced, dissolving the filaments and driving the element from LRS back to HRS. The thermal image in Fig. 9.51c shows hot spots that likely arise from conduction along the metallic filaments from the top Al contact.

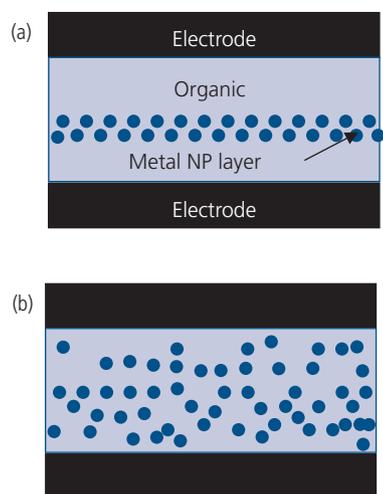

Note that voltage applied to query the memory state can reverse either of these electrochemical processes, ultimately destroying the information held within the element. The CuTCNQ system can be used for  $\sim 10^4$  cycles before a refresh voltage pulse is required (Kever et al., 2006). A drawback of this memory mechanism is its sensitivity to the fabrication process and ambient conditions, making it somewhat irreproducible and unreliable when fabricated in

**Figure 9.51** (a) Proposed electrochemical process resulting in the formation of conductive Cu filaments (gold color) that penetrate the thin, porous oxide formed on the metal contact. This leads to transformation from the high resistance (HRS) to the low resistance (LRS) state. (b) Dissolution of the filaments due to oxidation of Cu. Oxidation is shown in red, reduction in blue, Cu<sup>+</sup> transport in green. (c) Infrared (thermal) image of a Cu/CuTCNQ/Al memory cross point. Yellow areas are hottest, blue are coldest. Note the hot (pinhole) spot within the central cross point (Billen et al., 2007).

different labs, or when used under less than perfectly controlled conditions. This sensitivity is expected for a process that depends on the random formation of pinholes whose density and dimensions are subject to variability. These variations can be significantly reduced by intentionally growing thin oxide layers using chemical vapor deposition (CVD) or atomic layer deposition (Muller et al., 2009). Of greater concern is that  $I_{on}/I_{off} \sim 10\text{--}100$  is too small for use in large-scale memory arrays.

Metal NP dispersions within an organic matrix have also exhibited reversible resistance over several orders of magnitude, along with very fast switching between the LRS and the HRS. This resistive memory device does not require the adventitious and somewhat uncontrolled formation and dissolution of filaments, and hence it can potentially result in less process-dependent, more predictable performance. Illustrations of two different NP resistive memory architectures are provided in Fig. 9.52a and b. The NPs can be intentionally deposited in a narrow zone or layer (Ma et al., 2002, Yang et al., 2006), or they can be homogeneously dispersed throughout the bulk of the resistive zone (Tseng et al., 2005, Lin et al., 2007b).

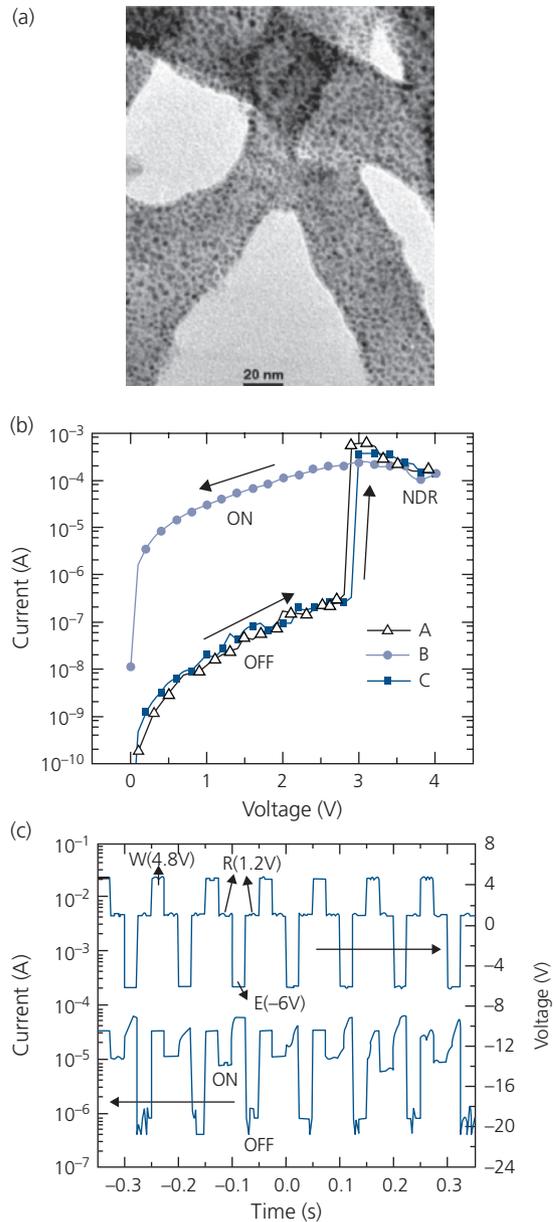

**Figure 9.52** Resistive memory devices employing (a) a layer of metal nanoparticles (NPs) embedded in a conducting organic matrix sandwiched between two metal electrodes. (b) A homogeneous blend of NPs and organic.

The layered structure (Fig. 9.52a) is conveniently fabricated by vacuum thermal evaporation of a combination of thin ( $\sim 50$  nm) small molecule organic layers that sandwich a thin ( $\sim 20$  nm), non-wetting metal

layer. The blend memory cell comprises a conducting polymer mixed in solution with the metal NPs and cast onto the substrate. Both devices show nearly identical performance, and are largely independent of the composition of the NPs and the conducting organic thin films. Applying a voltage larger than a threshold,  $V_1$ , between the counter electrodes induces an abrupt increase in current. The LRS has a conductivity that is  $100\text{--}10^4$  higher than the HRS. Applying a reverse potential returns the resistor to its HRS.

Results from a metal NP/polymer blend memory element are shown in Fig. 9.53. The device comprises a 70 nm thick Au NP/PANI film spin coated onto an Al electrode, and then coated with a vacuum deposited Al counter-electrode. An image of a region of the Au NP/PANI nanofiber film is provided in Fig. 9.53a. There is a high density of NPs that condense within a fibrous conducting network. Switching is observed for NP diameters  $< 20$  nm, whereas at larger diameters the device switches into its LRS only once. Three switching cycles of the device are shown in Fig. 9.53b. In sweep A, the bias is ramped from 0 to +4 V. At  $V_1 = 3$  V, the current abruptly jumps from 100 nA to 100  $\mu$ A. At higher voltages, there is a weak decrease in current due to a negative differential resistance. The voltage is then decreased from +4 V back to 0 V (sweep B). The device remains in the LRS during this sweep, with the current falling at the same rate as when the device is in the HRS. The LRS is returned to the HRS (i.e. the contents of the memory are erased) by applying a reverse bias of  $-5$  V. It can be turned on once again by following the same voltage sweep as used initially (sweep C). It is noteworthy that the LRS and HRS during this and subsequent sweeps are nearly identical. The response to a sequence of read, write and erase voltage pulses is shown in Fig. 9.53c, showing the reproducibility of the switching characteristics over several cycles (Tseng et al., 2005).

The data are retained with no significant change in conductivity for over 3 days even if small voltage stresses are periodically applied. Importantly, the switching time is  $\sim 25$  ns, which is limited by the resistance-capacitance ( $RC$ ) charging time of the resistor. Note that similar qualitative and quantitative behavior is obtained for the layer structure (Fig. 9.52a) employing a 20 nm thick Al layer sandwiched between two 50 nm thick AIDCN organic thin films (Ma et al., 2002). Microscopic images of Al layer indicate its coalescence into NPs embedded into the organics due to dewetting during deposition (Yang et al., 2006). We have seen in Section 7.5.2 that thin Ag layers deposited onto organic surfaces can diffuse deep into the film bulk, and hence the structure may

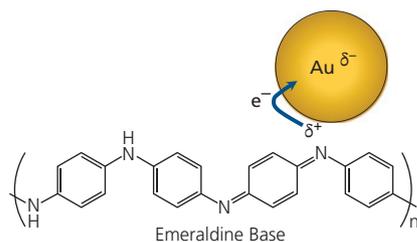

**Figure 9.53** (a) Transmission electron micrograph of a section of a Au NP/PANI blend. The nanofiber regions contain a high density of NPs visible as black dots. (b) Switching characteristics of the blend showing an approximately 1000 times increase in current from the HRS to the LRS. Current switching occurs at  $V_1 = 3$  V. The memory contents are erased at  $V_2 = -5$  V. There is a small negative differential resistance (NDR) above  $V_2$ . (c) Top: Sequence of write (W), read (R), and erase (E) voltage pulses. Bottom: Current response to the voltage cycle (Tseng et al., 2005).

actually be a more homogeneous dispersion of NPs than suggested in Fig. 9.52a.

The nearly identical resistance switching properties of devices containing an apparently uniform metallic layer and one in which NPs are dispersed within the polymer, and the independence of the characteristics

to the choice of metal, suggest that the same mechanism is responsible for switching in both. The source of the switching has been attributed to several factors, including tunneling of charge into the metal NPs (Bozano et al., 2005) and trap filling that creates large changes in the space charge limited current (Lin et al., 2007a). However, neither of these mechanisms appears to explain the long retention time of the memory state, nor the very fast switching time of <25 ns.

A plausible suggestion for conductivity switching is analogous to that used to describe switching of PEDOT:PSS in the WORM memory, and in CuTCNQ in filamentary memories. Prior to switching, the Au NP and the PANI are both neutral, and hence the film conductivity is low. When the voltage exceeds  $V_1$ , there is partial charge transfer from PANI to Au, as illustrated in **Scheme 1**. As in the case of the  $\text{Cu}^+\text{TCNQ}^-$  complex,  $\text{NP}^-\text{PANI}^+$  becomes conductive. To reverse the process, a negative voltage is applied to neutralize the two components of the film. The charge transfer process is extremely rapid, consistent with the fast switching time of the devices. Further, the transferred charge is stable due to the large energy barrier between the metal and the polymer, making the relaxation time (i.e. memory state decay) long compared to that expected for trapping at deep levels within a semiconductor energy gap. The existence of a charge transfer state has been affirmed using X-ray photoelectron spectroscopy, where it was found that the  $\text{N}_{1s}$  state of the PANI is shifted in the composite compared to a neat film. Similarly, the binding energy of the Au electrons in the  $4f_{5/2}$  state is found to decrease in the composite. Finally, microscopic probing of the NPs using conducting tip atomic force microscopy shows a switching behavior similar to that observed by the film as a whole (Tseng et al., 2005). Taken together, these data provide a compelling case for charge transfer switching, consistent with phenomena observed for the other resistive organic memories described above.

#### 9.4.4 Ferroelectric capacitors and diodes

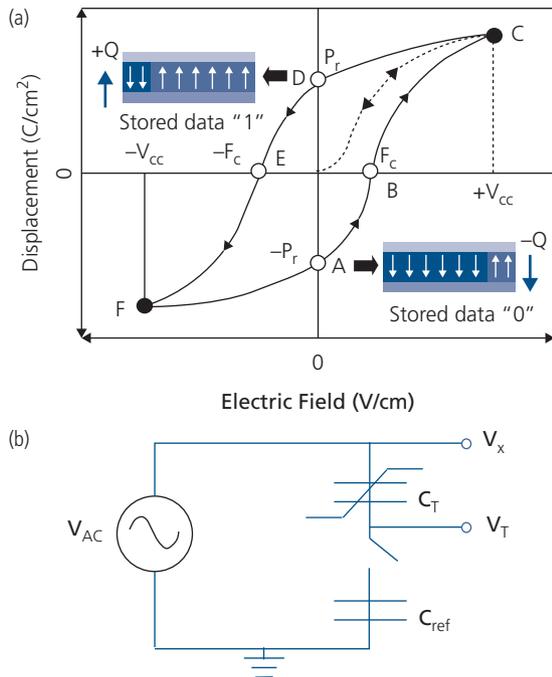

The last two-terminal structure to be considered is based on the *ferroelectric effect*. Analogous to a ferromagnetic material, a ferroelectric is a dipolar material that has a spontaneous polarization below its *Curie temperature*. When an external electric field of sufficient magnitude is applied opposite to the direction of the dipoles, the dipole moment flips to find a new equilibrium. The field required to rotate the dipole moment is the *coercive field*, or  $F_C$ . Once the field is removed, the polarization relaxes to its *remnant polarization*,  $P_r$ . Since ferroelectric polarization requires alignment of molecular dipoles, the materials must be ordered, and preferably crystalline. Also, polarization switching entails the physical rotation of the molecules, and hence it is slow compared to charge transfer in resistive memories.

The polarization is related to the electric displacement vector,  $\mathbf{D}$ , via

$$\mathbf{D} = \vec{\epsilon}_r \mathbf{F} + \mathbf{P}, \quad (9.33)$$

where  $\vec{\epsilon}_r$  is the relative permittivity tensor,  $\mathbf{F}$  is the field, and  $\mathbf{P}$  is the polarization vector. The characteristic  $D$  vs.  $F$  behavior of an archetype ferroelectric is shown in Fig. 9.54a. At electric fields that are insufficient to switch the polarization state, or for a completely depolarized sample, the relationship between  $D$  and  $F$  is approximately linear and reversible, as shown by the dotted line near the origin. In a spontaneously polarized sample (point A in Fig. 9.54a) or after applying a high electric field, most but not all of the molecules are aligned (inset A, equivalent to logical 0), resulting in a net polarization  $-P_r$ . Applying an electric field in the direction opposite to  $-P_r$  results in a monotonic reduction of the displacement, until  $F = F_C$ . At this point (B), the material is completely depolarized. Further increases in  $F$  result in preferred alignment along the field direction until the displacement saturates at voltage  $V_{CC} = F_{CC} \cdot t$ , where  $t$  is the film thickness. The polarization then relaxes to a new remnant value,  $P_r$ , with the dipoles pointing opposite to that of their original orientation (inset D, logical 1). The hysteresis is complete by reversing the field to  $-F_C$  (point E), and then to  $-V_{CC}$  at point F, and back to  $F = 0$ . The open loop created by the variation in  $D$  with  $F$  provides a memory window of width  $2F_C t$ . The read-write memory function is achieved, therefore, by sweeping the external field between  $\pm F_C$ . A larger  $F_C$  results in a lower error rate in distinguishing between the 1 and 0 states. Note that at temperatures larger than the Curie temperature, the memory window vanishes, although the  $D$  vs.  $F$  characteristic retains its S-shape. At these temperatures, the material is *paraelectric*.

The field applied to a ferroelectric changes its polarization, and hence the capacitance of the element. The memory state is determined by measuring its

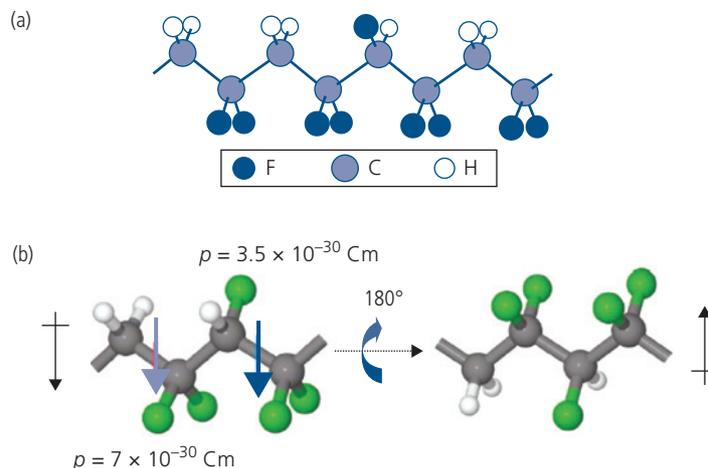

**Figure 9.54** (a) Hysteresis in the electrical coercivity of a ferroelectric. The remnant polarization,  $P_r$ , and the coercive field  $F_c$  are shown. The dotted line from the origin to point C shows the displacement,  $D$ , vs. electric field in the initially unpolarized state. The orientations of the electric dipoles in the film are illustrated in the insets. (b) Sawyer–Tower circuit used for measuring the test capacitance,  $C_T$ , of the ferroelectric using a second reference capacitor that can be switched out during ferroelectric polarization. Applying a voltage  $V_x = \pm V_{cc}$  polarizes  $C_T$ .

capacitance,  $C_T$ , employing the Sawyer–Tower circuit in Fig. 9.54b (Sawyer and Tower, 1930). This is a capacitive voltage divider network comprising the unknown ferroelectric capacitor, and a known reference,  $C_{ref}$ . The state of the ferroelectric capacitor is set by closing the switch, applying a d.c. voltage,  $V_x$ , and an a.c. test signal supplies the series capacitance network. Then,  $C_T$  is determined by measuring the voltages,  $V_x$  and  $V_T$ . Since a small voltage is applied during the read cycle, the polarization state of the capacitor is changed, degrading its contents. After a number of read cycles, the memory is refreshed to restore it to its original logic state.

The ferroelectric effect in organics is obtained using dipolar molecules that undergo a conformational reorientation when placed in an electric field. Ferroelectricity was noted in polyvinylidene fluoride by Kawai (1969) and later in various nylons. Today, the most commonly employed ferroelectric in both two and three terminal devices is a copolymer of VDF and TrFE (P(VDF-TrFE)) in a molar ratio of 2:8. This material has a large remnant polarization of approximately  $10 \mu\text{C}/\text{cm}^2$  and is stable in air. Small molecules have also shown ferroelectric effects. However, given their steric bulk, it is difficult to reorient the molecules in the solid state, whereas polymer chains only need to be twisted about the backbone axis. Liquid crystalline small molecules have the ability to undergo rotations required to exhibit ferroelectric dipole reorientation.

A segment of the copolymer P(VDF-TrFE) in Fig. 9.55a illustrates the atomic orientation along the backbone. Its ferroelectric properties are inferred from

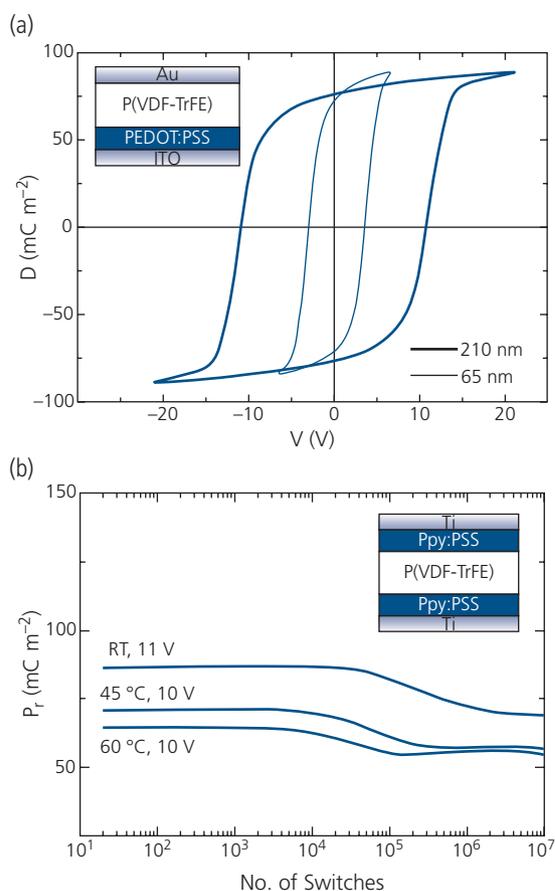

**Figure 9.55** (a) Structure of ferroelectric polymer P(VDF-TrFE). (b) The molecule is twisted about its molecular backbone by  $180^\circ$  under the influence of an external electric field. The dipole moments due to the regular orientation of the electron withdrawing F atoms (green) and the donating C atoms (gray) along the backbone segment are large, giving this molecule its ferroelectric properties. Hydrogen atoms are shown in white. The total molecular dipole moment orientation is shown by the arrows to the left and right of the molecules. Adapted from Heremans et al. (2011).

Fig. 9.55b. The *trans* conformation of both the VDF and TrFE segments results in parallel dipole moments pointing between the electron rich F atoms, and electron deficient C atoms. The dipoles of the individual segments add to create a large, spontaneous polarization when the film is deposited and thermally annealed at 140–150°C, or by stretching to elongate the polymer chains (Naber et al., 2004, Nguyen et al., 2008). The higher dipole moment of  $7 \times 10^{-30}$  C m is contributed by VDF, and a similarly oriented TrFE has a dipole moment of  $3.5 \times 10^{-30}$  C m when oriented in the all-*trans* configuration. A coercive field of 500–700 kV/cm directed opposite to the dipole can twist the chain to lower the dipole energy. The information state is changed by the physical rotation of the polymer chain to reverse its polarization state. For P(VDF-TrFE), this takes approximately 160  $\mu$ s (i.e.  $\sim 6$  kHz) (Kim et al., 2009). The large coercive fields require high switching voltages, or the use of very thin films. The magnitude of the ferroelectric polarization is reduced in the thinnest films, perhaps due to surface roughness and pinning of the dipole near the polymer/electrode interface.

The switching behavior of a Au/P(VDF-TrFE)/PEDOT:PSS/ITO capacitor is shown for two different ferroelectric layer thicknesses in Fig. 9.56a. The low switching voltages, even for films as thin as 65 nm, is attributed to the smooth surface presented by PEDOT:PSS along with the Au electrode that do not react with the P(VDF-TrFE) to create a non-ferroelectric dead zone near its surface, as is observed using an Al electrode. The switching time ranges between 100  $\mu$ s to 16  $\mu$ s as the coercive field is increased from 800 to 1400 kV/cm. Over this range, no significant penalty in the memory window width is observed (Naber et al., 2004).

Figure 9.56b shows the memory retention (or *fatigue*) of a substrate/Ti/Ppy:PSS (9 nm)/P(VDF-TrFE) (50 nm)/Ppy:PSS (15 nm)/Ti capacitor at room temperature, 45°C, and 60°C. The Ppy:PSS film prevents reaction with the electrode metals, or their diffusion into the ferroelectric film. This permits the use of very thin P(VDF-TrFE) layers, leading to switching at only 2.6 V and  $2F_{Ct} = 0.85$  V. The thin film device also features a switching time of 30  $\mu$ s (30 kHz). At room temperature, the device suffers a 20% loss in remnant polarization after  $10^7$  cycles, with an increase in coercive voltage to 4.5 V and a concomitant closing of the memory window to  $2F_{Ct} = 0.32$  V. The maximum  $P_r$  and the retention time decrease as the Curie temperature is approached (Xu et al., 2007).

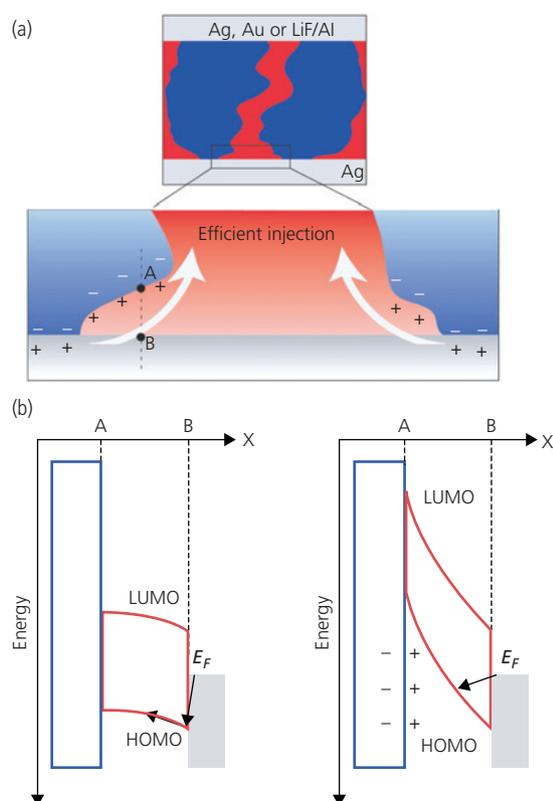

**Figure 9.56** (a) Hysteresis loops of the ferroelectric capacitor shown in inset for two different P(VDF-TrFE) film thicknesses (Naber et al., 2010). (b) Remnant polarization vs number of switching cycles and temperature of the device in the inset (Xu et al., 2007).

A shortcoming of the capacitive memory is the destructive nature of the read-out cycle: a voltage pulse required to read the memory state leads to degradation or loss of that state. A diode composed of a ferroelectric material, however, serves as an electrically switchable resistive memory element whose logic state can, in principle, be non-destructively queried. Rectification also is useful for reducing sneak currents in memory arrays (see Fig. 9.46).

Rectification can be achieved by blending a second component with the ferroelectric, thereby forming a junction, or the ferroelectric material itself can form a rectifying Schottky barrier with its contacts. The diode conductivity is then switched as follows. Under forward bias, polarization oriented parallel to the electric field and perpendicular to the junction, decreases the local depletion region width. This permits tunneling across the junction, leading to a large forward current. When the polarization is reversed, the depletion region becomes large, consequently

increasing the resistance and hence decreasing the conductivity. Since the diode forward current is exponentially dependent on voltage, the difference in current between logic states can be several orders of magnitude. However, ferroelectrics tend to have very low conductivities, which reduce the contrast between logic states. To increase the conductivity, the material needs to be doped, although mobile charges from the dopant screen the dipole field, thus reducing  $P_r$ .

The tradeoff between conductivity and polarization can be substantially reduced by using blends of conducting and ferroelectric polymers. The phase separation of the components results in a bicontinuous network that forms a bulk heterojunction between the electrodes. An example BHJ switching diode structure is illustrated in Fig. 9.57a. The conductive region comprising P3HT is contacted by blocking anode and cathode (e.g. Ag) contacts, or a Ag contact on one surface and an ohmic (e.g. LiF/Al) contact on the other. The former, symmetrically contacted device

**Figure 9.57** (a) Illustration of the nanostructure domains of a phase separated P3HT (red regions)/P(VDF-TrFE) (blue regions) diode memory element. (b) Unpolarized (*left*) and polarized (*right*) energy level diagrams of the memory element. The diagrams correspond to the region marked A-B in (a), with the ferroelectric to the left of point A, the polymer between A and B, and the metal to the right of B (Asadi et al., 2008).

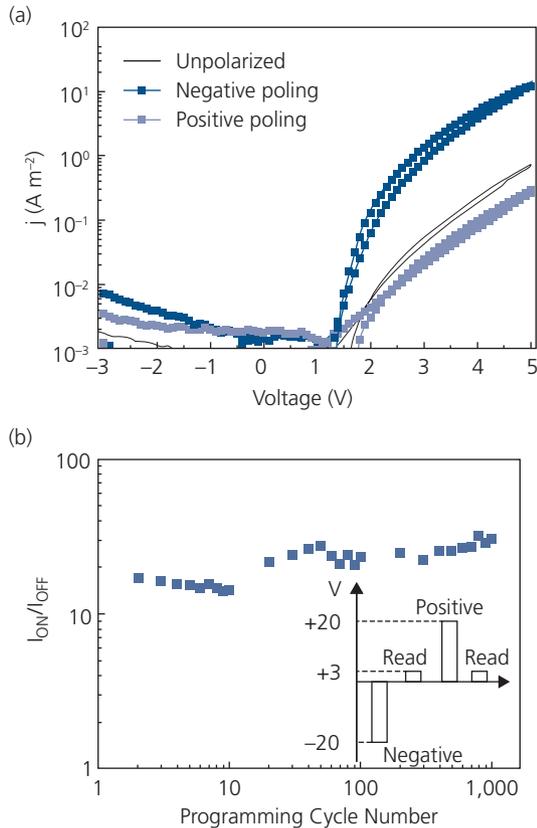

is resistive, whereas the latter is a diode useful in cross-point memory arrays.

The memory diode operation is understood from the energy level diagrams in Fig. 9.57b. In the unpolarized state (Fig. 9.57b, left), the metal/polymer barrier prevents charge injection, and the diode is non-conducting. The ferroelectric is polarized by applying a voltage pulse to result in an internal field with  $F > F_C \sim 500$  kV/cm. The polarization field tips the bands of the conducting polymer, resulting in a large tunneling injection current into the HOMO, as shown in Fig. 9.57b, right. Note that a polarization pulse of the opposite polarity can also induce charge injection, but into the LUMO instead (with a consequent reversal of the current direction). The magnitude of the tunneling current is exponentially dependent on the barrier width. Hence, the nanostructure of the interpenetrating polymers must be thin (typically  $\leq 20$  nm). The structure successfully separates the conductive and ferroelectric regions, with the high energy barriers between P3HT and P(VDF-TrFE) preventing neutralization of the dipoles by free charges that reside within the separate thin film domains.

The current–voltage characteristics of an asymmetric Ag/P3HT:P(VDF-TrFE) (1:10, 14–25 nm)/LiF/Al diode are shown both before and after poling at  $\pm 20$  V in Fig. 9.58a. The current ratio is  $I_{on}/I_{off} \sim 50$  at +3 V, with a reverse leakage current of approximately  $300$  nA/cm<sup>2</sup>. The switching time between the states is  $500$   $\mu$ s. The memory state of the diode extends to more than 1000,  $-20$  V write/ $3$  V read/ $+20$  V write cycles, as shown in Fig. 9.58b. The  $I_{on}/I_{off}$  shows no change over this large number of pulses, indicating that the cycle scheme is nondestructive of the contents of the memory. Furthermore, the data retention time is  $>11$  days, comparable to that of P(VDF-TrFE) capacitive memories. This device shows that separating the conductive and ferroelectric memory regions is possible using organic thin films. However, the switching times and on/off ratios still fall short of capacitive memories using this same ferroelectric materials system. This is compensated, to some degree, by the simplicity of integration of the resistive memory element with a diode in a single device.

### 9.4.5 Transistor memories

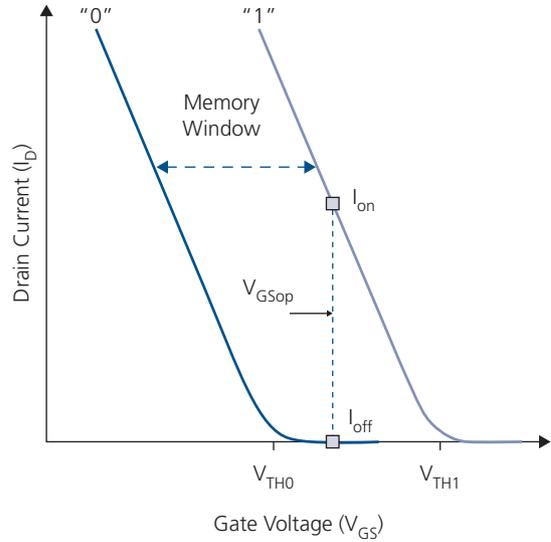

Organic thin film transistors present an alternative architecture for achieving a resistive memory. In a transistor memory, charge is introduced and retained in the gate insulator, resulting in a hysteretic shift in the threshold voltage ( $V_T$ ). Equivalently, the dielectric

**Figure 9.58** (a) Current–voltage characteristics of a Ag/P3HT:P(VDF-TrFE) (1:10)/LiF/Al diode in the unpolarized, negatively and positively polarized states. (b) On/off current ratio vs. number of programming cycles. Inset: Programming cycle pulse sequence (Asadi et al., 2008).

constant of the insulator can be changed by the excess charge, or by changing its dielectric properties. The change in dielectric properties changes the potential at the channel/insulator interface. This in turn results in switching the transistor channel between a conducting (logical 1 state) and a non-conducting (logical 0) state at the same gate voltage. The drain current ( $I_D$ ) vs. gate voltage ( $V_{GS}$ ) characteristics of a transistor memory element are shown in Fig. 9.59. By shifting the threshold voltage by  $\Delta V_T = |V_{T1} - V_{T0}|$ , the current at the operating voltage of  $V_{GSop}$  can differ by several orders of magnitude between  $I_{on}$  and  $I_{off}$ . The memory window of the transistor is  $\Delta V_T$ , and serves the same purpose of memory retention as do the hysteresis loops that characterize WORM, filamentary and NP resistive memories.

An advantage of using transistor memory elements is that they combine the variable resistive medium (i.e. the channel) with a nonlinear switch (activated by the gate potential) used to access the element. By using three interconnections for each memory cell as

**Figure 9.59** Drain–gate transfer characteristics of a memory transistor whose threshold voltage is increased from  $V_{TH0}$  to  $V_{TH1}$  when switched from the 0 to the 1 logic state, respectively. The corresponding currents at the operating voltage,  $V_{GSop}$  are  $I_{on}$  and  $I_{off}$ .

illustrated in Fig. 9.47, the gate potential can switch the channel from  $I_{on}$  to  $I_{off}$ . To be effective, the change in gate voltage must not simultaneously change its memory state. This is avoided by integrating a second transistor within each cell, where one is used for accessing the other transistor that retains the data. The combination of functions of access and memory storage can minimize sneak currents in arrays. The transistor memory also eases integration of the memory function with other transistor circuit elements such as digital logic.

Switching the charge trapped within the gate insulator changes the potential at the insulator/semiconductor interface. The charge modulates the voltage required to achieve a desired drain current. In Eq. 8.75, we showed that the change in threshold voltage is given by

$$\Delta V_T = \frac{q\Delta N_{tr}}{C_i}, \quad (9.34)$$

where  $\Delta N_{tr}$  is the change in trapped charge in the insulator and  $C_i$  is the insulator capacitance. A memory transistor relies on the reversible and intentional injection of charges into deep traps that are controllably introduced into the dielectric during fabrication to achieve reproducible retention times and a large memory window.

A dielectric whose charge density is controlled, and that can retain the charge or polarization state (and hence its value of  $C_i \propto \epsilon_r/t$ , where  $t$  is the insulator

thickness), is called an *electret*. An electret can take on many different forms, although the most common realization in organic memory transistors are based on (i) charge trapping at interfaces within the dielectric layer, (ii) floating gates, (iii) NP dispersions, and (iv) ferroelectric gate dielectrics. The transistor memory is erased when the charge stored in the electret is neutralized, for example by reversing the gate “writing” voltage. Transistor memories, like resistive memories, can therefore be both non-volatile and programmable.

#### 9.4.5.1 Interface charge trapping

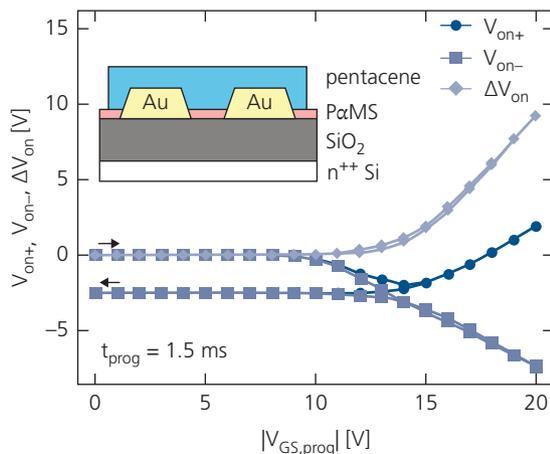

An electret can be formed by using a gate insulator comprising two different regions. One is an ultrathin dielectric that contacts the semiconducting channel, and a second is a thick dielectric of a different composition that forms the bulk of the gate insulator. The interface between the two dielectric layers provides a site for charge trapping, and hence long-term storage. The traps are charged by applying a sufficiently large gate potential to cause tunneling from the channel into the traps through the thin dielectric. To erase the memory, the gate potential is reversed to attract the opposite charges, thereby neutralizing the traps.

An example of a charge trap OTFT is illustrated in the inset of Fig. 9.60. The bottom gate, bottom contact (BG/BC) transistor consists of a  $n^{++}\text{Si}$  gate contact coated with a 20 nm thick, thermally grown  $\text{SiO}_2$ , first insulator. The Au source (S) and drain (D)

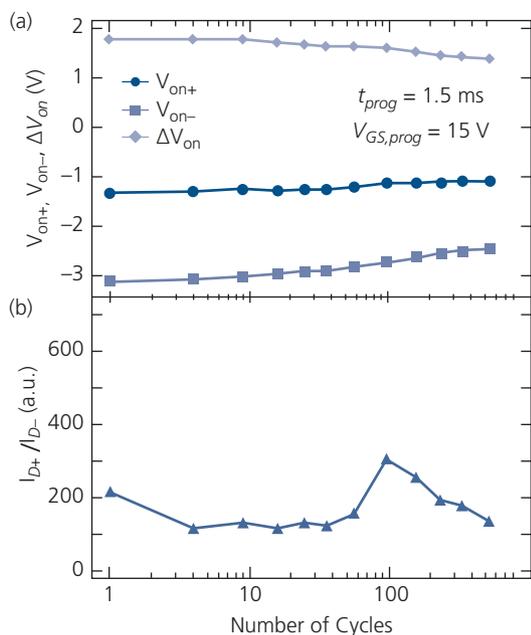

contacts are deposited, followed by dipping the structure into a solution containing a fluorinated thiol SAM that selectively attaches only to the Au surfaces. This monolayer serves as a “resist” that prevents attachment of the 4 nm thick PaMS second insulating layer that is deposited from a 0.1 wt% toluene solution. The pentacene channel coats the entire substrate to form OTFTs with gate lengths of  $L = 10 \mu\text{m}$  and widths of  $W = 1 \text{ mm}$ . The PaMS is sufficiently thin to permit tunneling of electrons and holes from the pentacene to the trap layer that resides at the PaMS/ $\text{SiO}_2$  interface.

The switching characteristics of the memory OTFT are shown in Fig. 9.60. Two onset gate voltages,  $V_{on-}$  and  $V_{on+}$  are defined at the point where  $I_D$  reaches 100 pA. The memory window is  $\Delta V_{on} = |V_{on+} - V_{on-}|$ , which is approximately equal to  $\Delta V_T$ . Here, the onset voltages are obtained by applying a programming gate potential,  $V_{GS,prog}$ , over a time window of length,  $t_{prog}$ .  $V_{on-}$  is the onset voltage after the negative write pulse of  $-V_{GS,prog}$  that attracts holes from the channel into the dielectric traps. By reversing the voltage to  $+V_{GS,prog}$  for the same duration, electrons are attracted to the traps. This opens a memory window by shifting the onset voltage to  $V_{on+}$ . The onset voltages change at  $V_{GS,prog} = 10\text{--}14 \text{ V}$ . At this point, there is hysteresis in the onset voltages but there is no memory retention since  $\Delta V_{on} = 0$ . However, above 14 V,  $\Delta V_{on}$  increases to 10 V when  $V_{GS,prog} = 20 \text{ V}$ , indicating that charge is stored via tunneling, and moreover, it can be removed when the programming voltage is reversed. The switching time of the memory state is  $t_{prog} = 1.5 \text{ ms}$ . The mobility in the channel is also a function of the memory state. That is, the hole mobility decreases from its peak of  $0.28 \text{ cm}^2/\text{V s}$  to  $0.16 \text{ cm}^2/\text{V s}$  when the traps are negatively charged, presumably due to increased scattering at the insulator/pentacene channel interface. However, there is no such effect on the mobility for positively charged, or neutral traps (i.e. when the memory state is erased) (Debuquoy et al., 2009).

Two important characteristics of a memory element are the fatigue experienced by the device after repeated read/write cycles, and the retention time after the memory state has been established. Repetitious cycling of a memory can induce irreversible damage to the interface, resulting in a decrease in the memory window. The current onset voltage and the memory window up to 800 read/erase cycles of the device in Fig. 9.60 are shown in Fig. 9.61a. The voltages are stable over the first 100 cycles, at which point the contrast between them begins to fade. However, even after 800 cycles, the memory window is only reduced from 1.8 V to 1.4 V. The drain current ratio

**Figure 9.60** Negative and positive turn on voltages ( $V_{on-}$  and  $V_{on+}$ , respectively), and their difference ( $\Delta V_{on}$ ) vs. gate-source programming voltage ( $|V_{GS,prog}|$ ) for a memory transistor employing a charge trap layer at the interface between two different gate insulators. Inset: Illustration of the OTFT with a bottom Si gate, and bottom Au S and D contacts. The traps exist at the interface between the PaMS and  $\text{SiO}_2$  gate dielectrics. **Figure 9.61** (a) Onset and memory window voltages as functions of the number of read/erase cycles of the device in Fig. 9.60. (b) The ratio in drain currents obtained at a transistor operating point of  $V_{GS} = -1.5$  V and  $V_{DS} = -0.02$  V. The write and erase states are obtained using programming voltages of  $V_{GS,prog} = \pm 20$  V (Debuquoy et al., 2009).

between the two states measured at an operating point of  $V_{GS} = -1.5$  V and  $V_{DS} = -0.02$  V remains stable at approximately  $I_{D+}/I_{D-} = 100$ . By comparison, Si flash memories tolerate  $10^5$  program cycles without significant closure of the memory windows (Bez et al., 2003).

Data retention provides a measurement of the trap discharge time. The retention of both the erased and written states of the transistor in Fig. 9.60 after storage in the dark in  $N_2$  is 3 mo. before all of the trapped electrons are lost, giving  $V_{on+} \rightarrow 0$  V. These data indicate that the transistors employing trapped charge layers are both programmable and non-volatile for read/write voltages  $\pm 15$ –20 V.

An interesting variant of the charge trap memory transistor is one that is optically programmable, shown in Fig. 9.62a. The Si substrate forms the gate electrode. A 5.1 nm thick  $HfO_3$  layer is deposited for the first insulator, followed by deposition of a diarylethene phosphonic acid SAM (DAE) that attaches to the  $HfO_3$  to provide the second, 2.6 nm thick dielectric. The pentacene channel is subsequently deposited by vacuum thermal evaporation, and Au stripes formed the bottom gate/top gate contact (BG/TC) transistor. The channel has a mobility of  $0.7$   $cm^2/V$

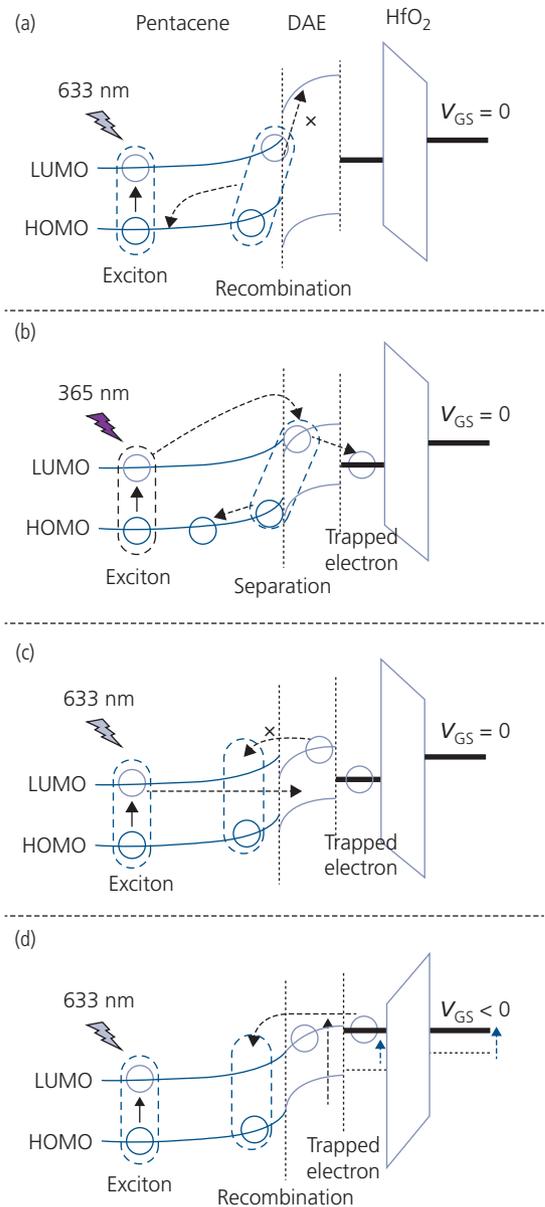

**Figure 9.62** (a) Illustration of an optically programmable pentacene OTFT with  $L = 100$   $\mu m$  and  $W = 1$   $mm$ . (right) Molecular structures show the closed (DAE-C) and open (DAE-O) SAM isomers, and the transition between them using UV or visible (vis) illumination. (b) Energy level diagrams of the DAE-O, pentacene, and DAE-C films. Black dashed lines: From DFT calculations, blue solid lines: measurements. Grey boxes from UPS and PES measurements. From Chen et al. (2015a).

s, typical of conventional pentacene OTFTs. The DAE is optically converted by UV illumination between the open C–C bond (DAE-O) and closed-bond (DAE-C) isomers. The increased  $\pi$ -electron delocalization of DAE-C leads to a reduced energy gap of 1.49 eV, compared to 3.91 eV for DAE-O (see Fig. 9.62b). The bond is reopened to convert DAE-C back to DAE-O using lower energy, visible radiation that is preferentially absorbed in the former isomer. The increase and decrease of the energy gap results in an optically controlled barrier to electron transport from the pentacene channel to the trap interface formed between the SAMs and the  $\text{HfO}_3$ . By this means, a persistent charge is maintained on the traps that can be written or erased based on the wavelength of the programming illumination.

The energetics of the memory write/erase process are shown in Fig. 9.63. In step **a**, photocurrent is generated by illuminating the pentacene channel with 633 nm wavelength light. The high energy barrier presented by the initially preset DAE-O layer prevents charge from reaching the trap levels between the DAE and the  $\text{HfO}_3$  dielectrics. The DAE-O is converted to the low energy gap DAE-C using UV illumination at 365 nm for several hundred seconds. This allows charge transport via tunneling from the SAM into the trap states, thereby writing the memory state (step **b**). The negative charge on the gate insulator is summed with the photocurrent to increase  $I_D$ . The channel current is progressively increased by generating further charge in the channel by continued illumination at 633 nm (step **c**). Applying  $V_{GS} < 0$  in step **d** discharges the traps to erase the memory contents. Finally, visible light at  $> 420$  nm is used to recover the DAE-O isomer, restoring the large energy barrier and thus the memory to its initial, preset state, **a**.

A shortcoming of this structure is that it takes several hundred seconds to program and erase, even at large optical powers (e.g.  $>1$  mW/cm<sup>2</sup> at 633 nm). Furthermore, the state of the entire memory is changed by blanket illumination over the array. As we will show below, this feature is useful for recording grayscale analog images, but cannot enable customized data storage unless each memory element is separately illuminated.

The drain current characteristics of the optical memory OTFT are provided in Fig. 9.64a. The memory window is approximately  $\Delta V_T = 4$  V. The very low voltage operation is enabled by the thin, high dielectric constant gate insulator. Applying  $V_{GS} = -3$  V erases the information before the DAE is converted back to its open-bond isomer. The initial and erased states show nearly identical  $I_D$  vs.

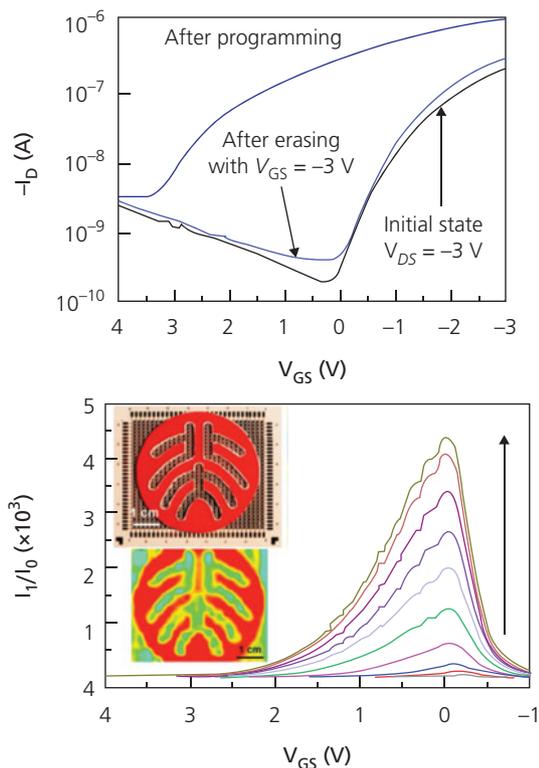

**Figure 9.63** Energy levels of the optically activated memory transistor in Fig. 9.62. The processes of charge storage (memory writing) and charge loss from the traps at the DAE/ $\text{HfO}_3$  interface are described in the text (Chen et al., 2015a).

$V_{GS}$  characteristics, indicating a lack of hysteresis between the programming and erase cycles. The drain current contrast between the programmed ( $I_1$ ) and erased states ( $I_0$ ) is  $I_1/I_0 = 4400$  under intense, 9.27 mW/cm<sup>2</sup> illumination at 633 nm (see Fig. 9.64b). Furthermore, there is only a small reduction in  $\Delta V_T$  after  $10^4$  cycles, with a retention time of at least 7 days (Chen et al., 2015a). This shows the ability of ultrathin SAM and dielectric layers to retain charge with little or no leakage over long periods, suggesting a notable

lack of pinholes or other defects between the traps and the channel.

This optical memory has been integrated into a  $(5 \times 5) \text{ cm}^2$ ,  $30 \times 30$  transistor array on a flexible PET substrate. The ITO control gate is coated on the back substrate surface, followed the deposition of the dielectrics and a 40 nm thick pentacene channel. Deposition of the Au S and D contacts completed the  $L/W = 120 \text{ }\mu\text{m}/800 \text{ }\mu\text{m}$  array. A patterned mask (Fig. 9.64b, upper inset) was placed onto the memory surface, which was then exposed to 365 nm wavelength illumination at  $100 \text{ }\mu\text{W}/\text{cm}^2$  for 200 s to create a latent image replica on the underlying transistors. The shape was retained for 24 h, and was repeatedly cycled between a programmed image and a blank, erased memory array by applying a  $V_{GS} = -3 \text{ V}$ , 1 s erase pulse. The array current output shows the stored image of the mask in the lower inset, Fig. 9.64b.

**Figure 9.64** Drain current characteristics of an optical memory OTFT at  $V_{DS} = -3 \text{ V}$  in its initial state, after programming by illumination from UV and 633 nm sources, and after memory erasure for 1 s at  $V_{GS} = -3 \text{ V}$ . (b) The ratio of drain currents in the written and erased states ( $I_1$  and  $I_0$ , respectively) vs. 633 nm wavelength illumination power from 0 to  $9.27 \text{ mW}/\text{cm}^2$  (increasing in the direction of the arrow). Illumination time is 200 s at  $V_{DS} = -3 \text{ V}$ . Inset: (top) Image of a  $5 \times 5 \text{ cm}^2$ ,  $30 \times 30$  transistor array with a patterned mask laid onto its surface. (bottom) Latent image written on the memory. The color scale varies from  $I_1 = 0$  (red) to 600 pA (green) (Chen et al., 2015a).

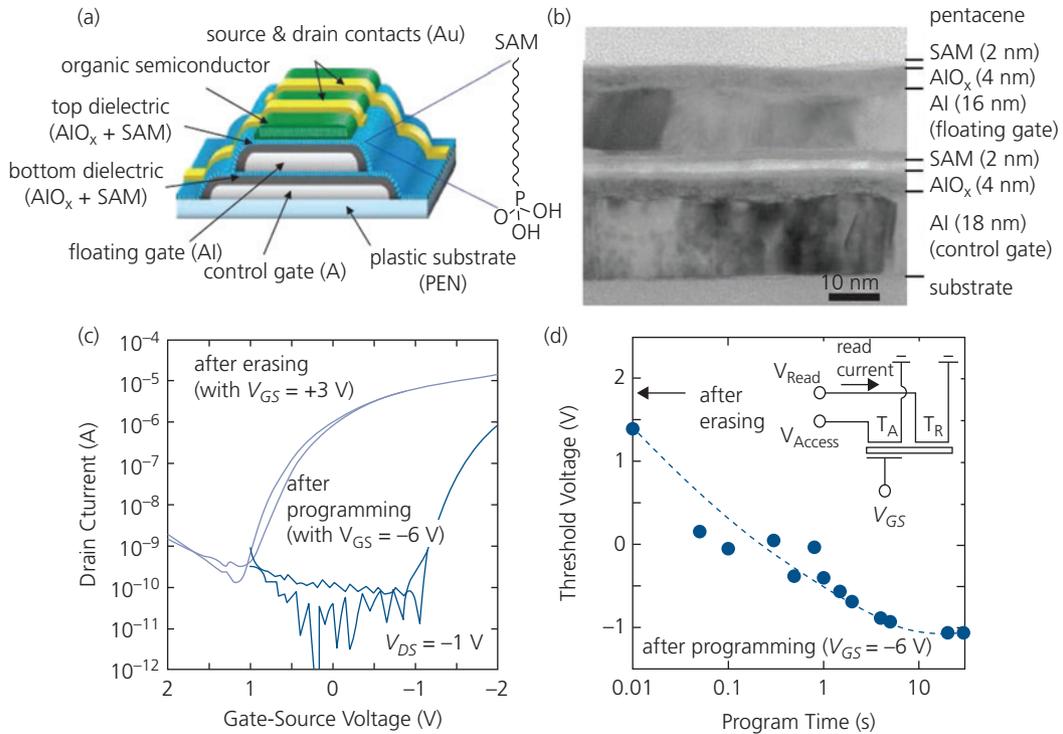

#### 9.4.5.2 Floating gate and metal NP charge storage

Charge trapping on an ultrathin metal sheet known as a *floating gate*, is a common means for data storage in semiconductor memories. The sheet is embedded in the gate dielectric within a tunneling distance of charge from the channel. Similar to dielectric interfacial traps, the charge on the metal layer is neutralized by applying a gate potential opposite to that used for writing, thus providing programming capability. Metal NP layers can substitute for a continuous metal sheet deposited from solution between the first and second layers. Both floating gate and metal NP memory transistors operate at very low voltages when sandwiched between thin dielectric layers.

An example of a floating gate memory OTFT is shown in Fig. 9.65a, with a cross-sectional image of the gate region in Fig. 9.65b. The 16 nm thick floating Al gate is set back from the pentacene channel by a compound insulator comprising oxygen plasma-deposited  $\text{AlO}_x$  (4 nm), and a solution deposited phosphonic acid SAM (2 nm) in contact with the channel. The floating gate comprises a 16 nm thick Al layer separated from the Al control gate (also 16 nm thick) by a second  $\text{AlO}_x$  (4 nm)/SAM (2 nm) dielectric. The BG/TC transistor is completed by depositing the Au S and D onto the pentacene channel.

The drain current characteristics in Fig. 9.65c show a memory window of 2 V. The transistor is written by hole tunneling into the floating gate at  $V_{GS} = -6 \text{ V}$  and  $V_{DS} = -1 \text{ V}$ . The memory state is erased by reversing the gate voltage to  $V_{GS} = +3 \text{ V}$ . The  $I_{on}/I_{off} = 10^5$  provides a suitable contrast for large memory array applications. Also, the  $I_{off}$  is apparently almost entirely due to  $\sim 10 \text{ pA}$  gate leakage that results in a slow discharge of the memory contents during each read cycle, requiring periodic refreshing of its contents. A notable feature of this architecture is the time ( $\sim 1 \text{ s}$ ) required for programming, shown in Fig. 9.65d. Finally, fatigue in the threshold voltage difference between the written and erased modes is apparent after 1000 cycles due to partially irreversible charge trapping along with damage to the floating gate after many programming cycles. Annealing the devices at  $140^\circ\text{C}$  in nitrogen recovers the initial value of  $\Delta V_T$ . Memory retention times of  $10^3$ – $10^4 \text{ s}$  are observed (Sekitani et al., 2009a).

Flexible memories employing the transistors in Fig. 9.65 consisting of  $26 \times 26$  cells on a  $5 \times 5 \text{ cm}^2$  PEN substrate have been demonstrated. Each cell comprises a pair of floating gate transistors sharing a

**Figure 9.65** (a) Schematic illustration of a floating gate, pentacene OTFT with  $L = 50 \mu\text{m}$  and  $W = 500 \mu\text{m}$  on a PEN substrate. The phosphonic acid SAM molecular structure is shown at the right. (b) Cross-sectional TEM image of the transistor. (c) Drain current characteristics at  $V_{DS} = -1$  V after programming and erasing of the transistor memory using the gate voltages indicated. (d) Threshold voltage after programming and erasing. The erase voltage is  $+3$  V. Inset: Memory cell circuit schematic used in a flexible,  $26 \times 26$  cell,  $50 \times 50 \text{ mm}^2$  pressure sensitive array memory. After Sekitani et al. (2009a).

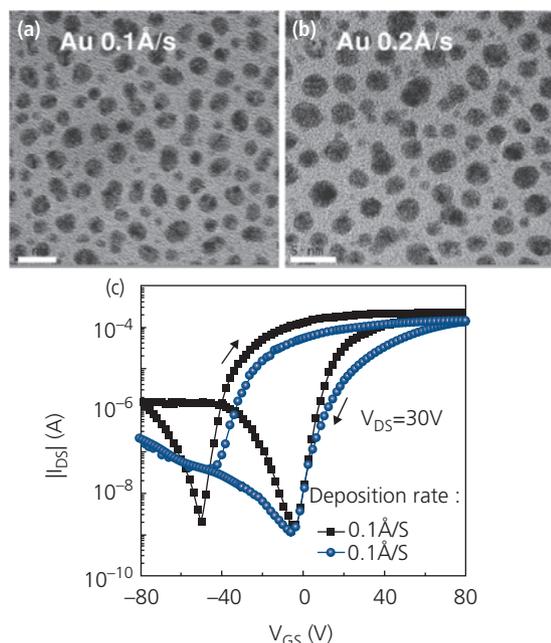

common channel, as shown in Fig. 9.65d, inset. The transistor,  $T_A$ , provides access to the readout transistor ( $T_R$ ) where the information is stored. At two transistors per bit, a total of 1352 transistors are used in the array. Each array cross-point is combined with a pressure-sensitive resistive element. Hence the circuit stores tactile information patterns at each memory site. The tactile pattern was stored for 12 h although there was considerable “image” distortion due to device leakage over that time period.

The dependence of the memory properties of OTFTs on metal NP composition and the gate bilayer dielectric structure has been widely investigated (Kim and Lee, 2010, Kang et al., 2013). We have seen in Section 7.5.2 that very thin layers of metal do not fully wet the organic surface. Hence, Au NP clusters form as shown in Fig. 9.66a and b for two different deposition rates on a PS dielectric.

These NP layers were used in TG/BC OTFTs with a P(NDI2OD-T2) n-channel semiconductor. The dielectric bilayers comprise a 40 nm thick PS layer, a 1 nm thick layer of vacuum deposited metal, followed by a 260 nm thick PMMA secondary dielectric. Write and

erase require  $V_{GS} = \pm 80$  V due to the thick PS/PMMA gate dielectric. Indeed, even the 40 nm PS first dielectric may be too thick to charge the NPs. Micrographs in Fig. 7.180 show that Ag NPs can diffuse deep into the organic layer, which may significantly reduce the tunneling distance. Figure 9.66c shows that the drain current characteristics are sensitive to deposition rate: the higher deposition rate results in a lower density of larger NPs than at lower rates. As a result, the memory window and  $I_{on}/I_{off}$  are reduced due to the lower density of trapped charge in the films with lower NP densities.

The dependence of memory transistor properties on metal (Au, Ag, Cu, and Al) composition are summarized in Table 9.4. The Au and Ag films coalesce into nanometer clusters that are uniformly distributed across the polymer surface. Copper, on the other hand, forms larger clusters at a lower density, whereas Al wets the polymer surface and thus no particles are observed. Higher densities of NPs results in a larger memory window, with the largest  $\Delta V_T = 51.7$  V for the Au NP device with a write-erase gate voltage of  $\pm 80$  V. In contrast, no memory window is

**Figure 9.66** Transmission electron micrographs of Au NPs formed by vacuum thermal deposition of 1 nm thick films on PS at (a) 0.1 Å/s and (b) 0.2 Å/s. The scale bars are 5 nm. (c) Drain current characteristics of PS/Au NP/PMMA transistors with  $L = 10 \mu\text{m}$  and  $W = 1 \text{mm}$  at two different NP film growth rates (Kang et al., 2013).

**Table 9.4** Characteristics of n-channel P(NDI20D-T2) memory OTFTs employing different metal films at the PS/PMMA gate dielectric interface (Kang et al., 2013)

Parameter	Au	Ag	Cu	Al
NP size <sup>a</sup> (ave.) (nm)	4.6	6.8	13	~200

<sup>a</sup> Nanoparticle sizes observed after deposition of 1 nm thick metal films.

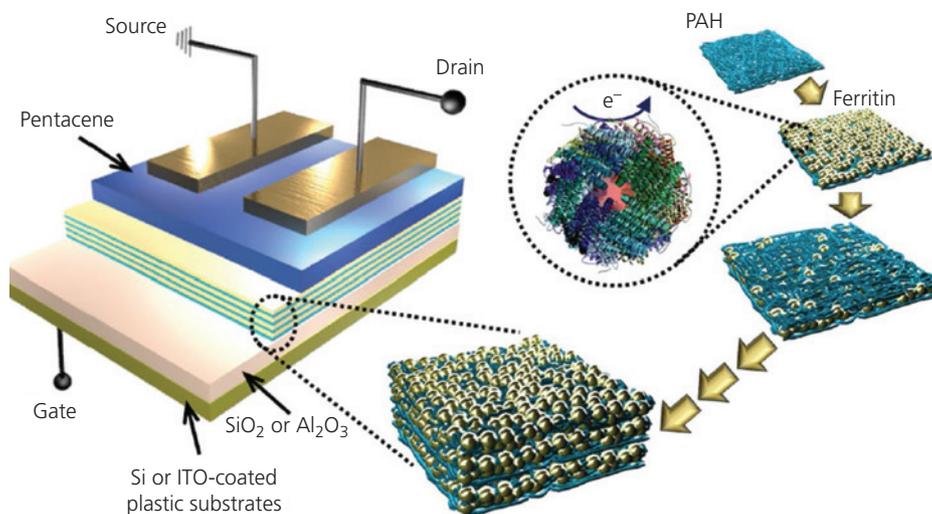

developed for Al, presumably due to the formation of a continuous film at the PS/PMMA interface. However, if the layer were perfectly flat, it would form a floating gate, in which case some programmability would remain. Since this is not observed, penetration of Al through the PS first dielectric may cause leakage that prevents charge storage. The memory window is progressively smaller for Ag and Cu due to the smaller NP surface density, which reduces the amount of charge that can be stored. Also, even  $V_{GS} = \pm 50 \text{V}$  is insufficient to change the memory state of the

transistors, again due to the use of thick dielectrics (Kang et al., 2013).

The retention time is lowest for the Ag NP device, possibly due to tunneling between the high density of particles at the interface that leads to their relatively rapid discharge. The lowest density Cu interlayer has the longest memory retention since the clusters are too far apart to allow for significant tunneling between them. Apparently, the NP size, shape and particularly distribution within the film bulk determine how rapidly charge can dissipate, and how large a memory window can be achieved. Indeed, the particle spatial distribution may be the most important attribute of NP-based organic memories. Diffusion into the dielectric bulk can be avoided using solution-deposited, non-metallic NPs.

Precisely controlled ferritin NP multilayer films on a SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub> gate dielectric have been used to store charge supplied from a pentacene channel (see Fig. 9.67). Ferritin is an iron-containing protein that forms 12 nm diameter spherical particles with a shell thickness of 2 nm. The particles are deposited one layer at a time from solution to form a multilayer stack whose depth is precisely controlled to achieve the desired charge density. Charges are stored in the volume comprising alternating layers of anionic PAH and cationic ferritin. The switching times of devices comprising 40 bilayers in pentacene OTFTs are  $> 10 \mu\text{s}$  which is considerably less than for the floating gate transistors discussed above. The memory windows are approximately 20 V,  $I_{on}/I_{off} = 10^4$ , and retention and fatigue characteristics are similar to those obtained for thin film floating gate devices (Kim et al., 2013a). These non-metallic NPs, therefore, show promise for charge storage applications, although the long term stability of the transistors has not been explored.

Ambipolar conduction of the channel is an important for to rapid charging and discharging of the floating gate or NP layer. We have seen that these two processes entail the attraction of charge of one sign from the channel during the program cycle, followed by the opposite sign charge during erase. Both charge types, therefore, must be transported through the channel, which can cause significant cycle time delays if the mobilities of electrons and holes are markedly different. Pentacene is an example material that has a higher hole than electron mobility, although the asymmetry is small enough that it is useful in memory transistors. Likewise, PDPP-TBT is an ambipolar polymer with nearly equal electron and hole mobilities of 0.051 cm<sup>2</sup>/V s and 0.037 cm<sup>2</sup>/V s, respectively, that has been

**Figure 9.67** Schematic illustration of the fabrication of PAH/ferritin dielectrics by layer-by-layer solution processing. The multilayer stack is deposited onto a  $\text{SiO}_2$  (200 nm) or  $\text{Al}_2\text{O}_3$  (50 nm) dielectric, and coated by the pentacene channel. Gold source and drain electrodes are deposited to complete the BG/TC memory transistor with  $L = 100 \mu\text{m}$  and  $W = 800 \mu\text{m}$  (Kim et al., 2013a).

used with Au NP charge trapping layers (Zhou et al., 2013).

#### 9.4.5.3 Ferroelectric memory transistors

We showed in Section 9.4.4 that the dipole moment of a ferroelectric can be reversibly switched by alternately applying a positive or negative voltage that exceeds the coercive field strength ( $\sim 50 \text{ MV/m}$ ). Higher fields are required for the thinnest films where the dipolar molecules become pinned at the film surfaces. The *ferroelectric memory* OTFT, or OFeFET, operates by applying a gate voltage that can switch the dipole direction within a ferroelectric gate insulator. This screens the gate potential at the channel/insulator interface, which results in an increase or decrease in charge density (and hence a shift in  $V_T$  and  $I_D$ ), depending on the dipole direction. Since the dipole orientation is bistable, the OFeFET can assume one of two different threshold voltages corresponding to a logical **1** or **0**. The device memory state is read by applying a gate voltage near  $V_T$ , and measuring the drain current.

We noted previously that ferroelectrics spontaneously polarize when heated above their Curie temperature,  $T_C$ , and then cooled. This process aligns the molecules into a crystalline film, or in a polycrystalline structure with low angle grain boundaries between domains. If unpolarized (i.e. at  $T > T_C$ , or before annealing), the materials are paraelectric, and the polarization depends linearly on the field strength. Alternatively, the crystalline domains can

be aligned using mechanical strain. This is illustrated for P(VDF-TrFE) deposited on PET films laminated with an Al contact layer in Fig. 9.68. The PET is a thermoformable plastic that can apply strains to the ferroelectric layer that approach 100% when stretched at elevated temperatures. The Fourier transform infrared (FTIR) spectra of several 900 nm thick P(VDF-TrFE) films subjected to different thermal treatments are shown in Fig. 9.68a. The  $1400 \text{ cm}^{-1}$  band intensity is most sensitive to ordering. The lower energy bands at  $850$  and  $883 \text{ cm}^{-1}$  are associated with the *trans-gauche* and the highly ferroelectric all-*trans* configurations, respectively. The peak at  $1286 \text{ cm}^{-1}$  corresponds to an extended *trans* sequence of more than four monomers. This latter feature indicates the state of polarization switching of the film. The conformational changes into the ferroelectric *trans* configuration require readjustment of the polymer chain organization. This is a thermally activated process that can be accelerated by applying physical strain. Spectrum (i) corresponds to the unannealed sample. Its low intensity is a consequence of a disordered structure. Likewise, the film stretched at room temperature (iii) shows relatively weak spectral intensity compared to an unstrained film that is ordered by heating in  $\text{N}_2$  for 2 h at  $T = 140^\circ\text{C} > T_C \sim 100^\circ\text{C}$  (spectrum (ii)). The film that is tensile strained by 50% at  $70^\circ\text{C}$  (spectrum (iv)) shows the greatest degree of crystallinity in the all-*trans* phase, even though the temperature is below  $T_C$ .

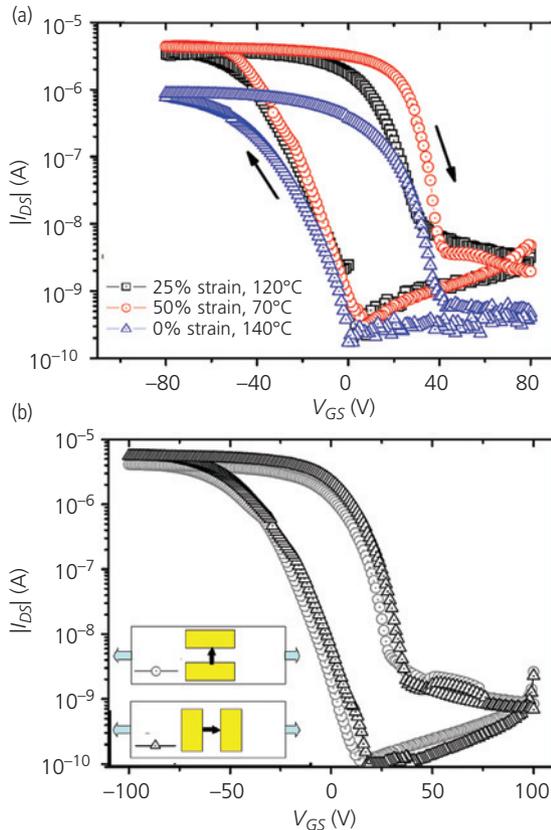

**Figure 9.68** (a) Fourier transform infrared spectra of P(VDF-TrFE) on Al-coated PET films. (i) As-deposited, (ii) annealed at 140°C, (iii) stretched by 50% at 25°C, and (iv) stretched by 50% at 70°C. (b) Hysteresis loops for ferroelectric capacitors whose films are treated as indicated in legend. Inset: Schematic diagram of the capacitor (Nguyen et al., 2008).

The ferroelectric hysteresis loops of capacitors using films strained to 25% and 50% at different temperatures are shown in Fig. 9.68b. The capacitive memories comprise a P(VDF-TrFE) film sandwiched between an Al back contact and a Au top contact. The remnant polarization of the high temperature annealed sample, as well as those strained at 50% at 70°C and at 25% at 120°C are roughly equal, at 10 μC/cm<sup>2</sup>. However, for 25% or 50% strain at 50°C,  $P_r = 4$  μC/cm<sup>2</sup> with a correspondingly higher coercive field than those exposed to higher temperatures. The results are consistent with the FTIR data: both strain and elevated temperature result in a higher degree of polarization. In addition, the strain and temperature effects reinforce each other. A higher strain requires a lower temperature than a lower strain (Nguyen et al., 2008).

The operating characteristics of pentacene channel BG/TC OFeFETs with stretched and annealed

P(VDF-TrFE) are shown in Fig. 9.69a. They show a hole mobility of 0.072–0.12 cm<sup>2</sup>/V s after stretching. The device with 50% strain and annealed at 70°C has the largest memory window of  $\Delta V_T = 60$  V and  $I_{on}/I_{off} = 10^4$ , which is even larger than obtained for the unstretched transistor annealed at 140°C. Furthermore, the 50% strain device showed an extrapolated data retention time of 10<sup>4</sup> s, at which point  $I_{on}/I_{off} = 10^2$ . Interestingly, the memory window is independent of the orientation of the channel relative to the stretching direction. Figure 9.69b shows the drain current characteristics of two OFeFETs whose channels are oriented perpendicular (circles) and parallel (triangles) to the direction that the substrate is distorted. In both cases, the performance is nearly identical, indicating that the polymer chains are equally poled along the ferroelectric *trans* direction. This directional independence makes the process adaptable to fabrication of large-scale memories without being

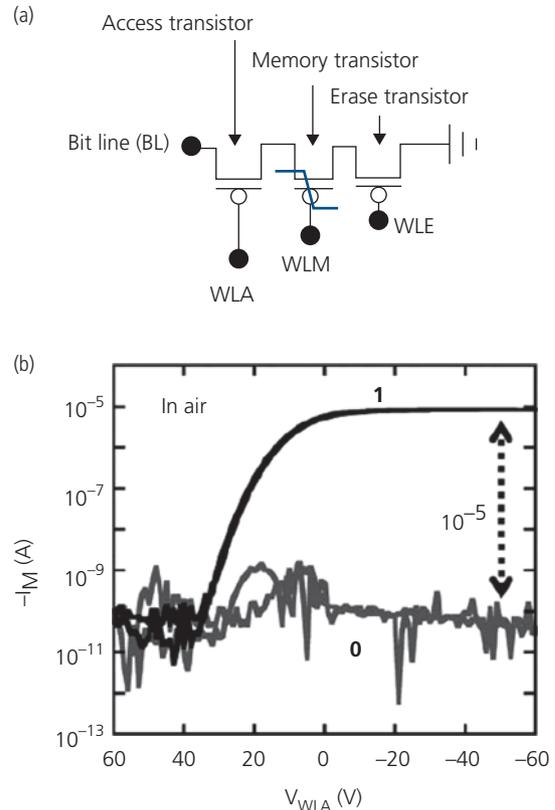

**Figure 9.69** (a) Drain current characteristics of pentacene/P(VDF-TrFE) OFeFETs with  $L = 7 \mu\text{m}$  and  $W = 4 \mu\text{m}$  on PET substrates strained at different temperatures. (b) Dependence of the drain current characteristics on orientation of the channel relative to the stretch direction of a 50% strained OFeFET at  $70^\circ\text{C}$ . Inset: Top illustration shows the channel (black arrows) normal to the stretching direction (colored arrows, circle symbols in plot); bottom illustration shows the channel oriented parallel to the stretching direction (triangle symbols) (Nguyen et al., 2008).

constrained by the orientation of one device block relative to others on the same substrate.

A P(VDF-TrFE) OFeFET memory array on flexible polyimide was implemented using the three transistor (3T) circuit for each memory cell shown in Fig. 9.70a. The 3T architecture is immune from destructive memory readout since it separates data storage, cell addressing (or access), and the erase functions between independent devices. This is a more robust design than either a 1T memory element where all functions are combined in a single device, or even a 1T1C (i.e. 1 transistor, 1 capacitor) network.

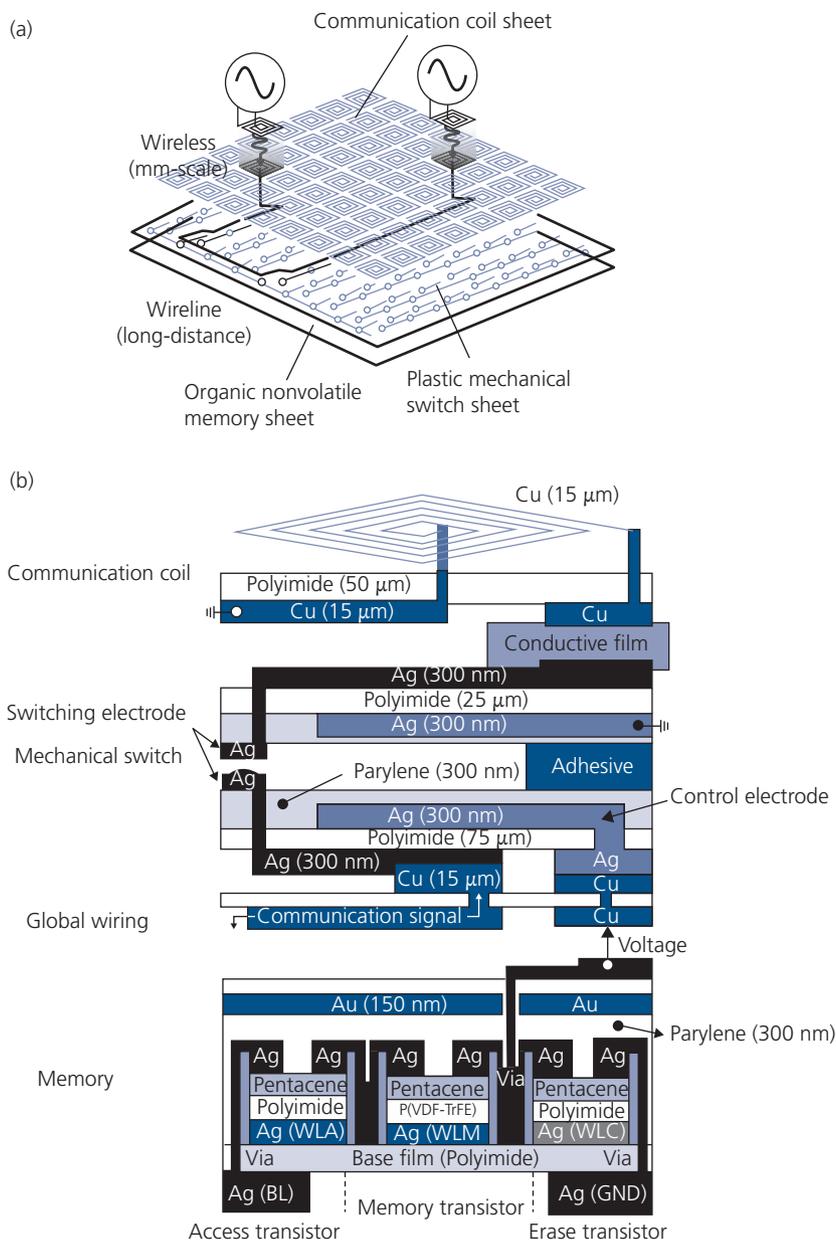

An interesting application of the OFeFET memory is the multilayer “communication system” in Fig. 9.71a, where a radiofrequency (r.f.) wireless transmitter signal is received by an integrated coil antenna. An r.f. receiver is positioned over a second

**Figure 9.70** (a) Three transistor (3T) memory circuit comprising an access, memory, and erase transistors. (b) Drain current along the bit line vs. the access transistor gate voltage ( $V_{WLA}$ ) for the memory transistor in the **1** and **0** states.  $I_{on}/I_{off} = 10^5$  (Sekitani et al., 2009b).

coil on the array. This activates two mechanical switches to form an *ad hoc*, hard-wired network between the transmit and receive locations whose positions are retained by the corresponding memory OFeFETs.

A conceptual diagram of the circuit architecture and one multilayer array cell is shown in Figs. 9.71a and b, respectively (Sekitani et al., 2009b). The circuit employs a  $8 \times 9$  array with dimensions of  $(25 \times 25) \text{cm}^2$ . The cell pitch is  $2.5 \text{cm}$  along both the rows and columns. The Ag BG/Ag TC transistors comprised a  $50 \text{nm}$  thick vacuum-deposited pentacene channel on a  $75 \mu\text{m}$  thick polyimide substrate. The contacts and the array word lines used Ag NPs that are sintered at  $180^\circ\text{C}$ . The  $400 \text{nm}$  thick P(VDF-TrFE) film used for the memory transistor is cured at  $90^\circ\text{C}$  and then annealed above  $T_C$  at  $135^\circ\text{C}$  for 2 h in air. The channel lengths of all the transistors were  $L = 30 \mu\text{m}$ , with  $W = 16.5 \mu\text{m}$ ,  $45 \mu\text{m}$ , and  $300 \mu\text{m}$  for the access, memory and erase transistors, respectively. Finally, the transistors were encapsulated by depositing a

**Figure 9.71** (a) Communication system architecture illustrating the coupling of a wireless transmitter and receiver positioned over the communication coil sheet to establish the *ad hoc* hard-wired connection between their positions. The connection is retained by the non-volatile OFeFET 3T memory. (b) The multilayer array element comprising a memory coil, an electrically activated mechanical switch, a global wiring layer, and the 3T memory cell (Sekitani et al., 2009b).

parylene/Au bilayer to prevent exposure of their active regions to the ambient.

All layers use printing techniques for patterning: screen printing for the Cu coil, inkjet printing for the Ag NP conducting lines, and a combination of inkjet and microdroplet printing for the 3T memory cell. The function of this circuit is as follows: The 2 MHz r.f. signals are inductively coupled to the adjacent Cu coil, inducing a voltage that appears on one electrode

of a mechanical relay. The opposite terminal of the relay is connected to the drain of the memory transistor. When the transistor is in the 1 state, 30 V from the bit line (BL) is supplied to the relay, closing the switch and connecting the cell to the “global wiring sheet” (Sekitani et al., 2007). A similar sequence occurs at the receive end, thereby completing a hard-wired interconnection through the wiring sheet between these two locations. The interconnection is maintained

until an erase signal is sent to either the transmit or receive array cross-points. This causes the memory voltage to return to the 0 state, which in turn disconnects the BL from the switch, opening the relay and dropping the connection to the other array location. The mechanical relays, comprising electrostatically deflected perylene arms, presents a resistance of  $\sim 1 \Omega$ .

The memory state is switched by applying  $V_{WLM}$  to the word line connected to the gate of the memory transistor, and its state is queried according to the voltages applied to word lines at the gates of the access and erase transistors ( $V_{WLA}$  and  $V_{WLE}$ , respectively). The bias conditions leading to read, write and erase are summarized in Table 9.5. The currents in the 1 and 0 states are shown in Fig. 9.70b as a function of the access word line voltage,  $V_{WLA}$ . The current contrast ratio is  $I_{on}/I_{off} = 10^5$ . The write time is 40 ms and the erase time is 10 ms, both limited by parasitic capacitances of the 3T circuit.

Hard wired interconnections in Fig. 9.71 are dynamic, secure, and non-volatile. That is, the interconnect is maintained by the memory state of the OFeFETs, and hence is sustained until an erase signal is sent. The interconnections do not require continual, free space communication, releasing the address electronics to perform other functions, such as establishing other routing paths within the same array. This circuit shows the degree of sophistication that can be achieved using flexible electronics, and the ability of integrated memories to enable new applications.

In concluding this discussion, we have seen that organic memories based on charge trapping, filamentary conduction and ferroelectric effects can have long data retention times, high stability, and fast write/read/erase cycle performance. The memory element itself can be a resistive or capacitive switch, a diode or a transistor. Both volatile and non-volatile memories are possible leading to WORM and DRAM architectures. A nonlinear element such as a diode or access transistor must be used in conjunction with the resistive or reactive memory element to permit scaling to

large, high capacity memory arrays. While their performance and bit density falls short of that attained with conventional Si technology, organic memories can be flexible and can extend over large areas. We have shown that both of these attributes enable special purpose applications that are not served by high-density Si-based memories. Organic memories have, indeed, made substantial progress during the last decade, yet further developments are needed to improve their speed, data retention time, and to reduce memory fatigue.

## 9.5 Organic/two-dimensional semiconductor heterojunctions

While previous discussions have dealt with 3D electronic systems, that is, those systems whose characteristics are controlled by bulk properties of the semiconductor, limited dimensional systems are playing an increasingly important role in modern optics and electronics. In particular, 2D and one-dimensional transport of charge and excited states may offer ultrahigh 2D mobilities, or 1D quantum interference effects. Much of the interest in limited dimensional systems stems from the fact that Moore's law of transistor scaling is nearing an end due to practical limitations on shrinking gate lengths to the atomic scale. The powerful economic drivers underlying Moore's law are, nevertheless, compelling scientists and engineers to seek methods to circumvent this limit by using materials and systems with superior electronic properties than Si. Two-dimensional materials, that is, those that comprise only a single or a very few number of monolayers, are such a class of solids. The archetype example of a 2D material is graphene—a single layer of fused, interconnected carbon rings. Graphene has exhibited an exceptionally high charge mobility and charge density (Bolotin et al., 2008). In its pristine form, it is a semimetal, although doping, strain, or externally applied fields can induce a band gap. Another example is hexagonal boron nitride (*h*-BN). This graphene isomorph comprises alternating B and N atoms that occupy inequivalent lattice positions. Unlike graphene, *h*-BN is an insulator.

Perhaps the most interesting class of materials for use in active organic electronic devices comprises 2D monolayers of transition metal dichalcogenides (TMDCs). Their molecular formula is  $MX_2$ , where M is a group IV, V, or VI transition metal and X is a chalcogen (S, Se, or Te). These materials are characterized by a direct or indirect bandgap whose magnitude depends on the number of monolayers

**Table 9.5** Voltages used to write, erase, and read the 3T memory element in Fig. 9.70 (Sekitani et al., 2009b)

Action	State	$V_{BL}$ (V)	$V_{WLA}$ (V)	$V_{WLM}$ (V)	$V_{WLE}$ (V)	$I_M$ (A)

Erase	1→0	-40	-40	+60	-40	$10^{-10}$
Read		-10	-60 to 60	0	-40	

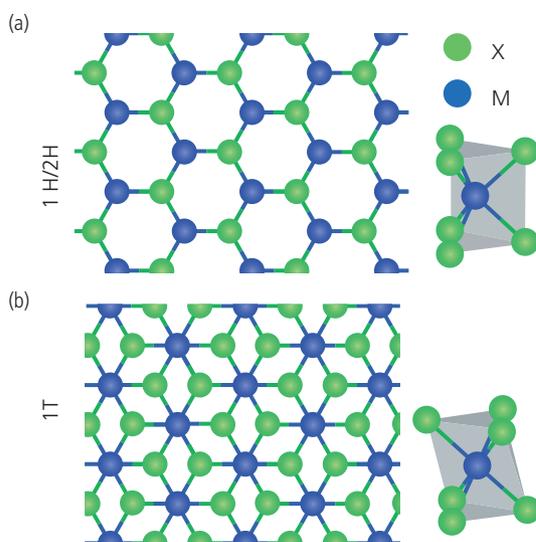

comprising the film. Like graphene, they have high mobilities and mechanical flexibility, and can be intensely luminescent.

Two-dimensional W-M excitons are supported by TMDC monolayers. The layers feature a large spin-orbit coupling that allows for rapid transitions between the singlet and triplet excited states. In this regard, HJs between 2D TMDCs and organics have the potential to create structures that combine the advantages of both systems while reducing their individual disadvantages. The Frenkel-like excitonic nature of organics gives them a high oscillator strength, thus providing strong optical absorption. Illumination generates excitons that dissociate at a TMDC/organic interface, and can be transported in the very high mobility 2D film. The large spin-orbit coupling of TMDCs may lead to efficient light emission from both singlet and triplet states generated within the organic region of the HJ. Both materials are flexible, and layering one on the other is possible using techniques such as vapor deposition of organics, and exfoliation of monolayers from TMDCs.

Monolayer TMDCs have a small absorbance even though they might have an exceptionally high absorption coefficient. Furthermore, it has not yet been possible to grow defect-free films over even modest areas. Films grown by CVD are polycrystalline, and consist of one or more atomic layers in island-like domains of unpredictably varying sizes. Each domain may possess significantly different electronic characteristics, depending on the number of layers. Moreover, a high density of chalcogen vacancies and defects at domain edges and within the monolayers themselves reduces the charge mobility well below the theoretical limit predicted for perfect films, while also reducing the exciton lifetime. However, organics have been shown to effectively passivate the surface defects of semiconductors (Lunt et al., 1991, Li et al., 2011, Yong et al., 2012, Lee et al., 2018). Hence, a judicious choice of organic may reduce the effects of chalcogen vacancies in the TMDC films.

### 9.5.1 Electronic characteristics of transition metal dichalcogenides

Covalent bonds between the M and X atoms provide strong intralayer adhesive forces. However, far weaker van der Waals bonds between the layers permit them to be separated into monolayers via exfoliation with properties unique from those of the bulk. The layers themselves can assume either a hexagonal (H) or tetragonal (T) symmetry, where the metal atoms have either trigonal (1H/2H) or

**Figure 9.72** Two crystal structures possible for TMDCs. (a) Hexagonal in one or two repeat units along the vertical, (0001) direction (1H and 2H, respectively), and (b) tetragonal (1T).

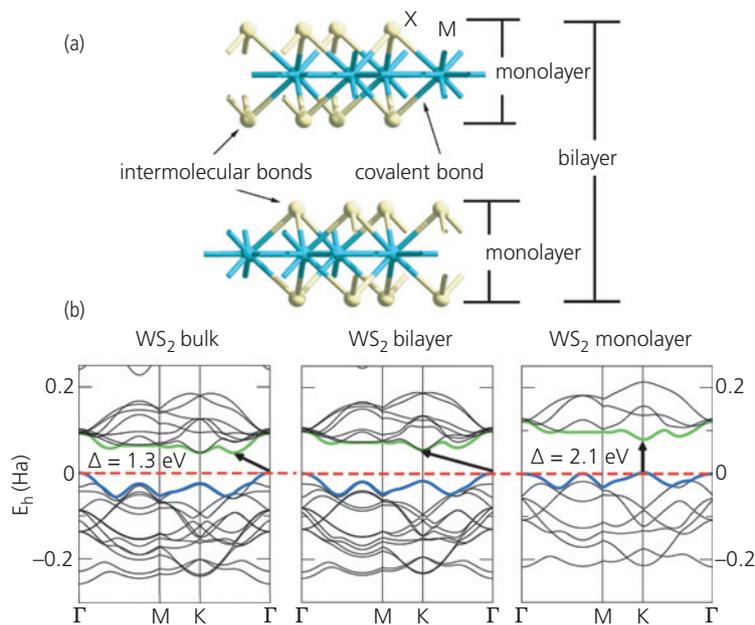

octahedral (1T) coordination with the X atoms in the basal plane (see Fig. 9.72). The hexagonal lattice can comprise either one or two layers for each unit along the (0001) *c*-direction, corresponding to the 1H or 2H structures, respectively. For many TMDCs, the 1T structure is unstable at room temperature. A 3D view of a bilayer of an  $\text{MX}_2$  compound is shown in Fig. 9.73a, showing the relative positions of the metal and chalcogen layers within and between the atomic planes. The lattice parameters for  $\text{WS}_2$  are  $a = 3.154 \text{ \AA}$  and  $c = 12.362 \text{ \AA}$ , and for  $\text{MoS}_2$ ,  $a = 3.160 \text{ \AA}$  and  $c = 12.295 \text{ \AA}$ , reflecting the large asymmetries of these 2D lattices (Wilson and Yoffe, 1969, Mattheiss, 1973).

An important feature of TMDCs is the tunability of their band gaps, depending on the number of layers. For example,  $\text{WS}_2$  can be tuned from an indirect bandgap, bulk semiconductor with  $E_G = 1.3 \text{ eV}$  to a direct bandgap monolayer with  $E_G = 2.1 \text{ eV}$ . The energetics of bilayers, trilayers, and so on, monotonically transition from their monolayer to bulk values. The indirect band gap increases with the number of layers, while the direct gap stays almost unchanged. Hence, the material transitions from indirect to direct gap between a bilayer and a monolayer. The band structure calculated for  $\text{WS}_2$  is shown in Fig. 9.73b, where the vertical axis is in Hartrees (Ha). A Hartree is given by  $E_h = m_0(q^2/4\pi\epsilon_0\hbar)^2 = 2R_\infty hc = 27.2 \text{ eV}$ , where  $m_0$  is the electron rest mass,  $R_\infty$  is the Rydberg constant, and  $c$  is the speed of light. Interestingly, the direct band gap is not at  $k = 0$  ( $\Gamma$ ), but rather at the K symmetry point. Similar band structures

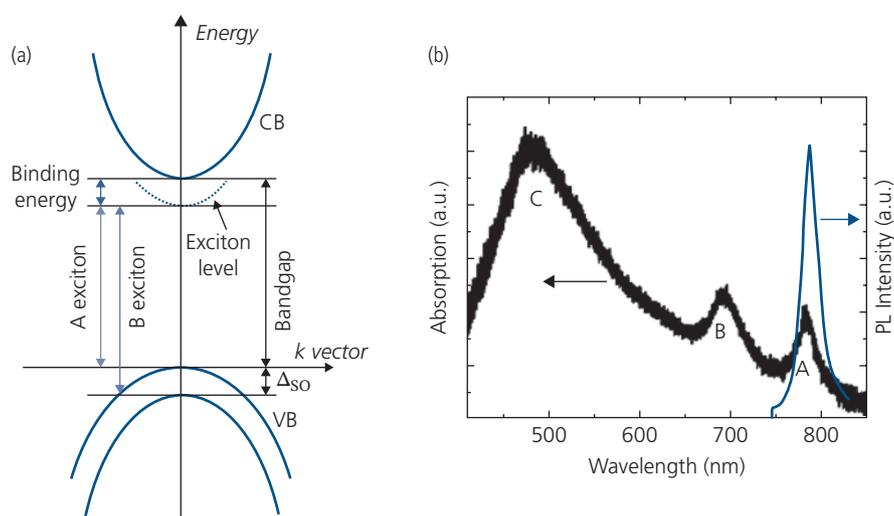

and behavior with decreasing numbers of layers are found for MoS<sub>2</sub> (Kuc et al., 2011).

A simplified energy band diagram of a TMDC monolayer at the band extrema is shown in Fig. 9.74a. The exciton level is shown by the dashed line. Several

features in the absorption spectrum of MoSe<sub>2</sub> in Fig. 9.74b are associated with transitions shown in the band diagram. Notably, the A and B excitons resulting from valence band splitting via a large spin–orbit coupling energy,  $\Delta_{SO}$ , appear at 790 nm and 700 nm,

**Figure 9.73** (a) Illustration of two monolayers of a TMDC. The individual layers are bonded via van der Waals forces between neighboring chalcogens (X), whereas the in-plane atoms are covalently bonded. M is the transition metal atom. (b) Calculated band structure of the WS<sub>2</sub> bulk, and a bilayer, and a monolayer. The conduction band minimum is shown by the green line, the Fermi energy by the dashed line, and the valence band maximum by the blue line. The energy gaps are indicated by arrows (vertical arrow for direct band gap and diagonal arrows for indirect band gaps) (Kuc et al., 2011).

**Figure 9.74** (a) Simplified energy band diagram of a monolayer TMDC at the band extrema identifying the A and B excitons, the conduction and valence bands (CB and VB, respectively) and the spin–orbit energy splitting,  $\Delta_{SO}$ . (b) Absorption and PL spectra of MoSe<sub>2</sub> indicating the A, B, and C exciton features (Liao, 2018).

respectively. Near the band extrema, the valence and conduction bands are parallel and symmetric about their maxima. Hence, excitations generate electrons and holes that propagate at the same velocities but in opposite directions. This larger energy transition commonly observed in many TMDCs gives rise to the broad C feature in Fig. 9.74b. The PL spectrum is due to recombination of the lowest energy A exciton.

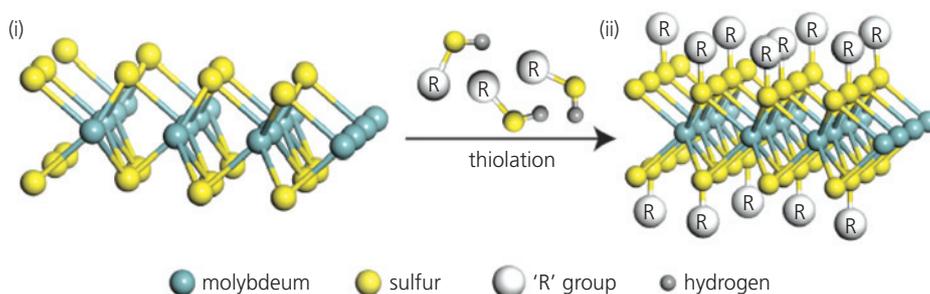

The mono- and multilayer samples contain a high density of surface and edge chalcogen vacancies that adversely affect the charge mobilities (Qiu et al., 2013) and exciton lifetimes (Amani et al., 2015), thus reducing conductivity and PL efficiency. The vacancies can be filled via passivation by thiolation. Indeed, attaching thiols or electron donating or withdrawing species onto TMDC monolayers can also result in n- or p-type doping that increases the layer conductivity.

A potential mechanism for defect passivation of a MoS<sub>2</sub> monolayer using thiol-based molecules is illustrated in Fig. 9.75. The S binds to Mo at the vacancy site, leaving the functionalizing R group exposed. Thiolation has been demonstrated using grinding-assisted ultrasonic exfoliation of MoS<sub>2</sub> in solution to generate a distribution of flakes ranging in size from 100–300 nm, and with thicknesses up to 5 nm. A monolayer (ML) of the TMDC is 0.7 nm thick. This suggests that the process generates a distribution of flake thicknesses from 1 to 6 ML. Exfoliation results in a high S vacancy that is repaired by introducing thiols into the suspension containing the flakes. Such thiols include *p*-mercaptophenol (S1), thiophenol (S2), 1-propanethiol (S3), 1-nonanethiol (S4), and 1-dodecanethiol (S5, see Fig. 9.76). Using a combination of infrared and X-ray photoelectron spectroscopy (XPS), the absorption at 2563 cm<sup>-1</sup> due to the S–H bond is absent in the functionalized monolayers, indicative of binding of the thiols to the MoS<sub>2</sub> sheets.

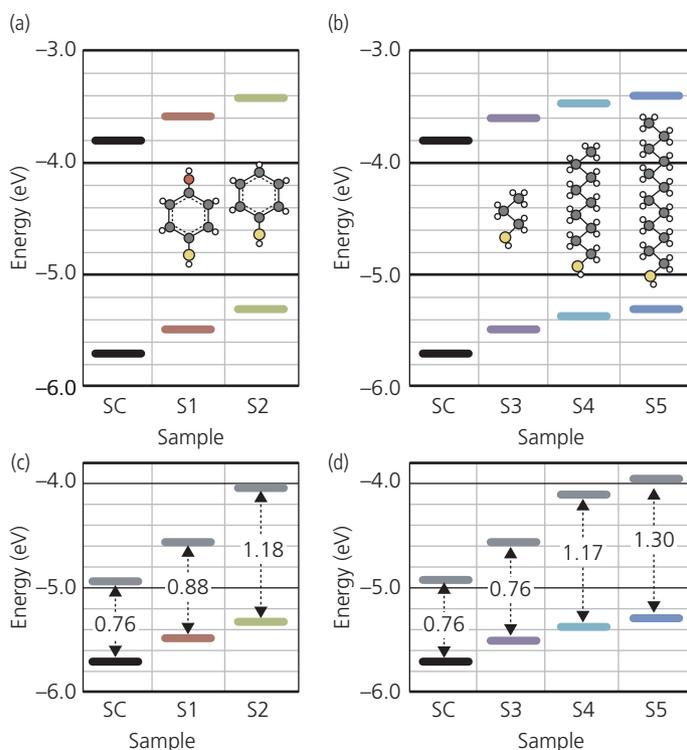

The energetic shifts engendered by the attachment of the several thiolating compounds have been

investigated by photoelectron and optical spectroscopy, with results shown in Fig. 9.76. The valence band energies are slightly destabilized by the thiol attachments due to their mild Lewis base nature. Figure 9.76a shows that the valence band energy is decreased relative to vacuum as the electron withdrawing strength of the functionalizing group decreases from the alcoholic substituted S1 to the less electronegative aromatic thiol, S2. Similarly, the shorter alkane chain of S3 is a more effective electron withdrawing moiety than the more extended chains of S4 and S5. The energy gap is correspondingly affected by thiolation. Thiol attachment results in longer wavelength PL emission, which is a consequence of electron-withdrawing functionalizing groups attached to the S-atom in the thin film. These effects are confirmed by the Fermi-energies in Fig. 9.76b. Thus, the aromatic S2 and longer alkane chain compounds S4 and S5 lead to pronounced n-type doping of the TMDC, shifting the Fermi energy toward the conduction band minimum, whereas the as-prepared film shows intrinsic conductive behavior with the Fermi energy at mid-gap (Nguyen et al., 2015).

Attachment of organic molecules with greater or lesser electron withdrawing character can be used to dope the 2D materials, thereby modifying their conductivity (and conductivity type) over a wide range. Density functional theory (DFT) calculations of monolayers of organic compounds on pristine (i.e. defect-free) MoS<sub>2</sub>, for example, have shown that they can serve as either electron donors or acceptors, depending on the positions of the HOMO and LUMO energies within the band gap of the monolayer (cf. Section 4.4.1). Examples of electron donating DMPD and accepting TCNE are shown in Fig. 9.77. The relative positions of the HOMO and LUMO energies within the bandgap of the monolayer film show that DMPD is an n-type dopant, contributing electrons from its filled HOMO into the conduction band of MoS<sub>2</sub>. Thus, the

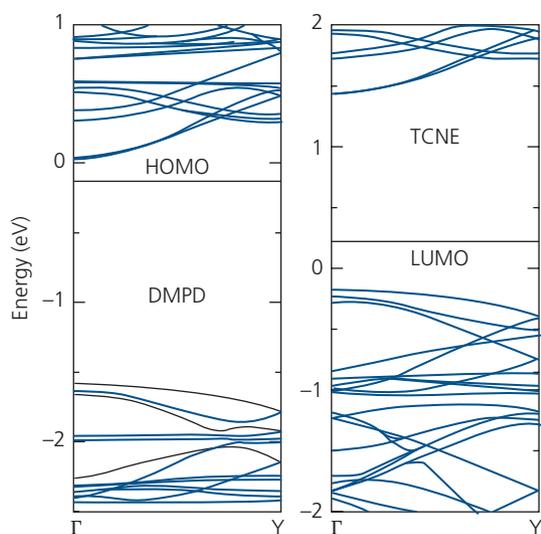

**Figure 9.75** (i) A monolayer of MoS<sub>2</sub> showing numerous S vacancies. (ii) Immersing the TMDC in a solution containing functionalized thiol moieties results in attachment of the S-atom to the TMDC, exposing the R-group (Nguyen et al., 2015).

**Figure 9.77** Band structure relative to the Fermi energy at 0 eV for a monolayer of MoS<sub>2</sub> with an adsorbed monolayer of DMPD and TCNE on its surface. The HOMO and LUMO energies of the respective molecules are indicated (Cai et al., 2016).

Fermi energy is positioned approximately at the conduction band minimum. Likewise, the LUMO energy of TCNE is within 0.5 eV of the MoS<sub>2</sub> valence band

maximum, at the high symmetry  $\Gamma$ -point, behaving as an acceptor.

The amount of charge transfer from an adsorbed organic layer is calculated by assuming a multistep process whereby charge transfer across the interface is followed by electronic polarization. That is, the total average in-plane charge density transferred at position  $z$  normal to the film plane is

$$\Delta\rho(z) = \rho_{org/TMD}(z) - \rho_{org}(z) - \rho_{TMD}(z), \quad (9.35)$$

where  $\rho_{org/TMD}(z)$  is the charge density of the combined organic/TMDC system and  $\rho_{org}(z)$  and  $\rho_{TMD}(z)$  are the charge densities of the respective, non-interacting systems. The total charge transferred is then

$$\Delta n(z_0) = \int_{-\infty}^{z_0} \Delta\rho(z) dz, \quad (9.36)$$

where  $z_0$  is the equilibrium distance of the organic molecule to the film plane (Cai et al., 2016, Shen and Tao, 2017). The amount of charge transfer depends sensitively on the fraction of the TMDC surface that is covered, the sites occupied by the organic molecules, and whether or not the dopant is positioned above an atomic vacancy. For DMPD and TCNE, for example, the total

charge density transferred to pristine MoS<sub>2</sub> at low molecular coverage is  $5 \times 10^{12} \text{ cm}^{-2}$  electrons and  $\sim 1 \times 10^{12} \text{ cm}^{-2}$  holes, respectively, whereas the density of electrons is approximately doubled if the dopants are positioned above a S vacancy (Cai et al., 2016).

As noted, surface passivation can have dramatic effects on the exciton lifetime and charge concentration within the monolayer. In Fig. 9.78a we show that exfoliated MoS<sub>2</sub> films treated with the organic superacid, TFSI, show a 190-fold increase in PL efficiency compared to the as-prepared sample. Furthermore, neither PL peak shifts nor line shape changes are observed due to coverage by TFSI. The PL quantum yields (PLQYs) of the two samples are plotted vs. charge generation rate,  $G$  (proportional to the pump intensity) are shown in Fig. 9.78b. The PLQY is possibly  $>95\%$  for the TFSI-treated 2D film at low fluence, compared to  $<1\%$  for the as-prepared sample. Caution, however, is warranted in claiming such high efficiencies in samples with unusual geometries as in 2D films. We can conclude, however, that the relative efficiency of the treated film is much larger than for the untreated film.

At high fluence, the number of photogenerated charges exceeds that of the background carrier concentration in MoS<sub>2</sub>. In this case, the number of electrons ( $n$ ) and holes ( $p$ ) are equal, and the recombination rate is proportional to  $np = n^2 \propto G^2$ . As shown in Section 3.10, at high fluence we expect that the exciton annihilation rate is proportional to the square of the number of excitons,  $N_{ex}$ . Hence, the PL

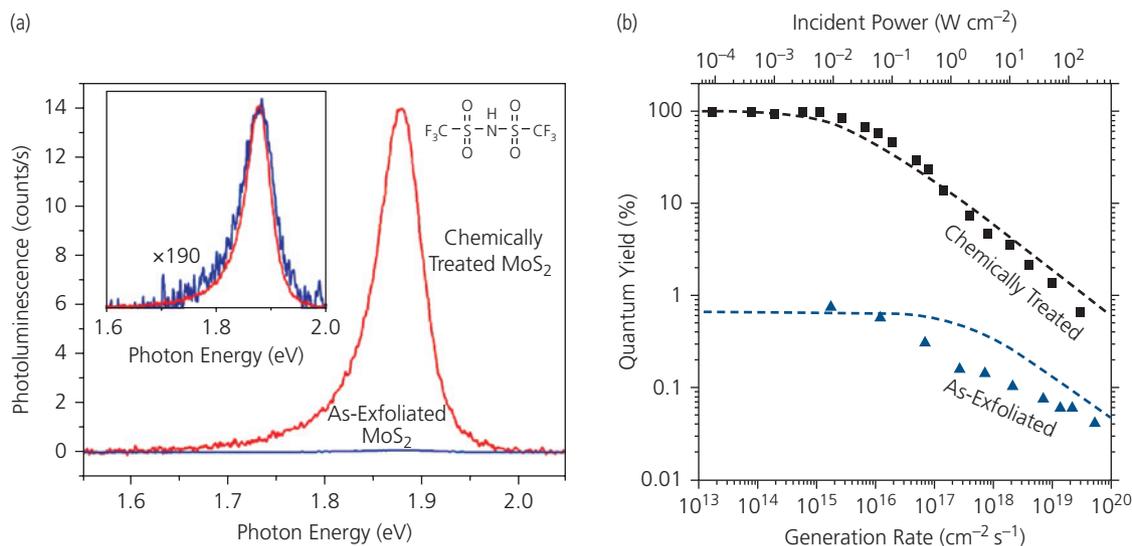

quantum efficiency is equal to the ratio of the radiative recombination rate to the total recombination rate, viz.

$$\eta_{PL} = \frac{k_r N_{ex}}{k_r N_{ex} + k_{nr} n^2 + k_{ex} N_{ex}^2}, \quad (9.37)$$

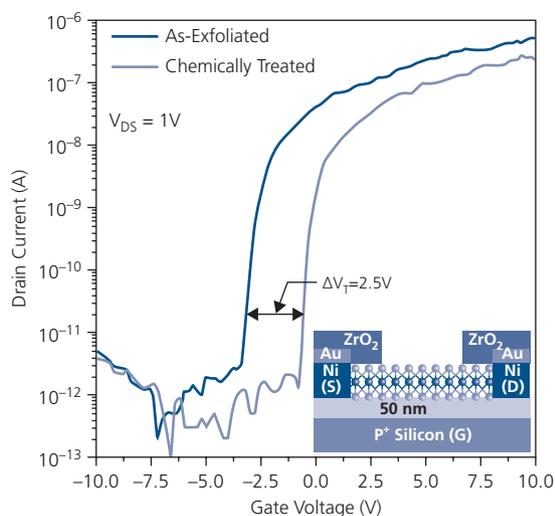

where  $k_r$  is the fluorescence recombination rate,  $k_{nr}$  is the charge recombination rate at defects, and  $k_{ex}$  is the biexcitonic recombination rate. For the treated sample, it was assumed that  $k_{nr} \rightarrow 0$ . Fits to the data in Fig. 9.78b using Eq. 9.37, as shown by the dashed lines yield  $k_{ex} = 2.8 \text{ cm}^2/\text{s}$  and  $k_{nr} = 1.5 \times 10^6 \text{ cm}^2/\text{s}$ . We note that the exciton lifetimes are similarly enhanced for the surface passivated samples. Transient luminescence measurements yield  $k_r = 0.3 \text{ ns}$  for the untreated, and 10.8 ns for the treated MoS<sub>2</sub> film, which is consistent with the PLQY results (Amani et al., 2015).

An additional consequence of surface passivation by TFSI of transistors employing a MoS<sub>2</sub> channel is a threshold voltage shift of 2.5 V in Fig. 9.79. This suggests that passivation dedopes the thin film, reducing the electron concentration in the channel compared to the as-prepared sample.

Questions remain as to what role is played by TFSI in passivating the TMDC surface. Apparently, TFSI does not directly affect the surface vacancies as in the case of the thiolated samples. However, this strong acid can reduce adsorbed -OH and water, agents that also introduce midgap states. Yet, to achieve such high

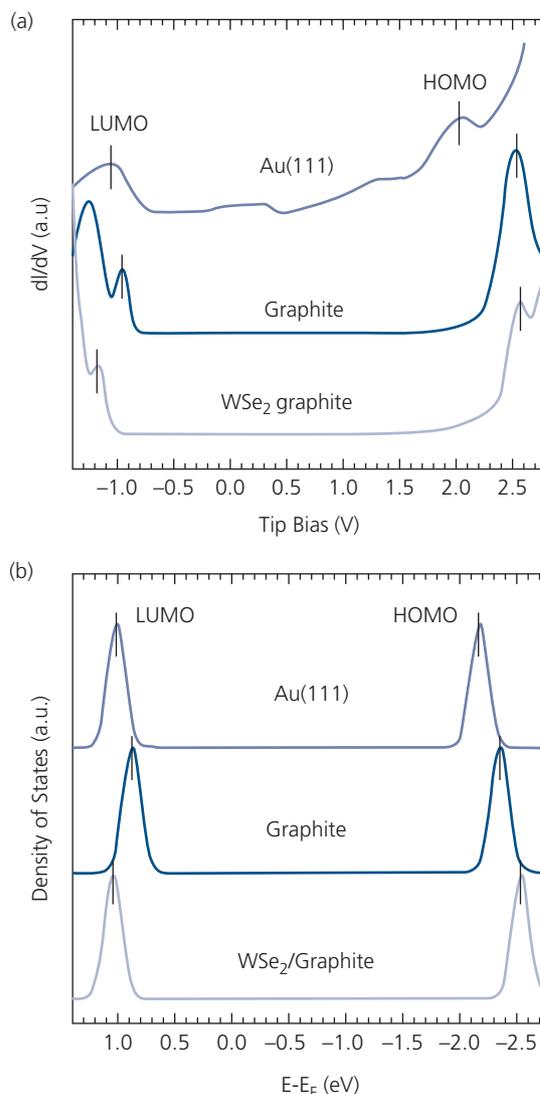

**Figure 9.78** (a) Photoluminescence spectrum of exfoliated and TFSI-treated MoS<sub>2</sub> thin films. Also shown is the molecular formula of TFSI. The spectra are obtained by pumping at  $10 \text{ mW}/\text{cm}^2$  at  $514 \text{ nm}$  wavelength. Inset: Detail of the spectra rescaled to overlap, shows no lineshape change between the samples. (b) Photoluminescence quantum yield for the TFSI-treated and as-exfoliated samples. Dashed lines show fits to theory of charge and exciton recombination vs. pump intensity (Amani et al., 2015).

**Figure 9.79** Drain current characteristics of MoS<sub>2</sub> BG/TC transistors employing exfoliated and TFSI-treated thin films. The ZrO<sub>2</sub> coating protects the Au/Ni contacts from attack by the TFSI superacid (Amani et al., 2015).

quantum yields, TFSI must have some effect in reducing the S-vacancy density since these also introduce midgap recombination centers. One possibility is that the elimination of the atmospheric surface contaminants by protonation by TFSI makes the dangling bonds available for surface reconstruction. This may result in clustering of S atoms, thus reducing the opportunities for exciton migration to randomly distributed defects at the MoS<sub>2</sub> surface (Amani et al., 2015).

Band gap narrowing, energy level alignment, exciton binding, and other interactions between adsorbed organic layers and TMDCs are strongly influenced by electronic polarization. Indeed, even single monolayer TMDCs can effectively screen electrostatic interactions between adsorbed organic layers from the underlying substrate. This is illustrated by dramatic changes in the energy gap of PTCDA when adsorbed onto the surface of WSe<sub>2</sub> on graphite, vs. when it is in direct contact with a substrate. Figure 9.80a shows *scanning tunneling spectroscopy* data for monolayers of PTCDA physisorbed directly onto a metallic Au(111) surface, a semimetallic graphite surface, and on a semiconducting WSe<sub>2</sub> monolayer on graphite. Scanning tunneling spectroscopy provides a relative measure of the electronic DOS at the film surface. Applying a time varying voltage between the microscope tip and the sample, and then measuring the magnitude of the tunneling current provides spatial information on the DOS. The d.c. tip bias offset corresponds to its energy relative to  $E_F$ , whereas the current is proportional

**Figure 9.80** (a) Scanning tunneling spectroscopy data for a monolayer of PTCDA on Au(111), graphite, and WSe<sub>2</sub>/graphite. (b) DFT calculations of the LUMO and HOMO densities of states for a flat-lying PTCDA molecule on these same substrates (Zheng et al., 2016).

to the magnitude of the local DOS (Zandvliet and van Houselt, 2009). For example, within the energy gap, the current is zero, whereas the current is large at the peak HOMO and LUMO densities of states.

Spectra for PTCDA molecules absorbed onto various substrates show significant energy gap narrowing, from 3.73 eV for the WSe<sub>2</sub>/graphite sample, to 3.49 eV for PTCDA directly on graphite, and 3.10 eV on the Au(111) substrate. This is compared with 4.7 eV for isolated PTCDA molecules in the gas phase (Dori et al., 2006). The calculated HOMO-LUMO gaps using DFT that include polarization effects shown in Fig. 9.80b yield 2.93 eV (Au(111)),

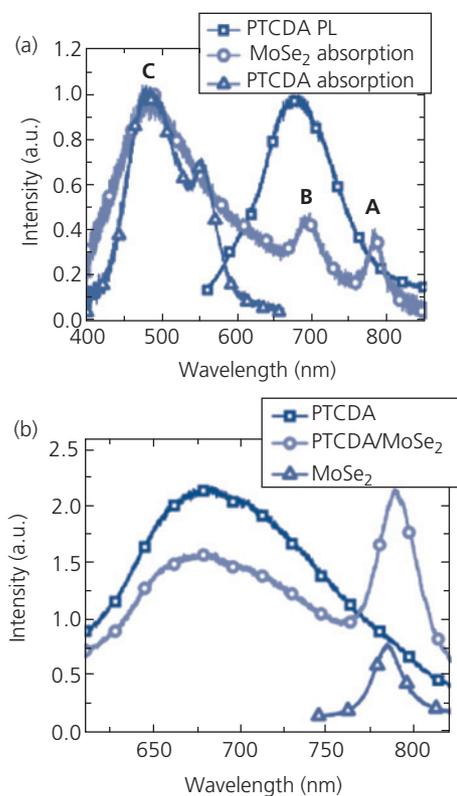

2.99 eV (graphite), and 3.40 eV (WSe<sub>2</sub>/graphite) (Zheng et al., 2016). These calculations are for isolated molecules, and hence ignore mutual polarization between molecules, thus underestimating the energy gap by approximately 0.3 eV. Nevertheless, in both the measured and calculated data, the WSe<sub>2</sub> monolayer screens image charges from metallic and semi-metallic substrates, considerably reducing energy gap narrowing. This example is evidence that band alignments and energy gaps of adsorbed organic molecules on the surfaces of 2D semiconductors are influenced by charge exchange and associated electronic interactions at the HJ.

### 9.5.2 Charge transfer at organic/2D semiconductor heterojunctions

Thus far we have considered the properties of monolayer MX<sub>3</sub> thin films and their modification by adsorption or chemical reaction with organics. We now consider the charge transport characteristics across organic/2D semiconductor HJs, and how these junctions can be exploited in practical devices. The reader is referred to Section 4.7.3 where the topic of hybrid organic/inorganic HJs is developed. Many of the phenomena and analyses discussed in the context of bulk structures are also applied to organic/2D HJs.

A disadvantage of using TMDCs in active photonic applications is the low optical absorption of single monolayers, even though they have exceptionally large oscillator strengths. Nevertheless, 2D materials have the advantage of large in-plane charge mobilities. The shortcoming of a low absorbance can be mitigated by using an efficient light absorbing organic layer that transfers energy to the TMDCs. Such hybrid systems can therefore benefit from broad absorption combined with efficient energy harvesting. Energy transfer from an organic to a TMDC can occur either via charge exchange across a type II HJ (Section 4.7.3), or if the emission spectrum of the donor (e.g. the organic) overlaps the absorption spectrum of the acceptor (e.g. the TMDC), Förster energy transfer may be active.

Efficient Förster energy transfer (FRET) has been observed for the archetype monolayer MoSe<sub>2</sub>/2 nm thick PTCDA HJ system. The excited state dipole moment of PTCDA grown by VTE lies in-plane, thus maximizing coupling to the W-M exciton of the TMDC (Gu et al., 2017). Previously, we have seen that PTCDA molecules prefer a flat-lying morphology on most substrates. Since the excited state dipole moment of PTCDA lies within the molecular plane, it stands to reason that the dipole will lie parallel to the 2D inorganic exciton dipole moment as well.

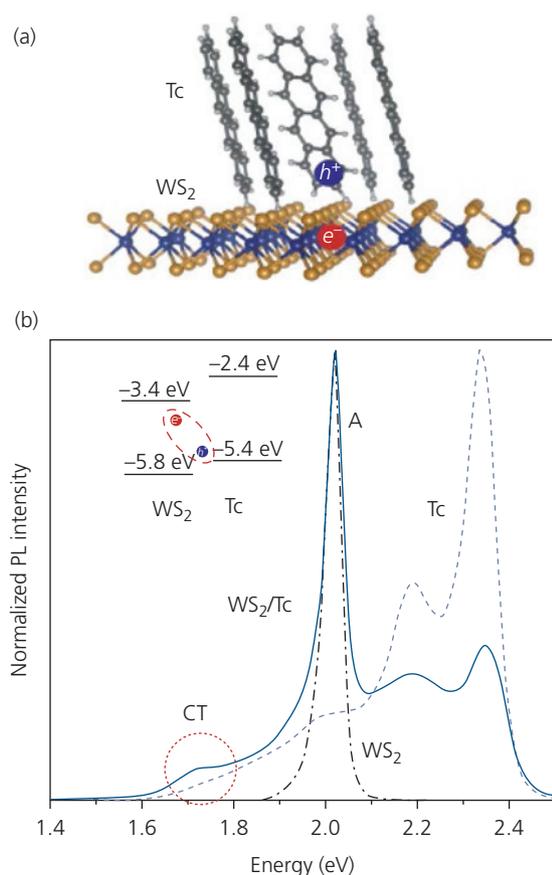

**Figure 9.81** (a) Normalized differential reflectivity spectra of PTCDA (triangles), and MoSe<sub>2</sub> (circles), and photoluminescence spectrum of PTCDA (squares). The A, B, and C excitons of MoSe<sub>2</sub> are indicated. (b) Photoluminescence spectra of PTCDA (squares), MoSe<sub>2</sub> (triangles), and MoSe<sub>2</sub>/PTCDA (circles). The measurements use a 510 nm laser source with a power of 1.28 μW/mm<sup>2</sup> (Gu et al., 2017).

The absorption spectra of the organic and inorganic films are shown in Fig. 9.81a, along with the emission spectrum of PTCDA. The PTCDA PL overlaps the A and B exciton absorption features of MoSe<sub>2</sub>, due to direct bandgap transitions at its high symmetry K-point, and the C feature is due to band nesting (cf. Fig. 9.74). The overlap between the PTCDA emission and TMDC absorption indicates that efficient energy transfer occurs, as observed in the PL spectra of the individual layers and for the HJ shown in Fig. 9.81b. The PL intensity of PTCDA is quenched in the hybrid sample, while that of MoSe<sub>2</sub> increases. The FRET efficiency,  $\eta = 1 - I_{DA}/I_D = 30\%$ , where  $I_{DA}$  and  $I_D$  are the spectrally integrated donor emission intensities with and without the acceptor layer on the PTCDA surface, respectively.

Contrary to PTCDA, vacuum deposited tetracene molecules stand up on WS<sub>2</sub>, as shown in Fig. 9.82a. These data also indicate efficient and rapid energy and charge transfer in this system. The steady state

PL spectra for the constituents of the HJ and of a 20 nm thick Tc/1 ML WS<sub>2</sub> are shown in Fig. 9.82b. Due to the band alignment at the type II HJ, excitons generated by 2.8 eV photons in the Tc migrate to the HJ, and then dissociate into more weakly bound HCTEs that are precursors to free electrons in the TMDC and holes in the Tc. The spectra explicitly show that the 2.0 eV, A exciton of WS<sub>2</sub> dominates the WS<sub>2</sub>/Tc HJ spectrum along with suppression of higher energy vibronics of Tc. Both spectral changes are expected when energy transfer is efficient. A CT feature appears at 1.7 eV, from which its binding energy of 0.3 eV is inferred. Transient absorption spectra of selectively pumped Tc and WS<sub>2</sub> layers shows that hole transfer occurs within 3.2 ps of the CT state formation, whereas electron transfer in the opposite direction may take the marginally longer time of 2.2 ps.

**Figure 9.82** (a) Molecular arrangement of tetracene (Tc) on a WS<sub>2</sub> surface. (b) Photoluminescence spectra of a monolayer of WS<sub>2</sub>, a Tc thin film, and a monolayer WS<sub>2</sub>/Tc heterojunction. The A exciton peak in WS<sub>2</sub> and the CT feature in the HJ spectra are indicated. Inset: Proposed energy level diagram of the WS<sub>2</sub>/Tc heterojunction illustrating the HCTE (dashed oval). After Zhu et al. (2018).

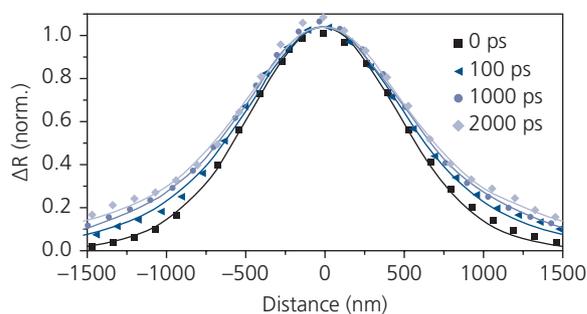

The diffusion of excitons at WS<sub>2</sub>/Tc HJs have been spatially and temporally mapped using a pump source that locally generates excitons, and then positioning a probe beam a prescribed distance from the pump to observe the reflectance as a function of time. The pump energy at 3.1 eV excites both the TMDC and Tc, whereas the probe at 2.0 eV is sensitive to charges in the WS<sub>2</sub>. The evolution of the exciton density is modeled using solutions to the time dependent diffusion equation (Section 7.1.4). The change in reflection (i.e. the ratio of the difference in reflectance with and without the pump beam, to the reflectance without the pump) obtained vs. position and time after the trailing edge of the pump pulse is shown in Fig. 9.83. Since the differential resistance is a function of exciton density, the profiles can be fit to solutions of the diffusion equation. Assuming two different Gaussian widths,  $\sigma_{1,t}$  and  $\sigma_{2,t}$  the exciton density is

$$N(x, t) = N_1 \exp\left(-\frac{(x-x_0)^2}{2\sigma_{1,t}^2}\right) + N_2 \exp\left(-\frac{(x-x_0)^2}{2\sigma_{2,t}^2}\right), \quad (9.38)$$

where  $N_1$  and  $N_2$  are the exciton populations at  $x = x_0$ , and  $x_0$  is the position of the pump. The implication of this fit is that two different exciton populations coexist, each with a different diffusion constant given by

$$D_{1,2} = \frac{\sigma_{1,2t}^2 - \sigma_0^2}{2t}, \quad (9.39)$$

where  $\sigma_0$  is the time-independent spatial variance of the distribution. The fits yield  $N_1/N_2 = 2/3$ , with corresponding diffusion constants of  $D_1 = 1 \text{ cm}^2/\text{s}$  observed for the fast-moving population at  $t > 100 \text{ ps}$ , and  $D_2 = 0.04 \text{ cm}^2/\text{s}$  for the more slowly moving excitons. Indeed, using an exciton lifetime of  $\tau = 2 \text{ ns}$

**Figure 9.83** Reflectance change of a monolayer WS<sub>2</sub>/Tc HJ as a function of distance and time relative to the position and trailing edge of the pump beam, respectively. The lines are fits to a double Gaussian function (Zhu et al., 2018).

taken from transient data, the diffusion length for the  $N_1$  population is  $L_{D1} = \sqrt{D_1\tau} = 450$  nm. This large diffusion length is not unexpected for 2D thin films, although it is undoubtedly less than can be achieved in defect-free films where diffusion constants are expected to be at least an order of magnitude higher. Using a similar analysis,  $L_D = 90$  nm, assuming that both populations have the same lifetime.

It has been proposed that the  $N_1$  population with its long diffusion length is due to free excitons, while the  $N_2$  population is due to excitons in energy sites extending deep into the  $WS_2$  energy gap (Zhu et al., 2018). An alternative explanation is that this slower moving population is due to states trapped at surface S-vacancies. Trapped CT excitons have been predicted and observed at organic/GaN and organic/ZnO HJs (Panda et al., 2016, Panda and Forrest, 2017), and hence it is possible that similar effects are active at  $WS_2$ /Tc interfaces.

Spectroscopic evidence for HCTEs and efficient charge transfer at pentacene/ $MoS_2$  (Homan et al., 2017) and  $WS_2$ /PTCDA HJs has also been reported (Liu et al., 2017). Excitons bound at the HJ can be modeled by assuming that the TMDC has only in-plane polarizability, and that holes in the TMDC bound to electrons on the organic side of the HJ are delocalized in the 2D film plane. Due to the asymmetry of the dielectric constants and effective masses of charges in the two materials, the HCTE wavefunction on the inorganic side has 2D W-M character, whereas on the organic side it has local Frenkel character (Renshaw and Forrest, 2014). Thus, the hole is Coulombically bound to an electron fixed on a molecule across the HJ. This assumption is justified by the lower dielectric constant and larger effective mass of charges in organics as compared to holes in TMDCs.

The potential energy of the hole is  $V(r) = V_{xy}(x, y) + V_z(z)$ , where  $V_{xy}(x, y)$  is the Coulomb potential between the electron and the hole which primarily depends on the 2D distribution of the hole in  $x$ - $y$  TMDC plane, and  $V_z(z)$  includes other potential terms such as the image charge potential and energy level offsets, which are constant in the  $x$ - $y$  plane. To simplify the analysis, the hole wavefunction is written as  $\psi(r) = \psi_{xy}(x, y) \psi_z(z)$ , where  $r = \sqrt{x^2 + y^2 + z^2}$ . Schrödinger's equation is then

$$\left( -\frac{\hbar^2}{2m^*} \nabla_{xy}^2 + V_{xy}(x, y) \right) \psi_{xy}(x, y) = E' \psi_{xy}(x, y), \quad (9.40)$$

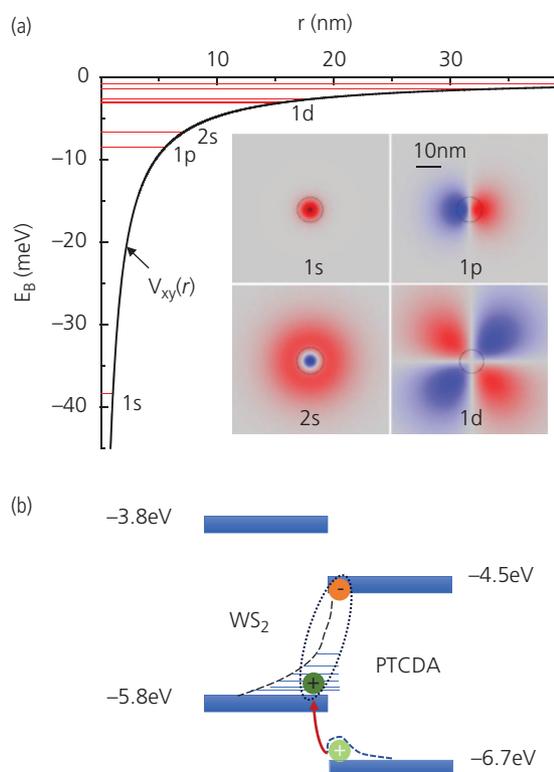

where  $m^*$  is the reduced effective mass of the HCTE and  $E' = E + \frac{\hbar}{2m^*} \frac{\psi_z''(z)}{\psi_z(z)} - V_z(z) = E - E_{free}$ , which is approximately the HCTE relative to the free hole energy. Also,  $\psi_z''(z)$  is the second spatial derivative of the wavefunction with respect to  $z$ . The Coulomb potential is  $V_{xy}(x, y) = -\sum_{i=1}^n \frac{q^2/n}{4\pi\epsilon_0\epsilon_r|\mathbf{r}_h - \mathbf{r}_i|}$ , where  $\epsilon_r$  is the dielectric constant of  $WS_2$ , and  $r_h = \sqrt{x^2 + y^2}$  is the position of the hole in the 2D film plane.

This analysis has been applied to electron and hole bound pairs at PTCDA/ $WS_2$  type II HJs. The charge distribution of the anionic PTCDA is found via DFT, and is simplified by using a summation over  $n$  discrete, fractional point charges at positions  $\mathbf{r}_i$  on the molecule. Due to the mirror symmetry of PTCDA, it is adequate to use  $n = 2$  separated by 0.56 nm on the two halves of the perylene core.

The energy eigenvalues of Eq. 9.40 yields the energy levels and the 2D eigenfunctions shown in Fig. 9.84a, using the energy barriers at the PTCDA/ $WS_2$  heterointerface in Fig. 9.84b. The lowest CT state has a binding energy of 38.2 meV, making it stable at room temperature. Also shown are the hole wavefunctions of the lowest four states corresponding to the 1s, 1p, 2s, and 1d orbitals, with average electron-hole separations of  $r_0 = 2.2, 7.5, 11.0,$  and 18.3 nm, respectively. The relative sizes of these several states are shown (Liu et al., 2017). Note, that in 2D systems, the angular momentum quantum number is not necessarily smaller than the principal quantum number, and that the eigenstates are spread over large distances along the 2D monolayer plane. This is characteristic of a large radius W-M state that is quantum-confined to a limited dimensional space, similar to the situation that obtains in inorganic quantum well structures.

### 9.5.3 Two-dimensional organic/inorganic heterojunction devices

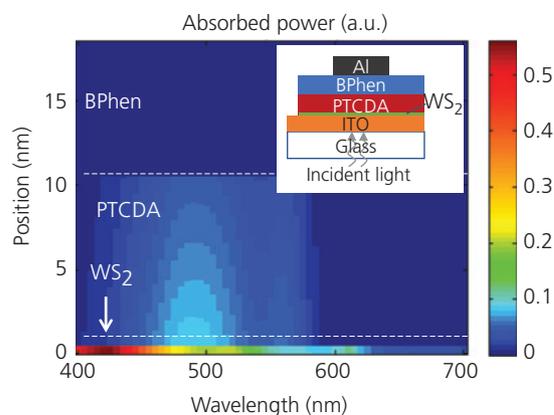

The efficient charge transfer across the PTCDA/ $WS_2$  heterointerface has been used for charge generation in a hybrid organic/inorganic photodiode, schematically illustrated in the inset, Fig. 9.85. The photodiode structure is ITO/TMDC/10 nm PTCDA/8 nm BPhen/100 nm Al. As in OPVs, the BPhen layer is an exciton blocking layer that also provides protection of the active layers during Al cathode deposition. The top electrode is patterned by a shadow mask with  $38 \times 38 \mu\text{m}^2$  square holes aligned to the exfoliated

**Figure 9.84** (a) Energy eigenvalues of HCTE ( $E_B$ ) vs. Coulomb potential,  $V_{xy}(r)$ , for an electron on PTCDA. Inset: Hole wavefunction of lowest four eigenstates within the 2D  $WS_2$  ( $x$ - $y$ ) plane. The black circle in the middle of each graph is a 10 nm-diameter scale. (b) Energy level diagram of the type II PTCDA/ $WS_2$  heterojunction showing the HCTE state and the process of hole capture (Liu et al., 2017).

$WS_2$  islands. Figure 9.85 shows the absorbed power for light incident normal to the substrate via the ITO anode vs. position along the device cross-section, calculated using the transfer matrix model in Section 7.1.4. Greater than 60% of the exciton population is generated in the  $WS_2$  layer when the junction is excited at  $450 \text{ nm} > \lambda > 600 \text{ nm}$ , whereas  $> 85\%$  of excitons are generated in the PTCDA at the intermediate wavelength range of  $450 < \lambda < 600 \text{ nm}$ . It is indeed remarkable that only a monolayer of the TMDC absorbs such a large fraction of the light—a result of its exceptionally high oscillator strength.

The peak external quantum efficiency is  $\eta_{ext} = 1.8\%$  at  $\lambda = 430 \text{ nm}$ , as shown in Fig. 9.86a. The photo-response maxima at  $\lambda = 430, 520,$  and  $625 \text{ nm}$  correspond to the absorption maxima of  $WS_2$ , while others match those of PTCDA. Figure 9.86b shows the internal quantum efficiency calculated using  $\eta_{int} = \eta_{ext}/\eta_A$ , where  $\eta_A$  is the absorption efficiency calculated from ellipsometric measurements of the optical

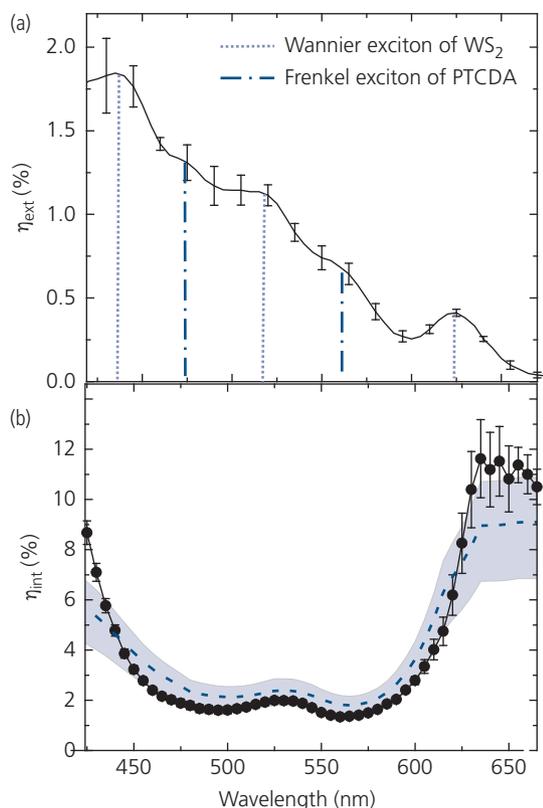

**Figure 9.85** Absorbed power distribution in a PTCDA/ $WS_2$  photodiode. The dashed lines demark the boundaries between the three films comprising the device. The color bar at right shows the relative intensity of the absorbed optical power. Inset: Schematic cross-section of the photodiode. Adapted from Liu et al. (2017).

constants of the various layers. The  $\eta_{int}$  is approximately 2% between  $\lambda = 450 \text{ nm}$  and  $600 \text{ nm}$ , and increases to 11% at  $\lambda < 450 \text{ nm}$  and  $\lambda > 600 \text{ nm}$ .

The internal efficiency has been analyzed using an empirical fit to the diffusion efficiency of excitons in the TMDC and the organic layer, the dissociation efficiency at the HJ, and the charge collection efficiency using a procedure similar to that adopted for the analysis of OPDs in Section 7.1. The procedure yields an accurate fit to the data shown by the dashed line in Fig. 9.86b. From these results we come to two conclusions. The first is that, despite the limited dimensionality of the organic/TMDC HJ, it behaves in many ways like bulk (3D) organic/inorganic junctions in that excitons are photogenerated in both materials. The excitons drift to the HJ where a HCTE forms prior to dissociation into charges that are detected in the external circuit. The second is that the quantum efficiencies of organic/TMDC are remarkably high considering that only a monolayer of material is needed to achieve an external efficiency of 2%, and an internal efficiency of  $> 10\%$ .

While these results illustrate the benefits of combining absorptive organic thin films with 2D materials, the structures are not a practical solution for photo-detections. The TMDCs are polycrystalline, and the exfoliated films result in very small flakes that are difficult to work with. The flakes come in a variety of shapes and sizes (most less than a few tens of microns across) that cannot be precisely positioned on a substrate, which is an essential first step in batch fabrication processes. Before we can begin to consider TMDC-based devices as useful for electronic

**Figure 9.86** (a) External quantum efficiency spectrum of the photodiode in Fig. 9.85, identifying the spectral features in the stand-alone layers. (b) Internal quantum efficiency spectrum. applications, large monolayer films, preferably single crystals, will need to be grown on substrates that provide stability as well as flexibility. Furthermore, a reproducible route to passivating chalcogen vacancies is required to achieve the high electronic performance that is projected for 2D materials. CVD appears to be the most promising growth method that may ultimately reach this goal, although defect-free, large area films have yet to be demonstrated even by this process.

In spite of the challenges, CVD grown monolayers of MoS<sub>2</sub> have been used in detectors employing a 16 nm thick PTB7 polymer. The CVD process uses hot (~500°C) MoO<sub>3</sub> and sulfur powder sources vaporized into an inert (Ar) carrier gas in a quartz reactor. As in organic vapor phase deposition (Section 5.4.2), the elemental source vapors are carried to the substrate where they react to form the MoS<sub>2</sub>. Raman spectroscopy indicates that ~80% of the substrate is covered by monolayer films, with the other 20% covered by bilayer and higher order multilayers. The CVD films are typically polycrystalline, with domain

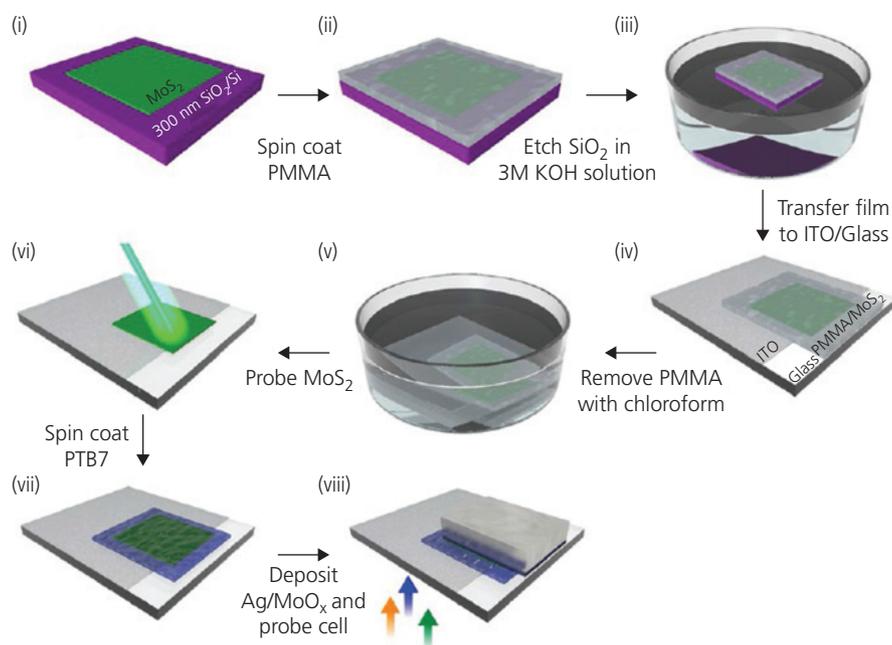

sizes approximating those obtained by exfoliation, that is, ~10–50 μm.

The process sequence used to fabricate the photodiodes is illustrated in Fig. 9.87. The CVD films are (i) grown on SiO<sub>2</sub> coated Si substrates, and (ii) are protected by spin coating a layer of PMMA onto the growth surface. (iii) The SiO<sub>2</sub> is removed by immersion in KOH, which results in the delamination of the monolayer film. Next, (iv) the free-standing MoS<sub>2</sub> is transferred onto an ITO anode-coated glass surface, (v) after which the PMMA protective coating is removed in a chloroform solution. (vi) The TMDC is probed for its properties before (vii) a 16 nm thick layer of PTB7 is spin cast onto its surface. (viii) The 1.6 mm<sup>2</sup> device is completed by vapor deposition of a MoO<sub>3</sub> buffer and a Ag cathode (Shastry et al., 2016). Although the films cover the surface of the parent substrate, the devices are kept small to avoid excess current leakage from high densities of defects at the grain boundaries, as well as along the film surface.

The proposed energy level diagram for the device is shown in Fig. 9.88a. The energy level offsets show that PTB7 functions as the donor, and MoS<sub>2</sub> as the acceptor. The PL of the HJ shows complete quenching of emission from the polymer due to efficient energy transfer to MoS<sub>2</sub>. Indeed, there is almost no emission from the HJ suggesting that the CT state itself does not radiatively combine, in contrast to the behavior of the Tc/WS<sub>2</sub> junction discussed previously.

The detector itself shows both a high absorbance from both the PTB7 between 500 nm and 750 nm, and the MoS<sub>2</sub> between 350 nm and 600 nm, with reduced absorption at longer wavelengths (see Fig. 9.88b). The external quantum efficiency features a peak of 20% at 450 nm, almost entirely due to absorption in the monolayer of MoS<sub>2</sub>. This corresponds to a calculated internal efficiency of 40%. Due to its broad spectral coverage, the same device has been tested under simulated solar illumination. The resulting solar cell characteristics are an open circuit voltage of  $V_{OC} = 0.21$  V, a short circuit current density of  $j_{SC} = 1.98$  mA/cm<sup>2</sup> and a fill factor of  $FF = 0.24$ , yielding a power conversion efficiency of  $PCE = 0.1\%$ .

These performance characteristics point to several challenges confronting TMDC-based HJ devices. The first is the low  $V_{OC}$  compared to the HOMO-LUMO HJ offset potential of  $\Delta E_{HL}/q = 0.8$  V. This is a direct consequence of significant non-radiative recombination at the organic/TMDC HJ. Non-radiative processes are likely due to sulfur surface and edge vacancies discussed above. Secondly, the very low

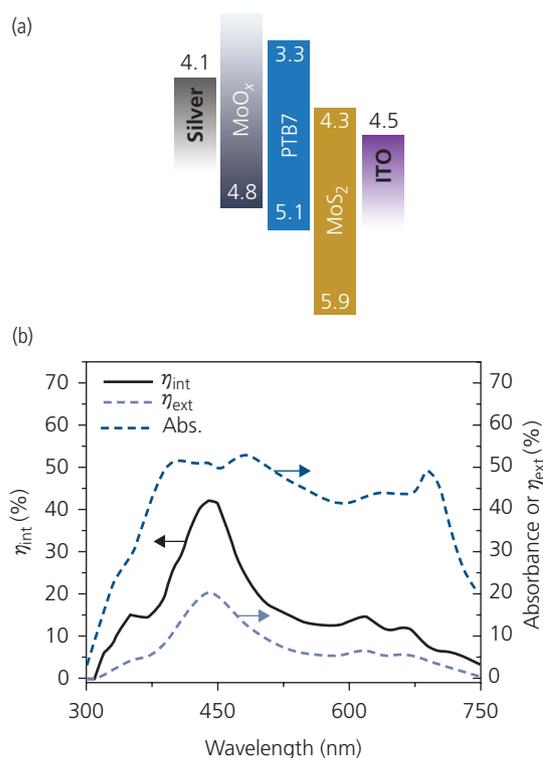

**Figure 9.87** Process sequence for fabricating a PTB7/MoS<sub>2</sub> photodetector (Shastry et al., 2016).

*FF* results from poor rectifying characteristics, possibly due to a large shunt leakage current through grain boundary defects. This is apparent from the nearly symmetrical  $j$ - $V$  characteristics in the reverse and forward biased directions (Shastry et al., 2016). Note that a similarly low fill factor has been reported for C<sub>8</sub>-BTBT/MoS<sub>2</sub> HJ photovoltaics. In that case, the energy level offset between the TMDC and the organic presents a large barrier that impedes electron transport, requiring tunneling to extract the charges (He et al., 2015). A large series resistance results in a very large forward biased ideality factor of  $n \approx 21$ , which may also manifest as a large *FF*. However, significant contact resistances are not readily apparent in the device in Fig. 9.88a, although injection limited conduction cannot be ruled out as being responsible for the low *FF* and large series resistance. Finally, the low  $j_{SC}$  is due to the limited quantum efficiency from the ultrathin layers.

MoS<sub>2</sub> has been used as a source injection contact in a pentacene channel in a BG/BC thin film transistor with a SiO<sub>2</sub> dielectric. As above, the MoS<sub>2</sub> forms a rectifying, type II HJ with pentacene. The ambipolar OTFT showed a low on-off drain current ratio of  $\sim 100$  to 200. This junction exhibits a source-drain photocurrent when illuminated due to charge dissociation at the HJ (Jariwala et al., 2015).

Significantly improved characteristics are achieved using graphene monolayers as the S and D electrodes

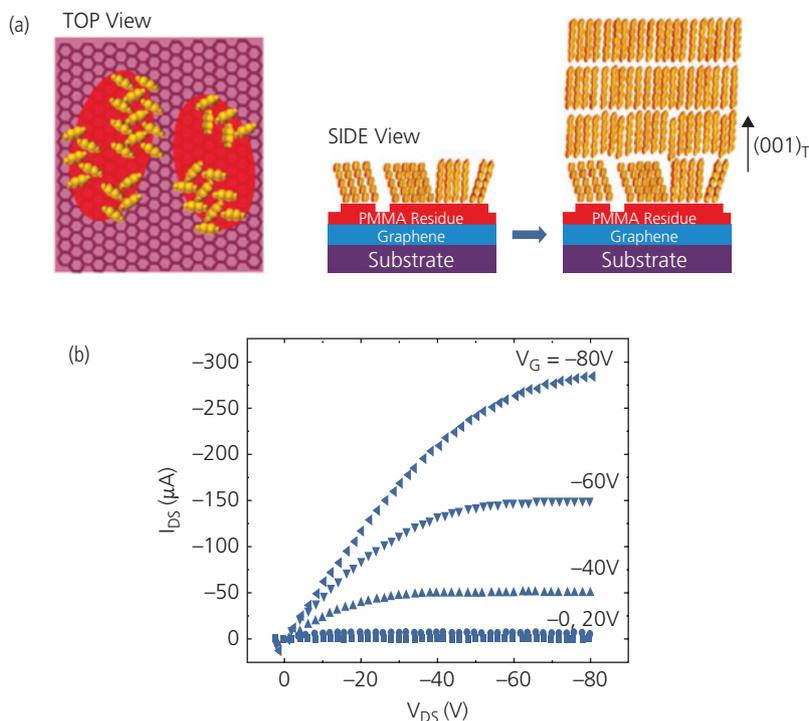

**Figure 9.88** (a) Proposed energy level diagram of the PTB7/MoS<sub>2</sub> photodiode showing frontier orbital energies in eV. (b) Internal (black line) and external (light blue line) quantum efficiencies, and the absorbance spectra (dark blue line) of the active region of the device in (a) (Shastry et al., 2016).

(Lee et al., 2011). The graphene is initially grown via CVD on a Cu substrate, and then detached using a PMMA "handle." The film is transferred to a 300 nm thick SiO<sub>2</sub> gate insulator, after which the PMMA is removed with acetone. However, a residue of PMMA remains on the surface that is removed by thermal desorption. The device is then completed by S and D patterning to form a  $L = 100 \mu\text{m}$  and  $W = 1 \text{mm}$  gap between the electrodes. The last step is deposition of the pentacene channel.

A fused polyaromatic hydrocarbon such as pentacene has a strong tendency to form  $\pi$ -stacks with itself, as well as with substrates that present the same fused phenyl group configuration. Hence, pentacene deposited on graphene forms elongated crystals with the molecules lying in the substrate plane. This stacking habit results in the highest hole mobility perpendicular to the substrate, which is disadvantageous for transistors whose channels are oriented along the plane. The flat lying configuration is frustrated, however, by the PMMA contaminated surface. Molecules that deposit onto PMMA islands that are left from the transfer process stand on end, as shown in Fig. 9.89a. Molecules that land in the gaps between PMMA islands are also held in the

vertical orientation due to interactions with neighboring, vertical standing pentacene molecules that are on the islands. Hence, the partial coverage of graphene by the residual PMMA has the combined effects of creating a vertical pentacene orientation which leads to a high channel mobility, as well as providing sufficiently large graphene regions between the islands to make low resistance contact to the channel.

The output characteristics of the graphene/pentacene OTFT are shown in Fig. 9.89b. The output conductance is low, as required for high gain circuit applications. More importantly, the channel mobility is  $1.2 \text{ cm}^2/\text{V s}$ , which is among the highest values achieved for pentacene OTFTs, primarily due to the order imposed by the electrodes. Furthermore,  $I_{\text{on}}/I_{\text{off}} = 10^8$ , which is competitive with the best pentacene-based OTFTs. Finally, the threshold voltage is  $V_T = 18 \text{ V}$ . Interestingly, the characteristics of pentacene deposited onto thermally treated (and hence uncontaminated) graphene has a field effect mobility of only  $0.4 \text{ cm}^2/\text{V-s}$ , although  $I_{\text{on}}/I_{\text{off}}$  is comparable to that obtained for the OTFT with residual PMMA. The lower mobility is consistent with channels where the flat-lying pentacene molecules have a

**Figure 9.89** (a) Illustrations of the orientation of pentacene (gold structures) on graphene with a PMMA residue (red regions). (b) Output characteristics of the BG/BC pentacene OTFT with graphene S and D electrodes (Lee et al., 2011).

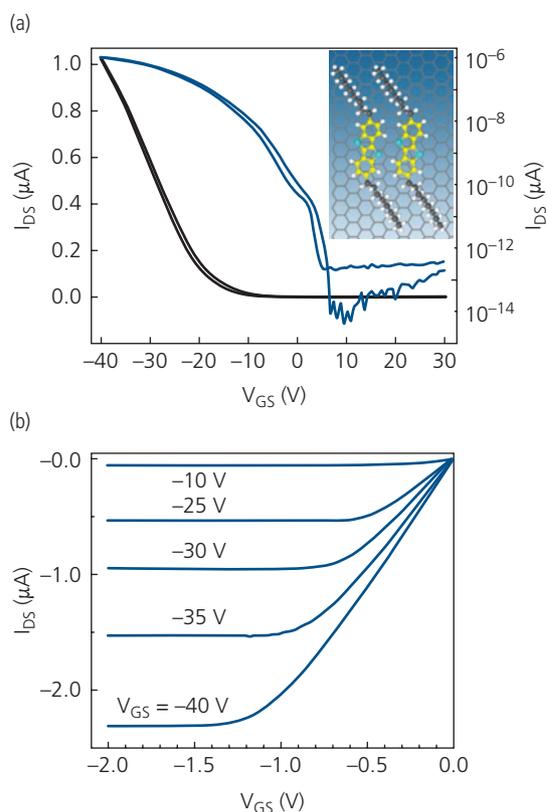

higher in-plane resistance than those where the molecules are up-standing (Lee et al., 2011).

The principal advantage of using graphene in thin film transistors is, therefore, its ability to template the growth of organic layers with large crystalline domains whose structure is guided by the 6-fold symmetry of the monolayer sheet. Van der Waals bonding between layers leads to nearly perfect interfaces with graphene contacts while also resulting in an organic crystal whose highest mobility direction is along the channel.

The graphene conductivity limits its use to a contact material rather than as the channel semiconductor itself (Lee et al., 2011, He et al., 2014). Electrically insulating *h*-BN has a similar symmetry as graphene, and thus also can serve as a growth template for the channel semiconductor. Thus, organics that are  $\pi$ -bonded to an *h*-BN monolayer can benefit from a high quality, low-defect interface. An example OTFT with a <10 nm thick *h*-BN gate insulator consists of a single monolayer of C<sub>8</sub>-BTBT grown by sublimation in a vacuum tube furnace on exfoliated *h*-BN, previously transferred onto 285 nm SiO<sub>2</sub> on a Si bottom gate electrode. The top Au contacts are deposited onto the organic surface to form an OTFT with  $W \approx L \approx 15 \mu\text{m}$ .

The organic molecules can assume several different registries on the 2D template, one of which is shown in the inset, Fig. 9.90a. The molecules nucleate at random locations, but in general lie nearly flat to maximize their  $\pi$ -system contact with the *h*-BN lattice. This results in a polycrystalline film grown layer-by-layer, with single and double layer domain dimensions of several microns. The high quality interface between the organic monolayer and *h*-BN results in a field effect hole mobility of  $10 \text{ cm}^2/\text{V s}$  extracted from the drain current-gate voltage characteristics in Fig. 9.90a. This is considerably higher than expected for similar organic layers deposited directly onto the SiO<sub>2</sub> gate insulator. Also, the mobility decreases to approximately half this value as the organic thickness is increased to create both monolayer and bilayer domains. The ratio,  $I_{\text{on}}/I_{\text{off}} = 10^6$ , is indicative of a high quality interface that prevents parasitic channel leakage. The transfer characteristics in Fig. 9.90b show very low output conductance in the drain current saturation regime, with a threshold voltage of  $-15 \text{ V}$  and a turn-on voltage of  $8 \text{ V}$ .

The transistor characteristics indicate a low density of grain boundaries in the channel, which is in part due to templated growth on the *h*-BN, as well as the relatively short channel length (He et al., 2014). While the first monolayer stacking habit is strongly

**Figure 9.90** (a) Drain current-gate voltage characteristics of an ultrathin *h*-BN/C<sub>8</sub>-BTBT OTFT. Inset: One of several possible substrate registrations of C<sub>8</sub>-BTBT on graphene, which is similar to that found on *h*-BN. (b) Drain current transfer characteristics of the device in (a) (He et al., 2014).

influenced by the substrate, the crystal relaxes to its equilibrium structure as the number of layers increases. Similar thickness dependences are observed in *h*-BN/pentacene OTFTs, with the pentacene hole mobility decreasing abruptly as the number of layers increases from one to two at a thickness of only 3 nm (Zhang et al., 2016). The changes are correlated with the mode of hole transport: it is primarily via hopping in the monolayer film, becoming more band-like in the multilayers. Also, recall that the monolayer films can significantly screen the electric field from the substrate. Field-screening, particularly from charges trapped at the SiO<sub>2</sub> surface, cannot be ruled out as a source of the exceptionally high mobilities observed in channels employing a compound SiO<sub>2</sub>/*h*-BN gate insulator.

We conclude from the foregoing discussion that organic/2D materials offer possibilities for understanding and exploiting the unique and significantly divergent properties of both materials systems. In Chapter 4, we saw that organic/inorganic HJs are

characterized by a combination of Frenkel- and band-like behaviors that define these two classes of semiconductors. In addition, the ultrathin inorganic layers have remarkable properties such as high oscillator strengths, charge mobilities, and room-temperature-stable quantum-confined excited states. Their thinness, combined with the compliant mechanical properties of organics suggests that organic/2D HJs may find uses in ultrathin, highly flexible electronic devices. Yet 2D materials also face significant challenges. The semiconducting transition metal dichalcogenides are plagued by a high density of atomic vacancies, both within the monolayer as well as at its edges. And it remains a challenge to grow large, crystalline sheets of any of these materials. Very often the crystals come in small flakes or domains only a few microns in diameter. While organic molecules can passivate surface defects, the small crystal sizes make it difficult to fabricate photonic or electronic devices that provide reproducibly high performance. Hence, while the science is rich with much yet to be discovered in the nascent field of limited-dimensional organic electronics, the exploitation of the organic/inorganic HJ in practical detectors, emitters and transistors remains only a promise.

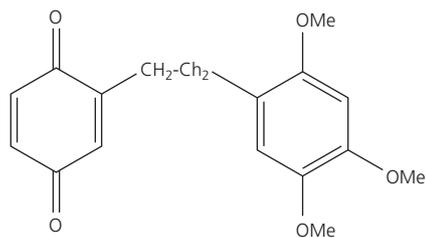

## 9.6 Single molecule electronics

In Section 9.5, we introduced many interesting and emergent physical phenomena found in 2D systems such as organic HJs with transition metal dichalcogenides, graphene and hexagonal boron nitride. The final step in this progression to limited dimensionality is in 1D (i.e. quantum wire) systems, which is the domain of single molecule electronics, or sometimes, *molecular electronics*. We note that zero-dimensional (0D) systems have been described in Chapters 6 and 7 in the context of quantum dot-based devices and associated phenomena used to describe single molecule luminescent centers in OLEDs, organic semiconductor lasers, and detectors. The 0D phenomena in those cases are observed by embedding the NPs or molecules in a bulk, host matrix. They fundamentally differ from the behavior of limited dimensional systems treated here in that 0D systems do not support charge transport.

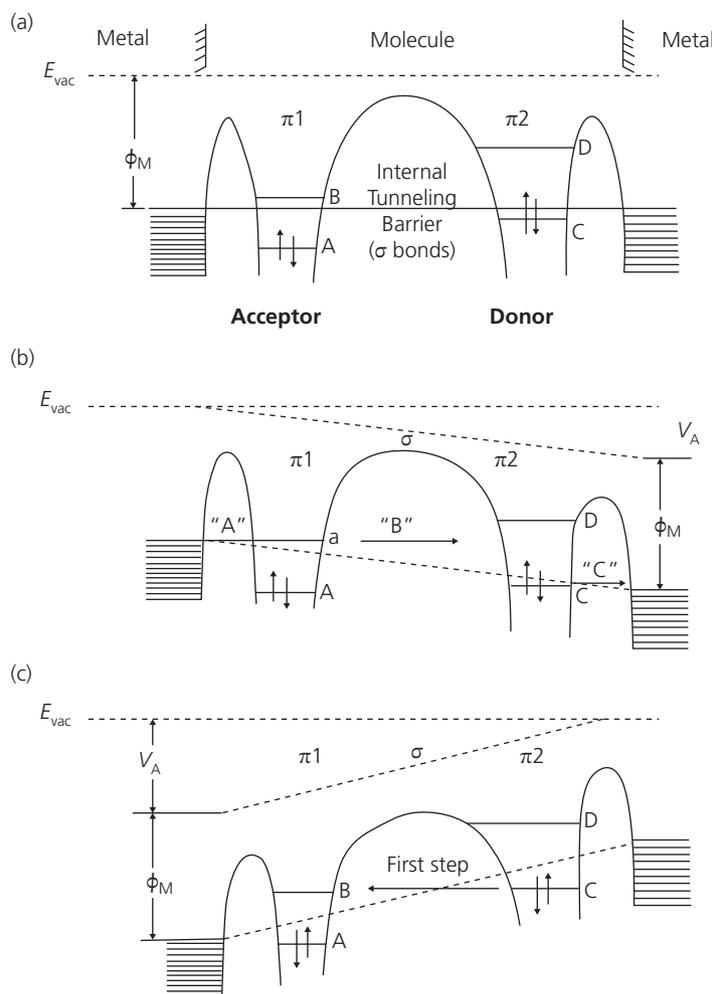

The scale of 1D molecular wires is such that only quantum mechanical descriptions are adequate for their understanding. Single molecules bridging metal electrodes, or forming the channels in single molecule transistors, have exhibited quantum interference (Aradhya and Venkataraman, 2013), the Kondo effect (Scott and Natelson, 2010), tunneling

between molecular states (Nichols and Higgins, 2015, Perrin et al., 2015), and so on. In spite of many difficulties encountered in their handling, single molecule transistors and electronic circuits have been demonstrated in many laboratories over several decades (Joachim et al., 2000). While these devices may eventually lead to scaling of gates with lengths  $<1$  nm, more immediate applications may emerge in chemical sensing. That is, the presence or absence of a single molecule between the nanometer scale gap between electrodes provides unprecedented sensitivity for detection of specific molecular species that selectively attach to functionalized contact surfaces (Nichols and Higgins, 2015).

The single molecule “p-n” junction device was originally envisioned to consist of a hemiquinone comprising an electron deficient quinone acceptor and an electron rich methoxy donor moiety bridged by a non-conjugated methylene bridge (see **Scheme 2**) (Aviram and Ratner, 1974). While this particular configuration is not the focus of current research on molecular devices, it is instructive to understand its operational concept. The equilibrium energy level diagram for the device is shown in Fig. 9.91a. The molecular contact with the cathode introduces a narrow energy barrier between the metal with work function  $\phi_M$ , and the  $\pi$ -electron system of the acceptor group. The  $-\text{CH}_2-$   $\sigma$ -bridge presents a tunneling barrier between the acceptor and the donor groups. A second barrier exists at the donor/anode interface. The LUMO energy of the acceptor and the HOMO energy of the donor lie near to the Fermi energy. By applying a negative voltage to the cathode (i.e. the molecule is forward biased), the LUMO of the acceptor aligns with  $\phi_M$ , allowing electrons to resonantly tunnel into the acceptor group (process A, Fig. 9.91b). Similarly, the filled HOMO of the donor is brought into alignment with the anode, allowing for electron tunneling (process C). The circuit is completed across the molecule by tunneling across the bridge (process B) from acceptor to donor. In contrast,

**Scheme 2** A hemiquinone molecule proposed for single molecule rectifiers.

**Figure 9.91** Conceptual energy level diagram of a molecular rectifier (a) at equilibrium and (b) in forward and (c) reverse bias. Filled energy levels have electrons with spins indicated by arrows. The  $\pi$ - and  $\sigma$ -bonds of the several moieties comprising the molecules are shown (Aviram and Ratner, 1974).

reverse bias in Fig. 9.91c results in misalignment between the metal work function of the anode and the donor, or between the energy levels of the donor and acceptor molecular units, thus inhibiting charge transport.

The architecture in Fig. 9.91 differs from modern molecular electronic devices that focus on molecules that lack separate donor and acceptor units. Nevertheless, it illustrates several features of all such devices. The contact barriers between electrodes influence the transport properties of molecular wires. Similarly, internal energy level alignments, intramolecular charge transfer, the width of molecular energy levels (and hence their overlap with the metal Fermi energy), and resonant tunneling are all important to device operation.

The 1D molecular wire can either contain an excess electron or hole via reduction or oxidation. The

electron energy is estimated by assuming that it is contained along a wire of molecular length,  $L$ . The energy difference between quantum states assuming a particle in a 1D box, is  $\Delta E = \frac{h^2}{2m^*} \left(\frac{\pi}{L}\right)^2$ . For  $L = 1$  nm, which is typical of many small molecules, spatial confinement leads to  $\Delta E \approx 0.4$  eV. A second important energy scale is the molecular charging energy. The large Coulomb repulsion between closely spaced charges makes it unlikely that more than a single excess charge can reside on the molecule at one time. The charging energy of the molecule is given by  $E_C = \frac{1}{2} CV^2 = \frac{1}{2} \frac{q^2}{C}$ , where  $C$  is the molecular capacitance. The charging energy is typically several hundreds of meV. The final consideration is the thermal energy, which determines molecular level broadening as well as occupation of the vibronics

within a given electron orbital. The room temperature thermal energy is  $k_B T = 25.9$  meV, but can be reduced when the sample is cooled.

A simple model that defines the energies of a single molecule device is shown in Fig. 9.92. The molecule is assumed to bridge the gap between two identical metal S and D electrodes. A barrier between the molecule and the contacts has coupling coefficients,  $\Gamma_S$  and  $\Gamma_D$ , respectively. Since the molecule, or its contact anchoring points may not be symmetric, we assume that  $\Gamma_S$  also differs from  $\Gamma_D$ . Furthermore, the neutral molecule has  $N$  electrons and a chemical potential of  $\mu_N$ . The molecule can attach to the contacts either via reaction with the electrode surfaces, or via electrostatic bonds. Adding an electron via tunneling or hopping from the S electrode to the molecule thereby shifts its chemical potential to  $\mu_{N \rightarrow N+1}$ . The imperfect energy alignment between the contacts (with chemical potentials  $\mu_S$  and  $\mu_D$ ) produces contact energy barriers, as illustrated for a device at equilibrium in Fig. 9.92b. In forward bias, the molecular energy level aligns with the S contact as shown in Fig. 9.92c, thereby promoting electron injection. In the diagram, it is assumed that the S and D electrode compositions and contact barriers are similar, and thus the voltage is divided equally between them.

We define three regions for injection and transport. In the *weak coupling* regime, the coupling coefficient is  $\Gamma_{S,D} \ll \Delta E, E_C, k_B T$ . Here, the molecule is only weakly coupled to the contacts, possibly due to physisorption via van der Waals bonds. The molecule thus retains its discretely defined energy levels that it has when isolated, and consequently the level broadening is small. Furthermore, the molecule can support only integer charges, and indeed only a singly ionized state is likely to exist due to electrostatic repulsion from the charge occupying the molecule. This creates a *Coulomb blockade* that arrests further charge injection. Charge transport between the contacts is due to incoherent hopping.

Level broadening is increased in the *intermediate coupling* regime. Molecules covalently bound to the electrodes exhibit  $\Gamma_{S,D}, k_B T \leq \Delta E, E_C$ . In this regime, non-integer charges can reside on the molecule by sharing orbitals with the contacts. The shared valences result in coherent transport across the molecule.

Small molecules are commonly used for metal–organic–metal devices. These molecules have widely separated energy levels. Thus, only a single energy level is in resonance with the chemical potentials of the electrodes at voltages too low to allow for direct tunneling between S and D. Then, the conductance of the device is given by

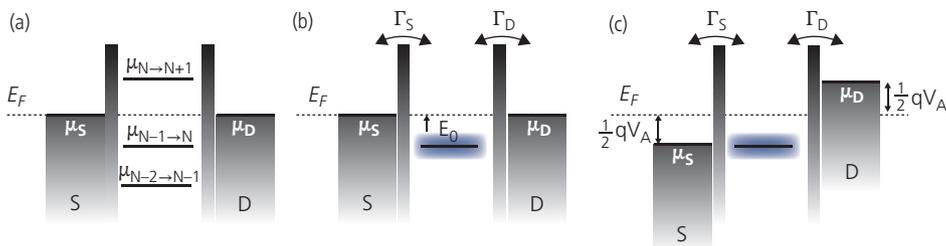

$$G = G_0 T_S T_{mol} T_D. \quad (9.41)$$

Here,  $T_S$  and  $T_D$  are the electronic transmission coefficients of the molecular linkages to the source and drain, respectively, and  $T_{mol}$  is the transmission coefficient of the molecule itself. Also,  $G_0$  is the *conductance quantum*, given by

$$G_0 = \frac{2q^2}{h} = 77.5 \mu\text{S}. \quad (9.42)$$

Now  $G_0$  is obtained from the 1D DOS given by  $g(E) = dn/dE = 2/hv$ , where  $v$  is the electron velocity,  $n$  is the charge density, and the factor of two results from the spin degeneracy of the state. Since the difference between energy levels is  $dE = -qdV$ , then from Ohm's law the conductance quantum follows from  $di = -qdE \left( \frac{dn}{dE} \right) v = G_0 dV$ , where  $di$  is the differential current.

The transmission  $T(E, V_A)$  through a molecular wire can be described in the intermediate coupling limit using the non-equilibrium Green's function approach (Haug and Jauho, 2008). The resulting Breit–Wigner probability distribution gives a DOS that has a Lorentzian line shape, from which we

**Figure 9.92** (a) Chemical potentials of a molecule with  $N$  electrons sandwiched between two electrodes with Fermi energy  $E_F = \mu_S = \mu_D$ , where  $\mu_{S,D}$  are the chemical potentials of the source or drain. The various potentials correspond to molecules with  $i$  missing or added charges ( $N - i, N + i$ , respectively). (b) A single level (energy,  $E_0$ ) molecule at equilibrium or (c) under a bias of  $V_A$  distributed equally across the symmetric electrodes. The source and drain coupling coefficients are  $\Gamma_S$  and  $\Gamma_D$ , respectively.

obtain the total electronic transmission function,  $T(E, V_A) = T_S T_{mol} T_D$  (Breit and Wigner, 1936):

$$T(E, V_A) = \frac{4\Gamma_S\Gamma_D}{(E - E_0(V_A))^2 + (\Gamma_S + \Gamma_D)^2}. \quad (9.43)$$

Here,  $T(E, V_A)$  represents the probability that an electron at energy,  $E$ , and applied voltage,  $V_A$ , will tunnel across the molecular junction. The alignment of the Fermi energy with the molecular level is given by the first term in the denominator, and the second term accounts for energy level broadening. Integrating this function over all energies gives the current–voltage characteristics (Haug and Jauho, 2008):

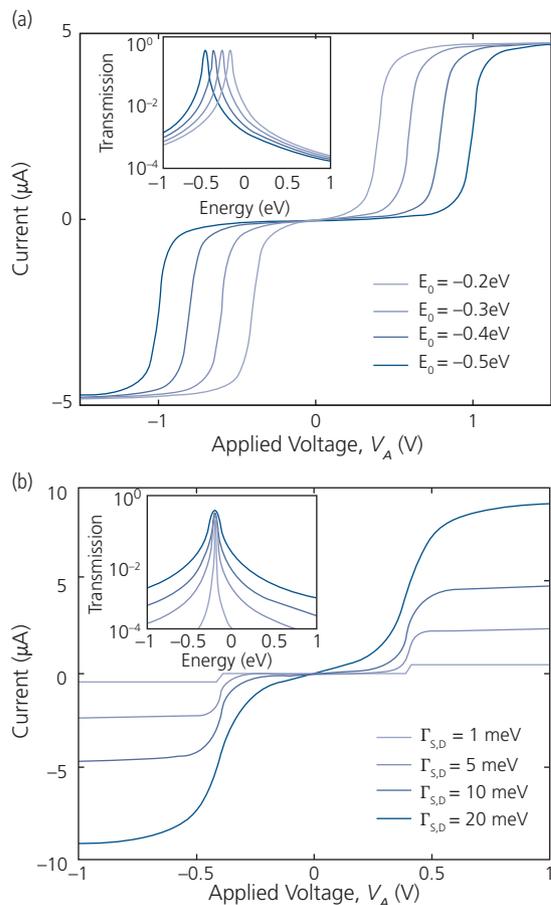

$$I(V_A) = \frac{q}{h} \int T(E, V_A) [f_S(E) - f_D(E)] dE, \quad (9.44)$$

where  $f_S(E)$  and  $f_D(E)$  are the Fermi–Dirac functions at the source and drain, respectively. Then, the current can be solved, to obtain

$$I = \frac{4G_0}{q} \frac{\Gamma_S\Gamma_D}{\Gamma_S + \Gamma_D} \times \left( \tan^{-1} \left( \frac{E_0 + \frac{1}{2}qV_A}{\Gamma_S + \Gamma_D} \right) - \tan^{-1} \left( \frac{E_0 - \frac{1}{2}qV_A}{\Gamma_S + \Gamma_D} \right) \right). \quad (9.45)$$

The current–voltage characteristics following Eq. 9.45 are plotted for several different molecular energies,  $E_0$ , and for a fixed  $\Gamma_S = \Gamma_D = 10$  meV in Fig. 9.93a. As  $E_0 \rightarrow 0$ , the voltage of the current step decreases. That is, the molecular energy comes into resonance with the metal Fermi energy at lower voltages (assumed to be the same for S and D for symmetric junctions), thereby lifting the Coulomb blockade. The energy dependence of the blockade is found in the plot of the transmission function,  $T(E, V_A)$ , Eq. 9.43, in the inset of Fig. 9.93a. The peak transmission occurs at  $E_0$ , and has a Lorentzian shape. The width of the transmission function increases with  $\Gamma_{S,D}$  as shown in the inset in Fig. 9.93b. Indeed, as the energy levels are broadened by approximately  $\Gamma_S + \Gamma_D$ , the current step is smeared out over a larger range of voltage, changing from an abrupt, step-like function for  $\Gamma_{S,D} = 1$  meV, to a smooth “S” shaped curve for  $\Gamma_{S,D} = 20$  meV at  $E_0 = -0.2$  eV.

Finally, the *strong coupling* regime is accessed when  $\Gamma, k_B T > E_C, \Delta E$ . In this limit, the energy levels of the organic are strongly influenced by those of the metal. This results from a pronounced hybridization of the energy levels due, for example, to covalent bonding that significantly broadens the molecular energy levels. The resulting transport is coherent, and the

**Figure 9.93** Current–voltage characteristics calculated for a single molecule spanning a junction between symmetric S and D electrodes as a function of (a) molecular energy level,  $E_0$  for  $\Gamma_{S,D} = 10$  meV, and (b) electrode coupling constant,  $\Gamma_{S,D}$  for  $E_0 = -0.2$  eV. Insets: Transmission vs.  $E_0$  for the corresponding  $I$ – $V$  characteristics (Perrin et al., 2015).

blockade is eliminated since the molecular conductor loses its distinctive character that is now fully shared with the contacts.

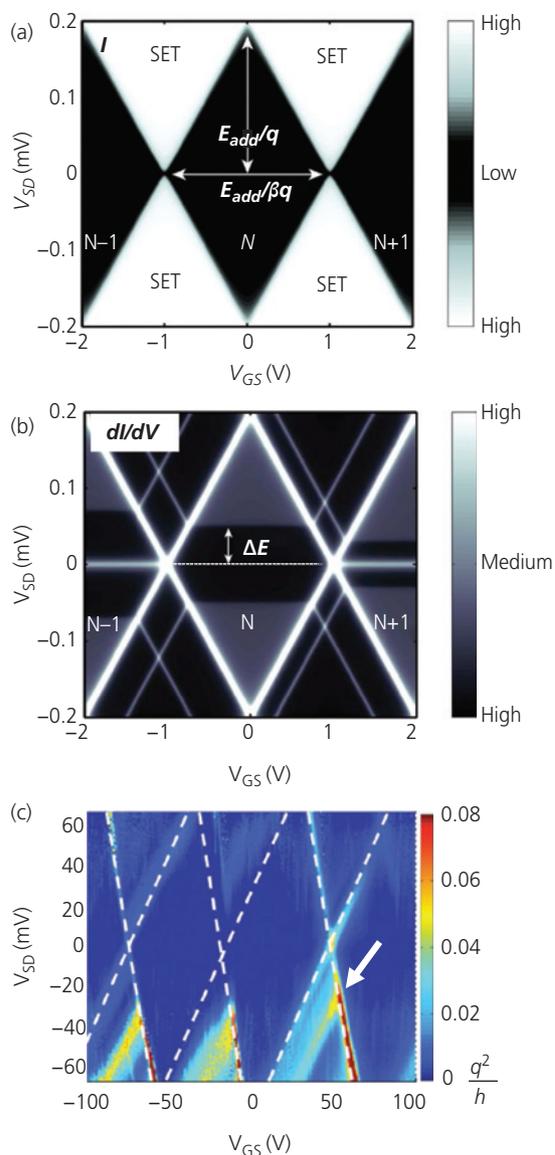

Thus far we have been concerned with two terminal devices. A three terminal molecular transistor can also be constructed, whereby the potential of the molecule bridging the gap between S and D is independently varied by an electrostatically coupled gate. The molecule may be suspended over the gate contact, the gate may be positioned laterally relative to the molecule, or the molecule can lie on the surface of the dielectric gate insulator with the gate electrode located on its opposite surface. In any case, the gate potential is used to change the energy levels of the molecule within the gap relative to the metal Fermi energy. The channel current thus provides quantitative information about the molecular energy levels. A negative gate potential repels the energy levels,

leading to oxidation. Conversely, a positive potential lowers the energy, with the effect of reducing the molecule. The molecular transistor, therefore, is a spectroscopic tool for revealing the density and energetic distribution of states of the molecule.

The interdependence of the source-drain voltage, and gate voltage leads to the diamond-shaped *stability diagram* in Fig. 9.94a. The high current regions (white in the diagram) correspond to bias conditions leading to resonant *single electron tunneling* (SET). Current in this region is supported under bias conditions that lead to alignment between the chemical potential of a molecular level and the electrodes. In the absence of alignment, the molecule forms a conductance blockade. The current is significantly decreased, forming a pattern of *Coulomb diamonds* (black regions). These regions are characterized by a suppression of tunneling, leading to a stable charge state of  $N$  electrons. The electron addition energy,  $\Delta E_{add}$ , is required to overcome the charge blockade. Additional states corresponding to  $N \pm 1$  electrons contact each other at the charge degeneracy points at  $V_{GS} = \pm 1$  V. Thus, the number of Coulomb diamonds is equal to the number of charge states accessible to the molecule.

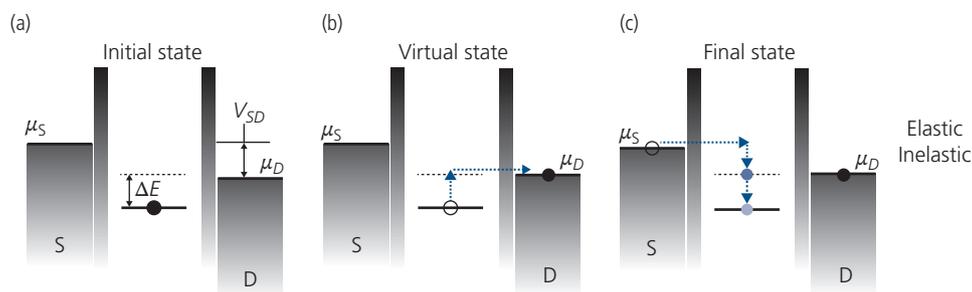

Additional features become apparent when the differential conductance,  $G = dI/dV$ , is mapped as in Fig. 9.94b. The edges of the regions are readily visible as high conductance boundaries to the diamonds. Lines running parallel to the diamonds are due to tunneling through additional excited states in the molecule. Such paths are enabled by higher electronic states, or molecular vibronics. Indeed, the existence of such features provide a spectroscopic tool for revealing the detailed energy landscape of the molecule forming the transistor channel.

The horizontal line of intermediate conductance connecting the diamonds is due to second order isoenergetic *co-tunneling*, illustrated in Fig. 9.95. The initial, charged molecular state is shown in Fig. 9.95a. In the elastic process, the misalignment of the initial state with the chemical potential of the drain electrode ( $\mu_D$ ) indicates that tunneling cannot occur between these states. However, it can occupy a virtual state under the condition that it does not violate the Heisenberg uncertainty principle, where its lifetime is shorter than  $\Delta\tau = \Delta E/\hbar$ . Here,  $\Delta E$  is the energy between the initial and the virtual state (dashed line, Fig. 9.95b). In elastic co-tunneling, the charge transfers back onto the molecule at  $t < \Delta\tau$ , returning it to its original state. By this sequence, an electron is transported from the S to D, as shown by the final state in Fig. 9.95c. Inelastic co-tunneling is identical except that the molecule does not return to its initial

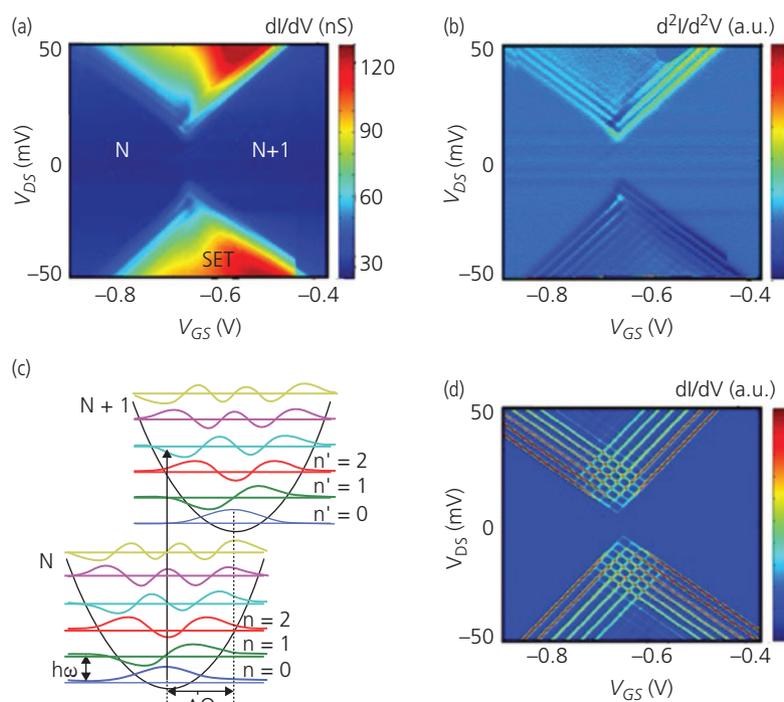

**Figure 9.94** Example stability diagrams of  $V_{DS}$  vs.  $V_{GS}$  for single molecule transistors. (a) Drain current map indicating the energy required to add an electron ( $E_{add}$ ) to the molecule. The high current single electron tunneling (SET) regions are separated from the low current non-resonant regions (black Coulomb diamonds) at the charge degeneracy points. Also,  $\beta$  is the gate efficiency parameter, which is the ratio of the energy change at the molecule to changes in gate potential. (b) As in (a) except the differential conductance is plotted to highlight additional features (Perrin et al., 2015). (c) Measured stability diagram of a single  $C_{60}$  molecule transistor. The white arrow at  $V_{GS} = 50$  V indicates the 33 meV intracage vibrational mode of the fullerene (Scott and Natelson, 2010).

state, but rather it occupies a higher vibrational or electronic manifold. Since the inelastic final state is higher than the initial state, it requires an applied voltage  $V_{GS} > \Delta E/q$ . This gate voltage dependence results in the horizontal lines in the differential stability diagram in Fig. 9.94b.

An experimental stability diagram for a  $\text{C}_{60}$  device is shown in Fig. 9.94c. This diagram exhibits some of the features of the calculated plots, in that there are three charge states (three diamonds) accessed at different  $V_{GS}$ . Also, the secondary parallel diagonal line at  $V_{GS} = 50$  V shows current via the higher 33 meV intracage vibronic of  $\text{C}_{60}$  (Park et al., 2000).

The high spectral resolution afforded by single molecule transistors is amply illustrated by the stability

diagrams for the small molecule magnet,  $\text{Fe}_4\text{SMM}$ , in Fig. 9.96. This molecule has an approximate length of 1.9 nm, with the structure of  $\text{Fe}_4\text{L}_2(\text{dpm})_6$  (L is a tripodal ligand,  $-\text{C}(\text{CH}_2\text{OH})_3$ , and dpm = dipivaloylmethane). The total spin of the molecule in its ground state is  $S = 5$  (Accorsi et al., 2006). The device comprises a single molecule that bridges Au S and D electrodes, and is suspended over a third, gate electrode in a planar configuration. A notable feature

of the stability diagram in Fig. 9.96a is that the SET regions do not share a charge degeneracy point. This is made more obvious by the second derivative of the current in Fig. 9.96b. Several equally spaced features parallel to the Coulomb diamonds are attributed to vibronic substates with resonant tunneling levels that are accessed as the drain and gate voltages are swept through 0 V. Low temperature (1.8 K) measurement is required to avoid washing out of the individual vibronic features (Burzurí et al., 2014).

The charge degeneracy point cannot be restored at any value of gate or drain potential. It is proposed that this results from a “Franck–Condon blockade,” understood from the configuration diagram in Fig. 9.96c. The bulky Fe<sub>4</sub>SMM undergoes a significant Franck–Condon shift from the  $N$  to the  $N + 1$  state due to strong electron–vibron coupling of  $\lambda'$ . The wavefunction overlap between the two states renders the lowest vibronics ( $n = 0, 1$ , etc.) inaccessible to direct transitions, thus forbidding resonant tunneling. This energy region is “vibronically blocked,” thereby eliminating the degeneracy point and shifting the threshold gate voltage to  $\pm 7.4$  meV. The energy level spacing between the parallel current lines gives a vibronic level separation of  $\Delta\varepsilon = \hbar\omega = 2.6$  meV.

We have shown in Section 3.6.1 that the Franck–Condon factor responsible for the configurational shift in Fig. 9.96c is:

$$FC_{n,0} = \frac{\lambda'^{2n}}{n!} \exp(-\lambda'^2). \quad (9.46)$$

The stability diagram in Fig. 9.89d is calculated based on DFT using the experimental values for  $\Delta\varepsilon$ , and assuming  $\Gamma_{S,D} = 1$  meV. These assumptions yield a best fit to the data in Fig. 9.96b of  $\lambda' = 2.21$  meV.

### 9.6.1 Fabricating and characterizing single molecule devices

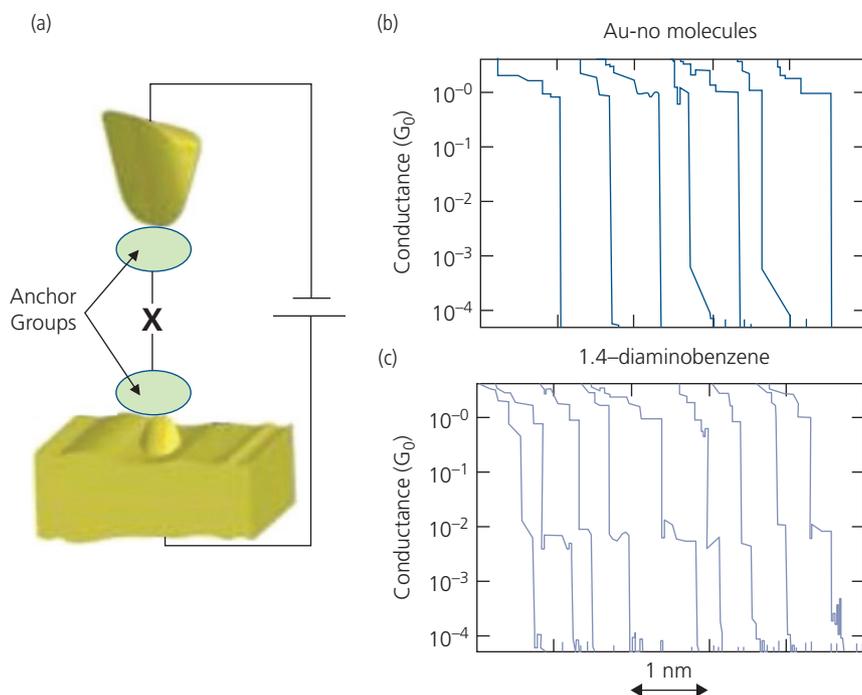

Numerous methods have been devised to create suitably small gaps, and then to fill the gaps with only a single molecule. This is a challenging process; one that must clearly distinguish the conduction current from direct tunneling between electrodes (avoiding the molecule completely), or via residues or other impurities between the closely spaced S and D contacts. A practical solution must avail itself to statistical analysis of a large number of junctions since the gap may be empty (but still conductive, as mentioned), or it may be filled with more than a single molecule.

The most common electrode material is Au due to its lack of reactivity and its ductility. One preferred method of forming a gap is by slowly withdrawing

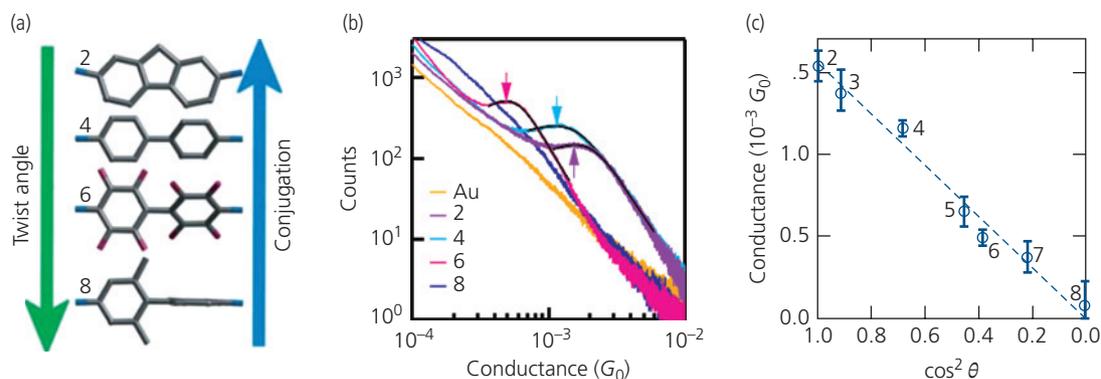

a Au-coated scanning tunneling microscope (STM) tip from a Au-metallized surface in a solution containing a suspension of the target molecules. As the tip is withdrawn, at some point the continuous metal contact is broken, creating a free-standing gap. A molecule, or many molecules, can then attach from the solution to bridge the gap. Its presence is detected by an abrupt increase in conductance. The process is illustrated schematically in Fig. 9.97a. The target molecule (X) is functionalized to anchor itself to the opposing Au surfaces. Conductance data obtained by separating the Au tip in vacuum are shown in Fig. 9.97b. As the distance of the tip is increased to  $\sim 1$  nm, the gap opens and the conductance vanishes. Repeated separations of the tip from the substrate results in the same conductance decrease, providing statistical assurance that the tip can be reproducibly opened by a comparable increase in tip distance. If the same procedure is performed in a 1 mM solution of 1,4-diaminobenzene molecules in a 1,2,4-trichlorobenzene solution, the conductance falls to a plateau at  $10^{-2}G_0$  for a tip separation of approximately one molecular length. As the tip is separated further, there is no change in conductance; this is known as the *molecular lock-in state*, where the molecule spans the gap even though there are small increases in gap length. Finally, the gap is made so large that the molecule breaks its connection to one or both electrodes, and the conductance falls to that of an empty gap. The fact that the conductance plateau reached on each separation event is approximately the same length and at the same conductance indicates that only a single molecule fills the gap.

An interesting application of this point-contact gap formation technique is to measure the conductance of conjugated molecules with varying twist angles between two anchoring phenyl groups. The twist angle is varied by the choice of substituents on the neighboring phenyls: the larger twist angles result in interrupting the conjugation of the electronic systems across the molecule. Several representative molecules used are shown in Fig. 9.98a. Molecule 2 connects the phenyls with a fluorene moiety, thereby planarizing the structure to create a continuous conjugated path across the molecular backbone. Attaching various groups induces a twist along the molecule via their steric hindrance. For example, methyl groups in compound 8 induce a  $\theta = 90^\circ$  twist. Each of the molecules is terminated with an amine that anchors to the Au electrodes.

Each of the molecular species is suspended in 1,2,4-trichlorobenzene solution during the formation of the gap. Conductance histograms taken at  $V_{SD} = 20$  mV

**Figure 9.97** (a) Illustration of a STM-tip junction bridged by a molecule (**X**) bonded to both Au surfaces via functionalized anchor groups. (b) Data from a series of gaps formed by repetitively separating the tip from the Au film surface in the absence of a target molecule, **X**. Each line in the series shows the conductance (in units of  $G_0$ ) as an approximately 1 nm wide gap is opened. (c) As in (b) with the tip immersed in a solution containing 1,4-diaminobenzene. The step at  $10^{-2} G_0$  is due to filling of the gap with a single organic molecule (Venkataraman et al., 2006).

comprising >10,000 contact breakages followed by loading the gap with the molecules are shown in Fig. 9.98b. The arrows locate the peak conductances that are obtained by fitting to a Lorentzian line shape according to Eq. 9.43. The peak widths are broadened by the distribution in conductances measured for the

several devices, as well as to broadening by orbital hybridization with the contacts. A plot of conductance vs. twist angle is shown in Fig. 9.98c for seven of the nine molecular species investigated. The straight line fit follows the theoretical expectation that the conductance is a function of orbital overlap across

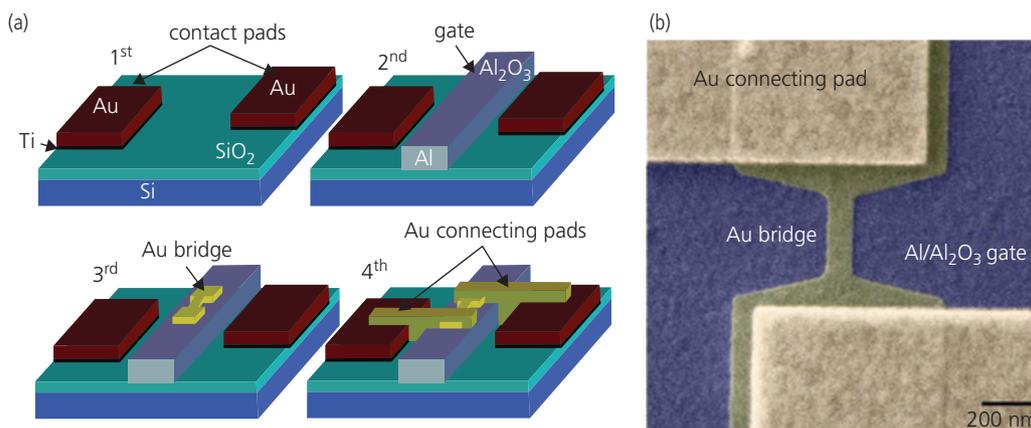

the molecule, which attenuates exponentially with the length of the molecule (Mujica et al., 1999), and follows an approximately  $\cos^2\theta$  dependence on twist angle between conjugating groups (Venkataraman et al., 2006).

Another common method for gap formation is the *break junction*. This comprises a thin metal wire that is broken by applying mechanical stress (Tsutsui et al., 2008, Perrin et al., 2013, Xiang et al., 2013), or by a current that induces Joule heating (and hence melting or burning) (Prins et al., 2011) or electromigration (Strachan et al., 2005, O'Neill et al., 2007, Prins et al., 2009). *Electromigration* is the process whereby current plus the applied electric field displaces metal ions in the solid via collisions by the electrons carrying the current. Generally, electromigration is a parasitic effect in semiconductor devices, whereby a high current causes growth of metal filaments that eventually short circuit the junction. In single molecule devices, it is used to the opposite effect. That is, a constricted metal region along a wire spanning the gap between S and D is thinned by current, and eventually breaks.

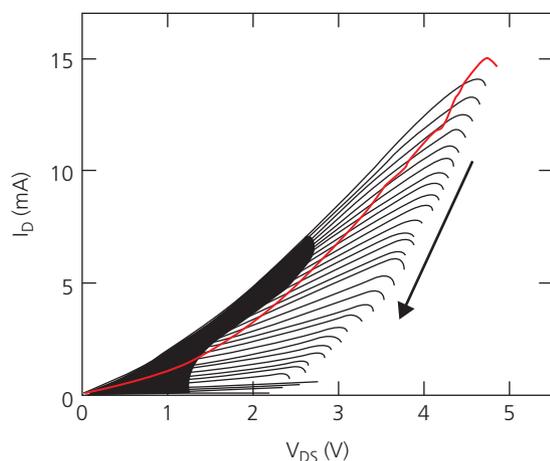

An example process for forming a molecular transistor via electromigration is shown in Fig. 9.99a. Step 1: Large contact pads are deposited onto the surface of the SiO<sub>2</sub> gate dielectric grown on a Si substrate. Step 2: A thin film of Al is deposited in a strip, and its surface is oxidized. The Al is the gate contact coated by the thin Al<sub>2</sub>O<sub>3</sub> gate dielectric. Step 3: The thin (~10 nm) constricted Au bridge is deposited, followed by nano-patterning using e-beam lithography or other suitably high resolution method. Step 4: The transistor is completed by depositing and patterning Au connecting pads to the bridge. A micrograph of the completed device (before gap formation) is shown in Fig. 9.99b.

The planar structure puts the molecule in direct contact with the gate oxide. Alternatively, the metal bridge can be suspended over an open gap, using air or vacuum as the dielectric, or the gate potential can be applied from the side using a separate, narrow gate electrode positioned close to the gap (Xiang et al., 2013). For broken gap structures, the molecules are introduced by immersing the contacts for several hours in a solvent containing the target molecular species, and then rinsing the sample to remove excess material once the gap is filled.

The controlled nanogap formation process proceeds by the methodical, stepwise application of a voltage ramp. Similar procedures are used in forming gaps by electromigration, Joule heating, or electroburning. An example current-voltage characteristic of a gap formed in graphene is shown in Fig. 9.100. The device consists of a few-layer mechanically exfoliated graphene flake placed on a degenerately doped Si gate/280 nm thick SiO<sub>2</sub> gate insulator. Contact to the graphene is made by depositing and patterning Cr/Au electrodes. To form the nanogap, the voltage between the electrodes is ramped at 1 V/s while measuring the drain current (red line). The sweep is halted once the drain current drops to 10% of its peak value, after which  $V_{DS}$  is returned to zero. The voltage is then swept repeatedly until the drain current no longer increases with  $V_{DS}$  (black lines). The decrease in  $I_D$  with each successive sweep is due to electroburning, that is, the graphene undergoes Joule heating that causes it to react with oxygen. On each sweep, the graphene is further eroded and can support less current, leading to additional loss of material. Since only a small amount of material is lost on each cycle, the process can be immediately halted following

**Figure 9.99** (a) Process sequence for fabricating a single molecule transistor. (b) Helium ion microscope image of the transistor prior to forming the gap by electromigration (Perrin et al., 2015).

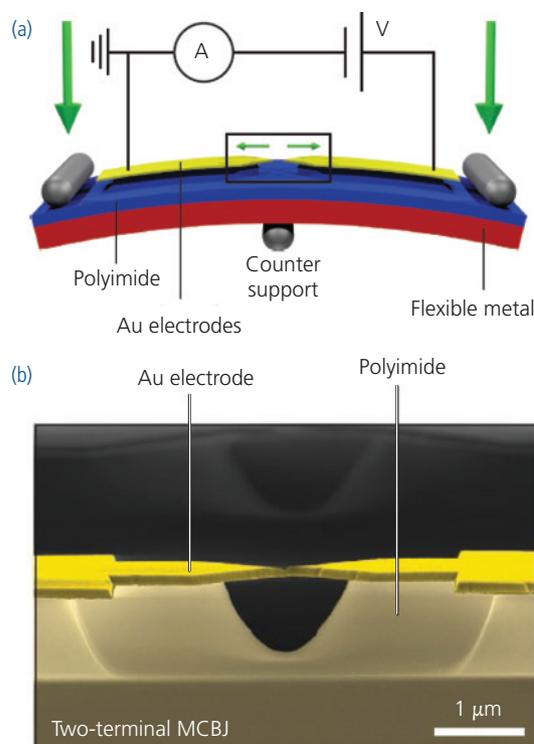

**Figure 9.100** Electroburning formation of a few-layer graphene S and D contact. The first sweep is shown in red. Successive voltage sweeps follow the direction of the arrow until the gap is completely opened, and  $I_D \rightarrow 0$  (Prins et al., 2011).

the opening of only the smallest gap, thereby controllably forming gaps of the required size. Note that the initial sweep current (red line) has a different, non-linear dependence on voltage than subsequent sweeps. This is attributed to volatilization of surface impurities during the first application of thermal stress to the graphene. Analogous procedures have been employed in forming Au junctions by electromigration (Perrin et al., 2015) and in single walled nanotube electrodes (Marquardt et al., 2010).

The mechanically controlled break junction (MCBJ) physically fractures a constricted region of the metal bridge, with the dimensions of the resulting gap determined by the stress applied. The MCBJ formation process is shown in Fig. 9.101a. The device (a simple junction or transistor) is fabricated on a flexible metal substrate such as phosphor-bronze, with the contact constriction centered over a stationary support. Pressure is applied via piezoelectric actuators to translate the edges downward (or in some configurations, in the opposite, upward direction via translation of the center support), creating a maximum stress at the constriction. Pressure is increased until the substrate is sufficiently flexed to break the contact. The magnitude of the translation of the center to the edges of the device determines the gap opening. This method can produce sub-Ångstrom control of the gap length (Tsutsui et al., 2008). A profile view of a Au MCBJ suspended over a preformed cavity on a polyimide substrate is shown in Fig. 9.101b.

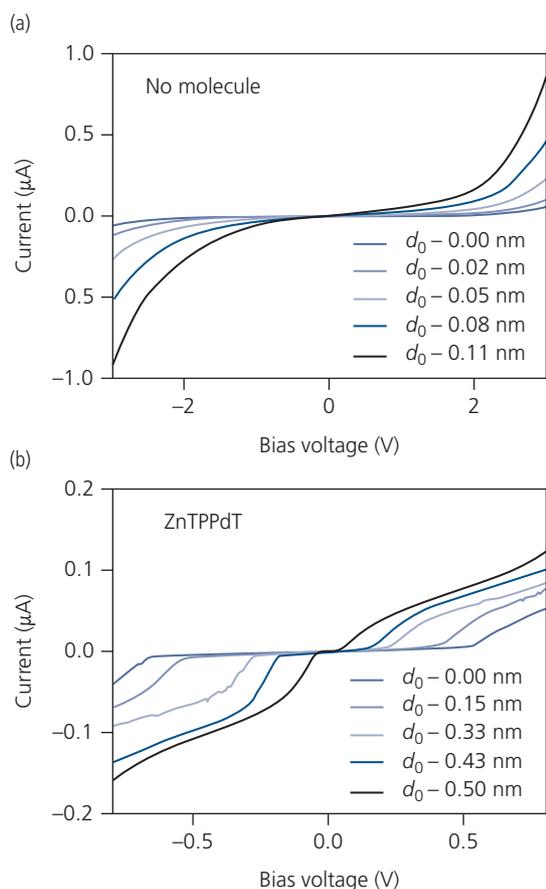

Data for a MCBJ with and without a ZnTPPdT porphyrin bridging two Au electrodes are shown in Fig. 9.102a and b, respectively. The ZnTPPdT is

**Figure 9.101** (a) Experimental configuration for forming a mechanically controlled break junction (MCBJ). (b) False color SEM image of a MCBJ (Perrin et al., 2013).

anchored to the electrodes via thiolphenyl terminating groups. The empty device shows that at the widest, initial displacement,  $d_0$ , the current is nearly zero, independent of  $V_{DS}$ , and it increases with decreasing gap width,  $d_0 - \delta$ . The small changes of  $\delta$ , from 0.02 to 0.11 nm, indicate the exquisite precision with which the nanogap can be controlled. As the gap is narrowed, the current at high voltage increases exponentially, characteristic of tunneling between electrodes.

Filling the gap with ZnTPPdT results in the appearance of steps in the  $I$ - $V$  characteristics in Fig. 9.102b. At the largest separation ( $\delta = 0$ ), the current around  $V_{DS} = 0$  is very small, indicative of weak coupling between contacts and molecule. In this regime, current is limited by the Coulomb blockade that allows only a single electron to reside on the molecule at one time. At  $V_{DS} = \pm 0.6$  V, the blockade is lifted and the current is increased by sequential electron tunneling. Interestingly, the voltage corresponding to the onset of conduction monotonically decreases with decreasing gap width, with a “mechanical gate efficiency” of  $\sim 1$  V/nm. As the current onset voltage decreases, the device shifts from the weak, to the intermediate coupled regime.

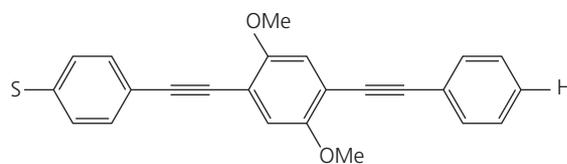

**Figure 9.102** (a) Mechanically controlled break junction data for a Au junction as a function of electrode displacement ( $d_0 - \delta$ ) relative to its initial value,  $d_0$ . (b) As in (a) but with the gap filled by a ZnTPPdT molecule (Perrin et al., 2013).

The dependence of the current onset vs. gap width is due to image charge interactions between molecular orbitals and those on the metal electrodes. The Zn porphyrin structure attached to two Au atoms on either side due to thiolation reactions is depicted in Fig. 9.103a. The calculated electron distribution for the HOMO is given in Fig. 9.103b, for the molecule within the gap in Fig. 9.103c, and for the LUMO, the distribution is shown in Fig. 9.103d. Notable features are that electrons on the HOMO are distributed across the molecule. In contrast, the LUMO distribution is to some degree, protected from exposure to the Au atoms by the thiol linkages since the electron distribution is localized on the porphyrin core. Within the gap, however, the electrons are attracted toward the anchoring groups due to image forces at

the large Au electrode metal surface. For the calculation, it is assumed that the electrodes are infinite metal planes positioned approximately 1 Å from the first atomic layer of the molecule. As the distance between the molecule and the electrodes is reduced (i.e. increasing  $\delta$ ), the image charge attraction increases, further hybridizing the Au and molecular orbitals along the anchoring thiol linkages. The net effect is to increase the HOMO–LUMO gap, as shown in Fig. 9.103e. The HOMO level shift is considerably larger than the LUMO due to the aforementioned greater exposure of the electron distribution in the HOMO orbital. Indeed, the LUMO states are positioned well above the Fermi energy, whereas the gap and HOMO levels are close to  $E_F$ , indicating greater participation in charge conduction between the contacts. The calculated shifts are approximately double that observed in the experiment. This is due to the assumption of an infinite metal plane in the simulations, which is expected to have a larger image force than the actual, sharply pointed electrodes formed at the break junction. Note that there are additional energetic consequences arising from molecular deformation as it is squeezed, or elongated within the electrode gap. However, DFT calculations show that these effects are far smaller (50–60 meV) than those due to image charges, and in fact only results in a rigid shift of the HOMO and LUMO energies without affecting the energy gap between them (Perrin et al., 2013).

From the foregoing, we see that anchoring of the molecule to the electrodes determines the degree to which the molecular and metal levels are hybridized, and hence whether the device itself is operating in the weak, intermediate or strong coupling regimes (Chen et al., 2006, Martín et al., 2010, Briechle et al., 2012). This assumption is tested using asymmetrically functionalized triphenylenethynylene (TPE) in **Scheme 3**. This molecule has two different anchoring moieties to a Au junction. The S-termination forms a covalent bond, whereas the phenyl moiety forms a weak, facial  $\pi$ -bond with the opposing electrode. Consequently, the coupling strength to the electrodes is highly asymmetric. The behavior of this compound (compound (i), labeled Au|S-TPE|

Au) is compared in Fig. 9.104 to that of the symmetric Au|S-TPE-S|Au molecule (compound (ii)) in a gap formed between an STM tip and a flat Au surface. Conductance histograms of the two compounds obtained by measuring  $I$  vs. separation distance,  $s$ , between the tip and planar contacts of approximately 450 junctions are shown in Fig. 9.104a. Typically, it takes  $\sim 1500$  measurement attempts to achieve a data set for 400–500 devices. The measurement failures are due to obtaining the conductance from direct tunneling between contacts across an empty gap, multiple molecules filling the

gap, and noisy data from poor contacts to a molecule, or to mechanical vibrations.

Several features appear for the TPE-based devices, depending on whether the current set-point of the tip is low (5 nA, left hand histograms) or high (60 nA). For example, at a low tip current, both molecules exhibit a low conductance ( $5 \times 10^{-6}G_0$ ) peak  $\pi$ -1, whereas only (i) shows peak  $\pi$ -2. Also, a third peak, A, is apparent at a higher conductance ( $2 \times 10^{-5}G_0$ ) for only compound (ii). At higher tip currents, the measured conductance is ten times that at lower currents, possibly indicating multiple electron

**Table 9.6** Characteristics and measured properties of compounds (i) and (ii) used in single molecule devices (Martín et al., 2010)

Molecule	Peak	$G$ ( $\times 10^{-5} G_0$ )	$s_{BO}$ (nm)	Mol. length (Au...Au) (nm)
i	$\pi$ -1	0.61	2.92	2.84
	$\pi$ -2	1.19	2.65	-
	T	4.86	2.10	2.19
ii	$\pi$ -1	0.57	2.82	2.82
	A	2.02	2.26	2.51
	B	10.7	2.02	2.27

conduction. There, peak T is found on the asymmetric compound (i), whereas compound (ii) exhibits peak B at double the conductance of peak T. A summary of these results, along with a measurement of their junction breakoff distances,  $s_{BO}$ , that corresponds to the tip separation where the conductance,  $G \rightarrow 0$ , is provided in Table 9.6.

The data in Fig. 9.104a and in the table reveal that the peaks arise from very different bonding properties of the covalently attached thiol groups of compound (ii), the asymmetric attachment including a facial  $\pi$ -bonding of compound (i), and a third species of two laterally  $\pi$ -stacked TPE molecules in a configuration labeled Au|S-TPE- $\pi$ -TPE-S|Au, shown in Figs. 9.104b-d. A clear picture begins to emerge from the relationship between the breakoff distance and the conductance of the various peaks. The calculated length of (i) is 2.19 nm, which is equal to  $s_{BO}$  for peak T. Similarly, the molecular length of (ii) is 2.5–2.3 nm, which is comparable to the A and B breakoff distances of 2.26 and 2.02 nm, respectively (Table 9.6). Hence, features A, B, and T are associated with a single molecule of either type spanning the gap between the STM tip and the Au base. Note, however, that the higher conductance of B compared to T at a high tip current suggests that the stronger anchoring of the two thiol groups of (ii) provide improved coupling compared to that afforded by the weak electrostatic facial coupling of the H-terminated phenyl group of (i). The conductances of these features along with A are all considerably higher than for  $\pi$ -1 and  $\pi$ -2 for either compound. (It is speculated that  $\pi$ -2 may also be present in (ii) but is obscured in the shoulder of  $\pi$ -1.) Further, the breakoff distances of the  $\pi$ -1 and  $\pi$ -2 peaks are 2.65–2.92 nm, which are considerably longer than the corresponding molecular lengths. This suggests that the gap contains a pair of  $\pi$ -stacking molecules that are anchored at their ends by thiol attachment to the Au contacts. This configuration is illustrated in Fig. 9.104d. Conductivity is considerably reduced from that achieved by direct Au|S-TPE-S|Au coupling. The inference of a  $\pi$ -stacked bridging molecular pair is supported by the absence of similar conductance features and breakoff distances for molecules that replace the –OMe functionalizing group with *tert*-butyl; a bulky group that sterically inhibits  $\pi$ -stacking. The conclusions are further supported by DFT calculations of the electron transmission coefficients for the various configurations and anchoring groups (Martín et al., 2010).

Different bonding configurations have also been explored using *N*-alkane chains between Au electrodes symmetrically terminated with carboxylic acid (–COOH), amine (–NH<sub>2</sub>), and thiol (–SH) groups. As noted above, thiols form strong covalent bonds with Au, whereas amine bonds are weaker. It is probable that carboxylic acid is bonded by a combination of ionic and coordinating interactions with Au, which forms the weakest coupling of the three terminations. Thus, varying the anchor groups can shift the coupling

from strong to weak. This is directly observed by comparing the breakoff distances and conductivities for the same molecular core. Indeed, it is found that the conductance of  $N$ -alkane molecules follows a relationship characteristic of tunneling, viz.  $G_N = A_N \exp(-\beta_N N)$ . Tunneling transport is via the alkane linkage comprising  $N$   $-\text{CH}_2$  groups spanning the contact gap. The prefactor,  $A_N$ , depends on the strength of the bond between Au and the anchoring units. Thus, its magnitude follows the progression,  $A_N(\text{Au-S}) > A_N(\text{Au-NH}_2) > A_N(\text{Au-COOH})$  (Chen et al., 2006).

### 9.6.2 Unique properties of single molecule devices

The conduction of single molecule devices is determined by the tunneling probability between electrodes via the molecular electronic states. Alignment of these electronic states with the contacts results in resonant tunneling that substantially increases conductivity. Quantum interference along multiple tunneling paths between electrodes will be present if the paths are electronically coupled. Consider  $N$  molecules, with the conductance of the  $i$ th molecule equal to  $G_i$ . Then, in a classical, non-interacting system, the total electronic transmission of the system is

$$T_N(E) = \sum_{i=1}^N T_i(E). \quad (9.47)$$

If all paths are equivalent, the transmission becomes, trivially,  $T_N(E) = NT(E)$ , where  $T(E)$  is the transmission coefficient of the  $i$ th molecule. Then, following Eq. 9.41, near  $V = 0$ :

$$G(E) = NT(E)G_0. \quad (9.48)$$

The case of quantum-coupled paths is considerably different, since the electronic wavefunction can experience constructive or destructive interference at the junctions, or nodes. These interference terms must be included in the total tunneling transparency, yielding (Magoga and Joachim, 1999)

$$T(E_F) = \sum_{i=1}^N T_i(E) + 2 \sum_{\substack{i>1 \\ i \neq j}}^N e^{i\Delta\phi_{ij}} \sqrt{T_i(E_F)T_j(E_F)}. \quad (9.49)$$

Here,  $\Delta\phi_{ij}$  is the relative phase of the wavefunctions at the nodes, which depends on energy as well as the interaction strengths between the several electronic levels of the molecules. In the ballistic transport regime, the output of such a "molecular interferometer" cannot be larger than the sum of the inputs, yet in the tunneling regime (corresponding to moderate to

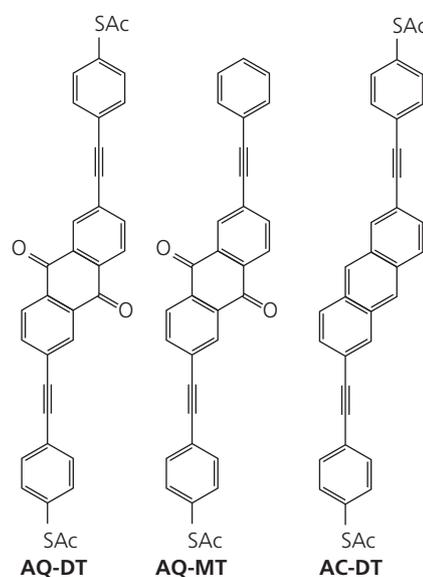

strong molecule/electrode hybridization), the constructive interference term can result in an output that is significantly greater than the sum of the inputs. Interference is expressed by the term on the far right of Eq. 9.49.

If the contributions from all levels are equal, and the levels are centered about the Fermi energy, then the phase shift is  $\Delta\phi_{ij} = 0$ . This leads to constructive interference, in which case the conductance is simplified to

$$G = \sum_{i=1}^N G_i + 2 \sum_{\substack{i>1 \\ i \neq j}}^N \sqrt{G_i G_j}. \quad (9.50)$$

Thus, the total conductance is higher than the sum of the conductances of the individual molecular "arms." This violates the classical Kirchhoff's circuit law that states that the total current in a parallel network is equal to the sum of the currents in the branches. Observation of a conductance larger than the sum immediately to the right in Eq. 9.50 establishes the presence of coherent tunneling along multiple, parallel paths.

Closely packed self-assembled monolayers attached to a Au substrate on one end and a Au-coated AFM tip on the other provide a model system with which to observe electron coherence between parallel molecules. A set of molecules used for these studies is shown in **Scheme 4**. The anthraquinone structures of AQ-DT and AQ-MT result in cross-conjugation that is absent in AC-DT. Here, *cross-conjugation* exists

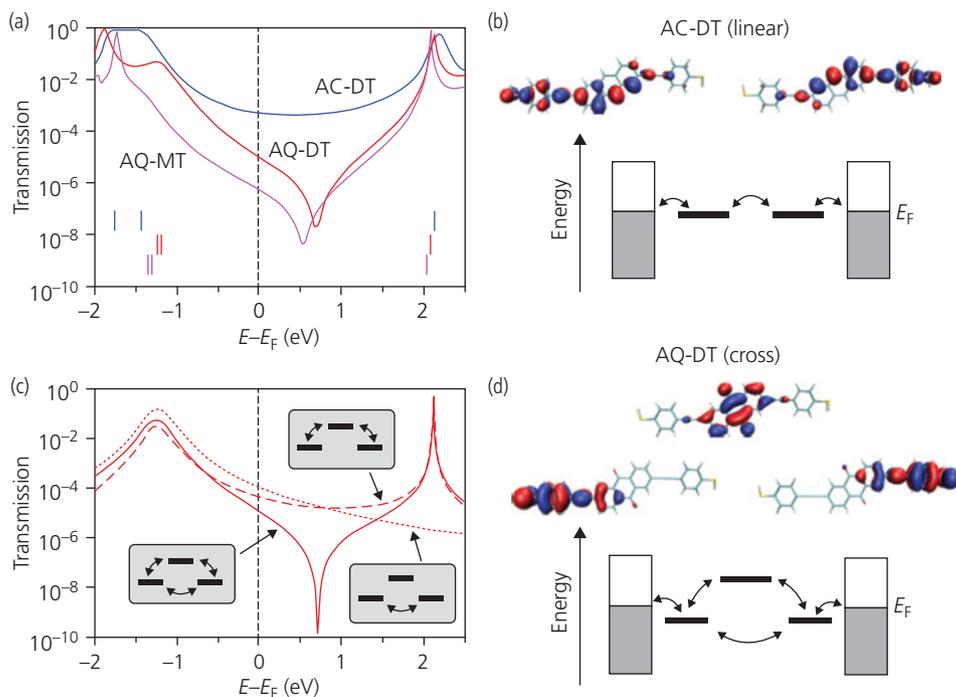

**Scheme 4**

in molecules where only two of three conjugated  $\pi$ -bonds interact. In contrast to linearly conjugated systems such as AC-DT, the  $\pi$ -bonds in AQ-DT and AQ-MT branch off, reducing the degree of conjugation. Thus, a comparison of the behavior of anthraquinone SAMs versus that of the fully conjugated AC can be used to quantify the degree of quantum interference. Note that both the dithiolated molecules AC-DT and AQ-DT are symmetrically and covalently bonded to the Au electrodes, whereas AQ-MT is monothiolated, with the opposing side of the molecule forming a weak electrostatic bond to Au by a non-hybridizing phenyl group.

Calculated transmission spectra of the three molecules are shown in Fig. 9.105a. The linearly conjugated AC-DT shows no particularly notable features. Indeed, its transmission smoothly varies across the energy gap, with peaks near the molecular orbitals due to resonant tunneling. This differs markedly from the cross-conjugated AQ compounds that have a pronounced dip at  $E - E_F = 0.5\text{--}0.6$  eV resulting from destructive interference between the two possible electronic paths taken along the anthraquinone

core. The calculated orbitals for AC-DT and AQ-DT are shown in Fig. 9.105b and d, respectively. In linearly conjugated AC-DT, the orbitals are symmetrically localized near their anchor groups, leading to a single transmission path illustrated by the energy level scheme in Fig. 9.105b. However, the cross-conjugated molecule has two different energy states symmetrically disposed about  $E_F$ . The high-energy path is via the core, and the lower energy route via direct tunneling between the anchors. These two paths undergo a  $\pi$  phase difference, and hence destructively interfere. The transmission calculated for these alternative paths is shown in Fig. 9.105c. Destructive and constructive interference results in dips and peaks in the transmission of the three-site process that are absent via tunneling through a single route comprising either the lower, direct tunneling process, or via only the upper level.

Since the conductance is  $G = G_0 T$ , the existence of interference should be reflected in the conductance spectra near  $V = 0$  (Guédon et al., 2012). Figure 9.106a shows a group of conductance spectra vs. voltage taken for AC-DT using a Au-coated AFM tip break junction.

**Figure 9.105** (a) Calculated transmission of the molecules in **Scheme 4**. The frontier HOMO and HOMO-1 orbital energies at  $E < E_F$ , and the LUMO energies at  $E > E_F$  are shown by lines in the lower quadrants of the plot. (b) Calculated electronic orbitals in AC-DT and the proposed energy level scheme of the molecule anchored via its thiolating groups to the Au electrodes. (c) Electronic transmission via upper and lower electronic pathways for the cross-conjugated AQ-DT shown in (d). Interference between the upper and lower energy branches results in pronounced peaks in  $T(E)$  (Guédon et al., 2012).

The conductance traces have symmetric bowing that is consistent with the smooth transmission vs. energy characteristic in Fig. 9.105a. Conductance histograms at  $V = 0$  V are compared in Fig. 9.106b. The conductance of the cross-conjugated AQ-DT is two orders of magnitude lower than for AC-DT, suggesting destructive interference between the upper and lower energy branches of the former molecule. The  $G(V)$  data of AQ-DT are identical in shape to Fig. 9.106a, which is surprising given the strong anti-resonance in transmission predicted by the calculations. In contrast, the anti-resonance is clearly apparent by the pronounced dip in the conductance data in Fig. 9.106c for the asymmetrically anchored AQ-MT. Indeed, contrary to the constant curvature of the conductance of AQ-DT and AC-DT, the curvature is negative across the entire voltage domain  $V = \pm 1$  V for AQ-MT. This is comparable to the width of the anti-resonance predicted in Fig. 9.105a. The symmetry of the data, even for an antisymmetrically contacted molecule, indicates that the transmission coefficient is nevertheless symmetric about  $E_F$ , which itself lies near the interference minimum.

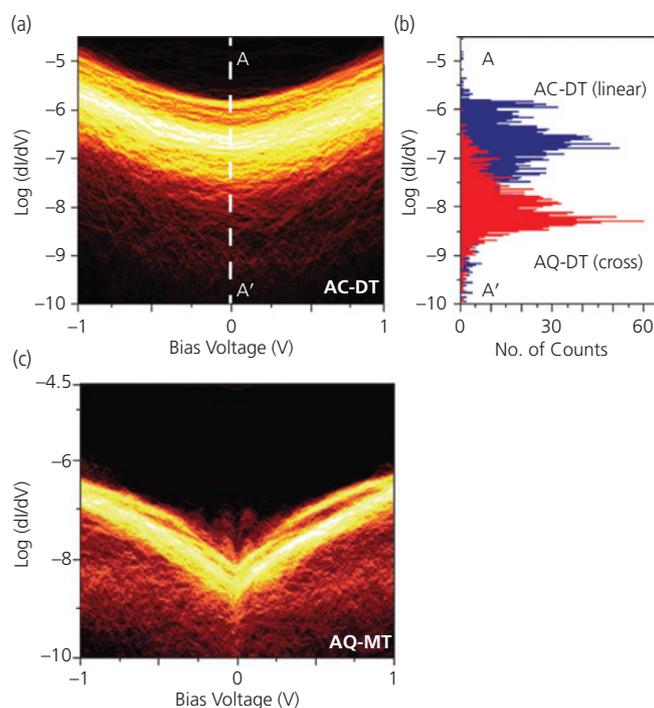

While the markedly lower conductance of the symmetric AQ-DT compared to AC-DT suggests that it, too, undergoes destructive interference, the question remains as to why there is no dip in conductance

similar to that found for AQ-MT. It is speculated that this is due to a shift in the transmission dip to above  $E_F$  in the symmetric molecule, making it beyond the reach of the experimental voltage range of  $\pm 1$  V (Guédon et al., 2012).

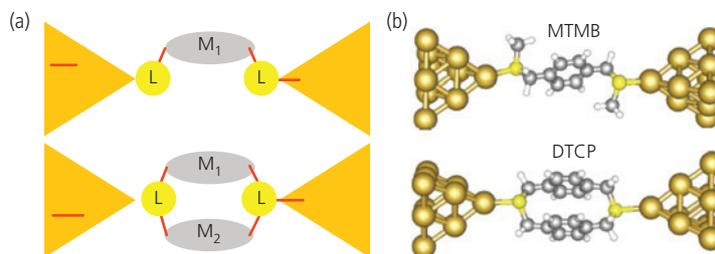

A more direct test of quantum interference is achieved by comparing the conductance of otherwise similar, single and doubly connected moieties symmetrically contacted between an STM tip and a Au substrate. Such a pair of molecules is shown in **Scheme 5**. Both molecules are anchored between Au contacts via their thiol groups. Whereas MTMB offers only a single conductive path via its phenyl

**Scheme 5**

**Figure 9.106** (a) Conductance vs. bias voltage for AC-DT. (b) Conductance histograms at  $V = 0$  V for AC-DT (along the vertical dashed line in (a)) and AQ-DT. (c) Conductance vs. bias voltage for AQ-MT (Guédon et al., 2012).

**Figure 9.107** (a) Illustration of the single and dual transport paths with similar linking moieties (L) between electrodes. (b) A molecular structural diagram of the two molecules in **Scheme 5** spanning the gap between Au contacts (Vazquez et al., 2012).

group, DTCP links a pair of phenyls that split the orbitals, to result in a quantum analog of a double-branched, optical *Mach-Zehnder interferometer* (see Fig. 9.107a). Equation 9.50 suggests that if the conductances of the two branches are similar, that is,  $G_M = G_{M1} = G_{M2}$ , then constructive interference between them should lead to a total resonant conductance of  $G = G_{M1} + G_{M2} + 2\sqrt{G_{M1}G_{M2}} = 4G_M$ . This is double the conductance possible assuming Kirchhoff's law of parallel circuit branches. This idealized situation assumes that the linkers and anchor branches are equivalent,  $E_F$  is at midgap, the electrode couplings,  $\Gamma$ , are independent of energy, and the coupling in the single molecular backbone species to the contact gateway states is small. These conditions are not completely met by MTMB and DTCP in the configurations shown in Fig. 9.107b. For example, the thiolating group in the singly branched MTMB is terminated by a methyl (Me) group, which is similar but not identical to the methyl linker in DTCP.

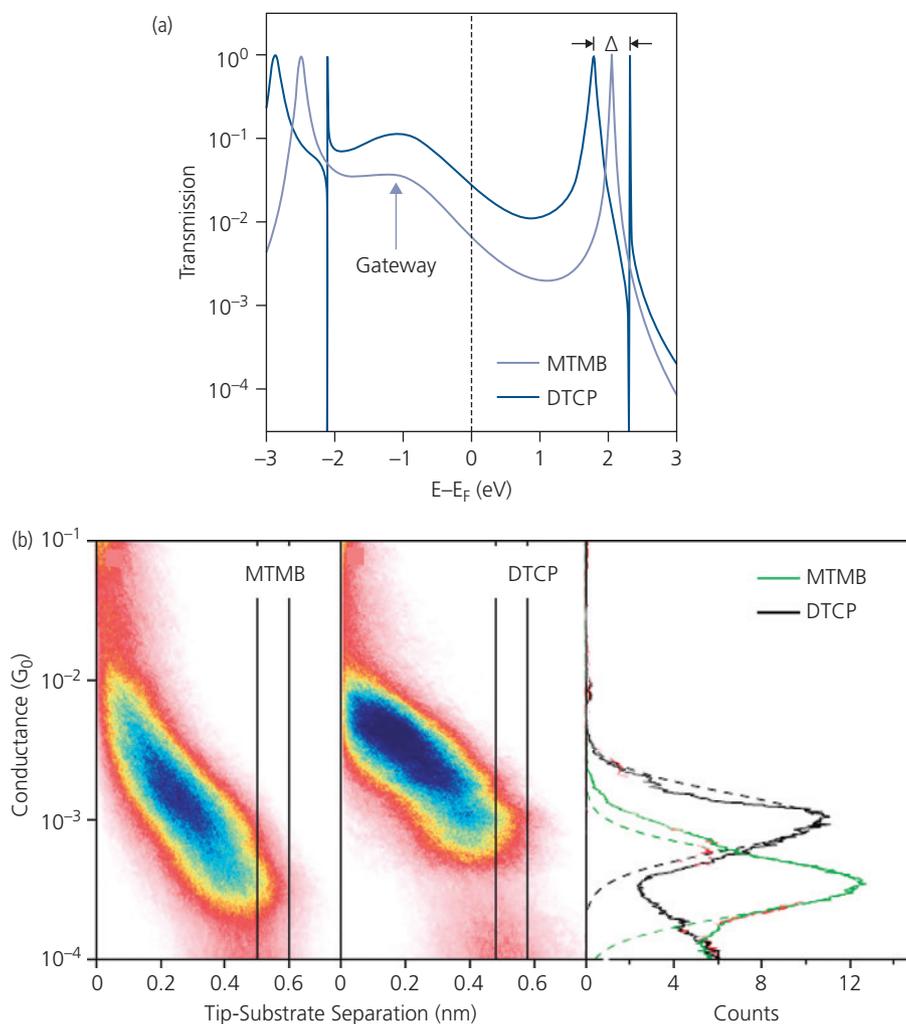

Transmission spectra calculated for the two molecular species are shown in Fig. 9.108a. These idealized results show that  $G(\text{DTCP}) = 4G(\text{MTMB})$ , as predicted. Furthermore, the transmission resonance corresponding to the LUMO is twice as broad as for the single branched MTMB. The splitting between the bonding and antibonding orbitals of the cyclic DTCP is  $\Delta$ , although only the bonding orbital is coupled to the gateway states, and thus it alone contributes to the junction conductance.

The constructive superposition of electronic states is inferred from the conductance histograms in Fig. 9.108b. The histograms each comprise >6000 measurements. They give the conductance as a function of tip/substrate separation,  $d$ , starting at a high conductance at  $d = 0$  where the connection between contacts is broken. The conductance decreases until the molecules are fully extended at  $d = 0.5\text{--}0.55$  nm, corresponding to molecular breakoff. The residual conductance beyond this separation is due to direct tunneling between the STM tip and the Au film substrate.

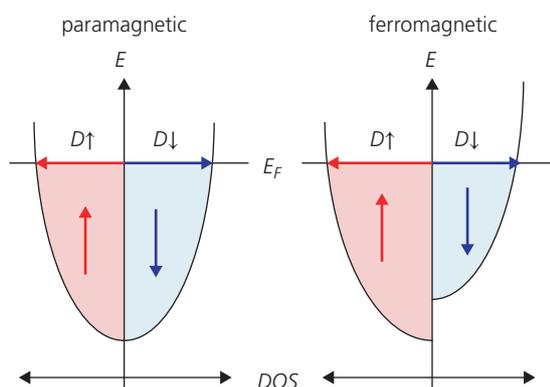

Histograms for the lowest conductance of both molecules near breakoff are replotted at the right in Fig. 9.108b. It is found that the minimum conductance for MTMB is  $2.8 \times 10^{-4}G_0$ , and for DTCP it is  $9.7 \times 10^{-4}G_0$ . Thus, the ratio of the conductance of the double branched DTCP to that of the single-path molecule, MTMB, is  $G(\text{MTMB})/G(\text{DTCP}) = 2.8$ . While this falls short of the theoretical ratio of 4, it is consistent with DFT calculations for this molecular system that yield a conductance ratio of 3.3. Differences may arise from non-idealities in molecular coupling to the contacts. This value is convincingly larger than predicted by Kirchhoff's law, providing evidence for quantum mechanical interference arising from tunneling across the closely coupled orbital systems of the double-backbone DTCP molecule (Vazquez et al., 2012).

Single molecule *spintronic* devices are those that exploit the quantum mechanical spin properties of the materials of which they are comprised. An example of a spintronic device is the magnetic memory that encodes data in domains in a ferromagnetic medium. More recently, coherent spin transport and detection has formed the foundation of quantum information processing, whereby data is encoded into the spin states of a population of atoms or molecules. In Chapter 3 we showed that the non-degenerate nature of electronic levels in organics make them particularly useful in spin-based devices. An obvious example of a spin-controlled organic device is the electrophosphorescent OLED that can achieve 100% internal quantum efficiency via spin-orbit coupling to the triplet state. In this context, a property that can be exploited in single molecule memory devices is *giant magnetoresistance* (GMR). GMR is exhibited when two ferromagnetic layers are separated by a non-magnetic, conducting spacer. If the spacer is an insulator, the effect is termed *tunneling magnetoresistance*, or TMR.

The resistance of the junction is determined by the spin polarized DOS that increases or decreases if the spin polarization of the two contacts is parallel, or antiparallel, respectively. This can be understood

**Figure 9.108** (a) Calculated transmission of MTMB and DTCP. The gateway energy of the anchor groups is indicated.  $\Delta$  is the bonding/antibonding orbital splitting of DTCP. (b) Conductance histograms of >6000 measurements for the MTMB and DTCP from the point of the Au contact breakage to molecular breakoff at 0.50–0.55 nm (left and center, respectively). Histograms taken for the lowest conductance near breakoff (as defined by the vertical lines) are shown at right along with Gaussian fits (dashed lines). Adapted from Vazquez et al. (2012).

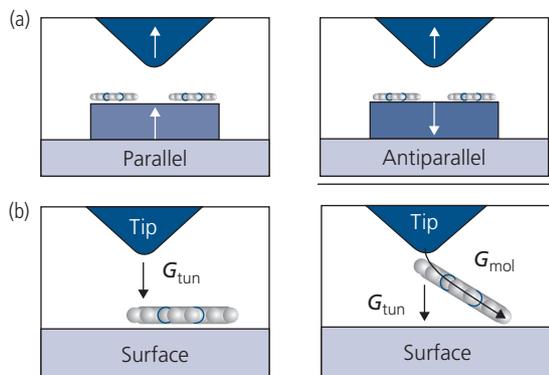

**Figure 9.109** Spin polarized densities of states (DOS) for paramagnetic and ferromagnetic materials. Here,  $D_{\uparrow}$  indicates spins in the “up” direction, and  $D_{\downarrow}$  indicates spins in the “down” direction.

from the densities of states shown for paramagnets and ferromagnets in Fig. 9.109. The net electron *spin polarization*,  $P$ , of a magnetic solid is given by the difference between spins in the “up” vs. the “down” direction,  $D_{\uparrow}$  and  $D_{\downarrow}$ , respectively. That is,

$$P = \frac{D_{\uparrow}(E_F) - D_{\downarrow}(E_F)}{D_{\uparrow}(E_F) + D_{\downarrow}(E_F)}. \quad (9.51)$$

Paramagnetic materials have zero net polarization, whereas  $P < 1$  for ferromagnets due to an imbalance of the majority ( $D_{\uparrow}$ ) and minority ( $D_{\downarrow}$ ) densities of states.

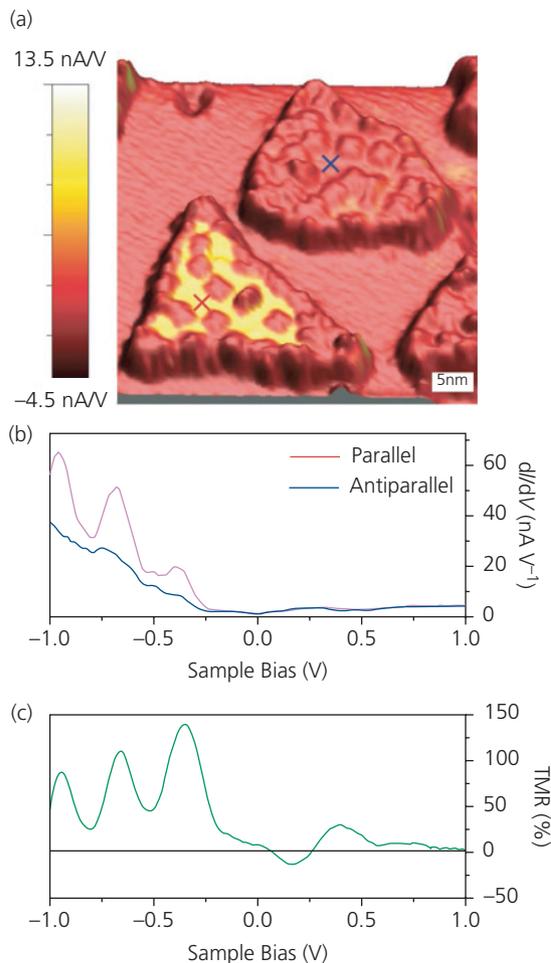

A single molecule device can exhibit GMR if a semi-conducting organic molecule bridges the gap between spin-polarized electrodes. This has been demonstrated in ultrahigh vacuum at 4 K using a spin-polarized

**Figure 9.110** (a) Parallel and antiparallel orientations of a spin-polarized STM (Sp-STM) tip relative to a ferromagnetic domain. (b) Configuration of a molecule on a substrate before (left) and after (right) it jumps to contact the tip as the gap with the substrate is decreased. Before pick-up, the conductance is due only to tunneling ( $G_{tun}$ ). After pick up the conductance is  $G_{tun} + G_{mol}$ , where  $G_{mol}$  is the molecular conductance (Schmaus et al., 2011).

cobalt-coated tungsten STM tip as one electrode, and a single crystalline Cu(111) substrate coated with single domain ferromagnetic Co nanoislands. The tips are polarized out of plane, whereas the dipole orientation of the nanoislands is either normal, or antinormal to the substrate plane, as illustrated in Fig. 9.110a. The islands were coated with  $H_2Pc$  at submonolayer coverage. The larger DOS that results from parallel dipoles leads to a higher tunneling current, and hence a higher tunneling conductance,  $G_{tun}$ , compared to the antiparallel configuration (Nguyen-Manh et al., 1998). When the tip is distant from the substrate surface, the current is due to direct tunneling from the tip. This current is due solely to TMR. However, if a  $H_2Pc$  molecule lies within the gap, the molecule will “jump-to-contact” the tip as it is brought near to the substrate, as shown in Fig. 9.110b. This leads to a higher total conductance equal to  $G_{tot} = G_{tun} + G_{mol}$ , where  $G_{mol}$  is the conductance of the molecule alone. The molecular conductance is then simply the difference between the non-contacted and the contacted conductances, and corresponds to GMR.

Prior to the molecular jump, the conductance increases exponentially as the tip distance is decreased, as is characteristic of tunneling. However, after the molecule jumps, the total conductance increases very slowly with decreasing distance since conduction now occurs via the molecular  $\pi$ -system. Note that the jump-to-contact method is opposite to the previously described break junction procedure, since in the former the starting configuration is with the tip and substrate in a non-contact configuration, whereas for the break junction, the tip and substrate initially form a welded contact.

**Figure 9.111** (a) Co nanoislands coated with a submonolayer of vacuum-deposited  $H_2Pc$  with the magnetic domain parallel (bottom island) and antiparallel (top island) to the Sp-STM tip polarization direction. High current (yellow regions) due to GMR is apparent in the bottom island. (b) Differential conductance vs. bias for the parallel and antiparallel domains in (a). The measurement points in both are shown by “X.” (c) Difference between the conductance of the antiparallel and parallel domains from the data in (b). The most optimistic estimate of TMR is due to the antiparallel orientation, and is plotted on the right. The tip bias is 10 mV (Schmaus et al., 2011).

A spin-polarized STM (Sp-STM) image of two Co domains whose polarizations are parallel and antiparallel to the tip is shown in Fig. 9.111a. The domains are coated by a submonolayer of  $H_2Pc$ , with individual molecules appearing in the image as surface roughness. The current from the antiparallel configuration is lower than when the tip and domain polarizations are parallel. The conductance of the two islands after the contacts are bridged by an  $H_2Pc$  molecule differ considerably, as expected due to the lower spin-polarized DOS of the antiparallel island.

The tip current for both tip/domain dipole orientations is shown in Fig. 9.111b, where the data are taken

from the locations marked by “X” in Fig. 9.111a. There are three pronounced peaks, with the largest at a bias of  $-350$  mV. Each of the conductance peaks is due to transmission maxima resulting from the molecular orbitals and molecule/contact couplings coming into resonance. The GMR is given by the ratio of the difference between the antiparallel ( $G_{AP}$ ) and parallel ( $G_P$ ) conductances:

$$GMR = \frac{G_P - G_{AP}}{G_{AP}}. \quad (9.52)$$

For the sample in Fig. 9.111b,  $G_{AP} = 0.16G_0$  and  $G_P = 0.25G_0$ , giving  $GMR = 61\%$ . This is 10 times higher than the tunneling current. Hence, it is concluded that the change in conductance is indeed due to GMR as opposed to TMR across an insulating gap. For comparison, the most optimistic TMR response is plotted on the right of Fig. 9.111c.

The origin of the magnetoresistance can be understood using DFT calculations of the orbital structure of  $H_2Pc$ . This analysis reveals that there is a doubly degenerate LUMO level on pairs of aromatic rings forming the Pc core structure. The N on the phthalocyanine coordinates with Co, resulting in a broad transmission peak within 100 meV of the Fermi energy. This hybridization, in turn, broadens the couplings,  $\Gamma$ , to both substrate and tip. Equation 9.43 implies that broadening increases  $T$ , and therefore the conductance, as observed. The modeling results indicate that hybridization of the anchoring bonds makes GMR relatively insensitive to the difference between  $E_F$  and the resonance energy, as long as these two energies are less than  $\Gamma$ . Furthermore, GMR depends primarily on the ratio of the majority to minority orbital broadening energies (Schmaus et al., 2011).

Quantum interference, energy level spectroscopy, and GMR are only three of the many unique properties that also include thermoelectricity (Hicks and Dresselhaus, 1993), optical emission and absorption, and a plethora of other phenomena exhibited by single molecule devices (Aradhya and Venkataraman, 2013). The 1D structures are governed primarily by quantum effects, and hence understanding their behavior requires a comprehensive knowledge of the energetics of the molecules and the systems. While it is challenging to control the gaps containing only a single molecule, progress in the technology of break junctions, e-beam nanopatterning, and single molecule transistor designs have brought this field to an impressive stage of maturity. While it remains unclear if there will be practical applications beyond molecular characterization, spin transport for quantum computing, and single molecule detection or “fingerprinting,” these limited dimensional devices provide

ample opportunities for discovering new physical properties and phenomena of molecular electronic materials (Joachim et al., 2000, Cuniberti et al., 2005).

## 9.7 Summing up

This chapter has focused on applications and phenomena that do not fit neatly into the main themes of the previous chapters. This does not by any means suggest that the selected topics are less important. They are simply included here to give a taste of the incredible breadth of the field known as organic electronics. Furthermore, the subjects that are considered cannot be viewed as representative of the vast array of interesting material that could have been included.

It is worthwhile to reiterate at this point how the topics were chosen for inclusion in this chapter. The first criterion is that the subject is clearly an organic electronic device, that is to say it must be current driven, and it should also exhibit an interesting excitonic property (i.e. light emission, light field interactions, etc.). Of course, there are numerous examples that could rightfully fall into the category of organic electronics that do not feature a conductive and/or excitonic material property. Major examples that are primarily organic electronic in nature without such characteristics are electro-optical devices exploiting nonlinear optical effects, electrochromic devices and phenomena, organic magnetic materials, and so on. Even among current-based devices, many important topics have been omitted, such as polymer batteries and spintronic devices (although this was briefly touched on in Section 9.6). Clearly, the list of topics is vast and growing every day. And many could easily fill a volume at least as long as this one!

Yet, it is hoped that acquainting the reader with ionic conductivity in LECs, strongly coupled states in optical microcavities, organic thermoelectricity and memories, and organics in limited dimensional (i.e. 2D and 1D) systems will encourage further exploration into the endless possibilities offered by organic electronics. More information on these and other topics can be found in the diversity of sources available in the ever-growing body of scientific literature. Several such references are provided in the following section on *Further reading*.

## Problems

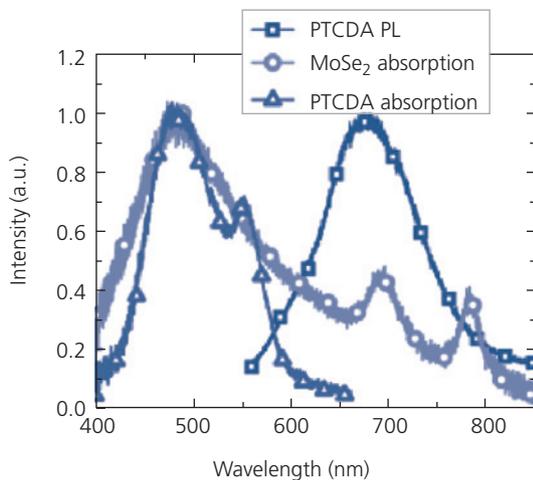

- A light emitting electrochemical cell consists of an anion-cation pair and a luminescent molecule. We want to consider the performance of such a device of length,  $L = 500 \mu\text{m}$ , and that has an anion/cation mobility ratio of  $\mu_A/\mu_C = 2$ , with  $\mu_A = 10^{-7} \text{ cm}^2/\text{V s}$ . Assuming that the density of salts is  $n_S = 10^{18} \text{ cm}^{-3}$ , and the applied voltage is  $V_a = 5 \text{ V}$  between Ohmic contacts,
  - Write an expression for the potential and electric field distributions vs. time, that is,  $V(x, t)$  and  $F(x, t)$  across the active layer. Assume that the charge mobilities are 100 times higher than the ionic mobilities.
  - Write an expression for the width of the emission zone vs. time. Assume the zone width is determined by the point at which the electron and hole concentrations drop to 30% of their peak values.
  - Assuming that the emission intensity is proportional to the width of the emission zone, plot the time evolution of the intensity.
  - What is the time needed to reach 50% of the peak intensity of this LEC?
- In an LEC, we find that the emission zone does not form into a straight line, but rather something like a zigzag.
  - Give three potential sources of this spatial variation between parallel contacts.
  - If the ratio of the radiative to the non-radiative rate in an LEC is  $k_r/k_{nr} = 10$ , and the activation energy of the anion and cation mobilities is 1.0 eV, plot the evolution of the peak luminescence efficiency vs. temperature for the device in Prob. 1.
- A Bloch surface wave (BSW) can be excited with light incident on the glass substrate side of a DBR at angle  $\theta$ .
  - Calculate the optical intensity profile shown for the DBR whose index profile is provided in in Fig. P9.3. The layer thicknesses are: 6 pairs of 100 nm  $\text{SiN}_x$  and 135 nm  $\text{SiO}_2$  (index = 2.0 and 1.5, respectively) as well as a thin top-most pair of 11.5 nm  $\text{SiN}_x$  and 15 nm  $\text{SiO}_2$ .
  - An organic thin film with absorption coefficient of  $\alpha = 2.5 \times 10^5 \text{ cm}^{-1}$  for an exciton with energy 2.2 eV, and index of refraction,  $n = 1.6$  is deposited onto the surface of the DBR. Calculate the total fraction of light absorbed vs. film thickness.

**Figure P9.3** Index profile and optical intensity profile of a surface Bloch wave.

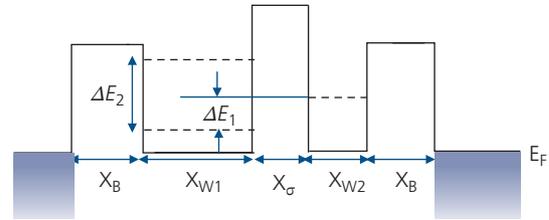

- Assuming that the BSW is excited by a laser at a wavelength of 544 nm, what is the angle at which the BSW can be excited using the Kretschmann configuration with a prism with index  $n = 1.75$ . The excitation field is TE polarized.
  - For a Rabi splitting of 250 meV, calculate and plot the reflectivities of the lower and upper polariton branches vs. angle for the material in b. in a BSW cavity.
- Show that:
    - The maximum efficiency of a thermoelectric refrigerator is given by
 
$$\eta_{COP} = \frac{T_C}{\eta_C T_H} \frac{\sqrt{1 + ZT} - T_H/T_C}{\sqrt{1 + ZT} + 1}$$
    - The refrigerator can support a maximum temperature difference of  $\Delta T_{\max} = \frac{1}{2} Z T_C^2$ .
    - Plot  $\eta_{COP}$  vs.  $Z$  from 1 to  $5 \times 10^{-3} \text{ K}^{-1}$ .
  - Assume that a memory consists of rectifiers in series with resistive elements in an  $N \times N$  array. If the reverse saturation current of the diode accompanying each element is  $I_0$ :
    - How does the size of the array ( $N$ ) scale with  $I_0$ , assuming that the memory current must be  $S$  times larger than the background current?
    - For a resistance  $R_{\min}$  of each resistive memory element in the 1 logic state, and  $R_{\max} = 10^3 R_{\min}$  in the 0 logic state, how does the readout time scale with  $N$ ? Assume a junction area of  $A$  and a depletion region width of  $W$  for an ideal organic diode with a series resistance,  $R_{ser}$ .

- (c) Assuming  $I_0 = 1$  nA for a  $0.01$  mm<sup>2</sup> diode with an active region thickness of  $300$  nm, calculate the largest array size,  $N_{max}$ , for  $R_{min} = 100$   $\Omega$ .
- (d) Calculate the memory bit readout time for the device in (c).
6. Figure P9.6 shows the absorption and PL spectra of the molecule, PTCDA, and a monolayer of the TMDC, MoSe<sub>2</sub>. The transition dipole moment lies within the plane of PTCDA, that is, along its perylene core. Furthermore, the transition dipole of the TMDC lies along the film plane. Assume a TMDC peak absorption coefficient of  $\alpha = 7 \times 10^5$  cm<sup>-1</sup>, and for PTCDA,  $\alpha = 2.5 \times 10^5$  cm<sup>-1</sup>. The in-plane dielectric constants are  $\epsilon = 4$  for MoSe<sub>2</sub>, and for PTCDA, the in-plane dielectric constant is  $\epsilon_{\parallel} = 4.5$  and perpendicular to the plane  $\epsilon_{\perp} = 1.9$ . The natural decay lifetimes of PTCDA and the TMDC are  $5$  ns and  $100$  ps, respectively.

**Figure P9.6** Absorption and PL spectra of materials used in Problem 6.

- (a) Calculate the Förster radius and FRET transfer rate for a Frenkel exciton from PTCDA to MoSe<sub>2</sub>. Assume that the PTCDA molecule lies flat on the TMDC surface.
- (b) Do the calculation in (a) but assume that the PTCDA molecular plane is parallel to, and is tilted at  $30^\circ$  from the plane of the 2D film.
- (c) An ultrathin film of Al<sub>2</sub>O<sub>3</sub> ( $\epsilon = 9.1$ ) is interposed between the organic and TMDC thin films. Calculate and plot the Förster radius and FRET transfer rates vs. Al<sub>2</sub>O<sub>3</sub> thickness,  $\delta$ . At what Al<sub>2</sub>O<sub>3</sub> thickness does the transfer rate decrease to 1% of its value at  $\delta = 0$ ?
7. Assume that two conjugated molecules are separated by a  $\sigma$ -bridge linkage. This type of compound may be approximated as two quantum wells separated by a barrier, as shown in Fig. P9.7. Assume that the free carrier density inside the wells and barriers are negligible.
- (a) At what applied voltage(s) will resonant tunneling be observed?
- (b) Write an expression for the electronic transmission coefficient for this molecular system. Assume that the quantized energy levels are thermally broadened, and

**Figure P9.7** Energy level diagram for a molecule between two contacts. The molecule has two conjugated segments of widths  $X_{W1}$  and  $X_{W2}$  bridged by a non-conjugated segment of width  $X_{\sigma}$ . The barriers to the metal contacts (at far left and right) are of equal height and width. Quantum states are shown by dashed lines.

- can be approximated by a Gaussian distribution. The effective mass is equal to the rest mass of the electron.
8. Assume that the energy levels of a material can be described by a simple model of a particle in a cubic box of infinite potential depth, and of length  $L$ .
- (a) Calculate the density of states and the energy levels for the bulk material. Plot your results.
- (b) Repeat (a) for a 2D solid (e.g. a TMDC).
- (c) Repeat (a) for a 1D solid (e.g. a molecular wire)
- (d) Repeat (a) for a 0D solid (e.g. a quantum dot within a polymer matrix).
9. Given the transmission coefficient (Eq. 9.43) for a single molecule device:
- (a) Derive the current–voltage function:
- $$I = \frac{4G_0}{q} \frac{\Gamma_S \Gamma_D}{\Gamma_S + \Gamma_D} \left( \tan^{-1} \left( \frac{E_0 + \frac{1}{2}qV_A}{\Gamma_S + \Gamma_D} \right) - \tan^{-1} \left( \frac{E_0 - \frac{1}{2}qV_A}{\Gamma_S + \Gamma_D} \right) \right).$$
- (b) Calculate the conductance,  $G$ , of the device at applied voltage,  $V_A$ .
- (c) Plot  $G$  vs.  $V_A$  for  $E_0 = 40$  meV, and  $\Gamma_S = \Gamma_D = 1, 5, 10,$  and  $20$  meV.
10. In Fig. 9.98, it was suggested that the conductance,  $G \propto \cos^2 \theta$ , where  $\theta$  is the twist angle between conjugated groups forming the molecule.
- (a) Give a plausible physical explanation why this relationship should be true.
- (b) Assuming the molecule is the biphenyl moiety, that is, compound **4** in Fig. 9.98, derive a simple expression for  $I(V)$  and  $G$  at  $V \rightarrow 0$  that reproduces the  $\cos^2 \theta$  behavior observed.
- (c) Plot  $I(V)$  and  $G$  vs.  $\cos^2 \theta$  for a triphenyl analog of compound **4**. For this, two angles,  $\theta$  and  $\phi$ , are required.

## Glossary of frequently used and common abbreviations

---

Acronym	Definition
A	Acceptor
AFM	Atomic force microscope
ALD	Atomic layer deposition
AM1.5G	Air mass 1.5 Global.
AMOLED	Active matrix OLED (display)
ANSI	American National Standards Institute
ARC	Antireflection coating
ASE	Amplified spontaneous emission
ASTM	American Section of the International Association of Testing Materials
BAPV	Building applied photovoltaic
BC, TC	Bottom contact, top contact
BG, TG	Bottom gate, top gate
BHJ	Bulk heterojunction
BIOS	Basic input–output system
BIPV	Building integrated photovoltaic
BP	Boiling point
BSR	Back surface reflector
BSW	Bloch surface wave
BW	Energy bandwidth
CCM	Color changing media
CCT	Correlated color temperature
CELIV	Charge extraction by linearly increasing voltage
CF	Color filter
CGL	Charge generation layer
CIE	Commission Internationale d’Eclairage
CMOS	Complementary metal oxide semiconductor
CNT	Carbon nanotube
CPS	Chance, Prock, and Sibley
CRI	Color rendering index
CRZ	Charge recombination zone
CT	Charge transfer
CVD	Chemical vapor deposition
D	Drain, donor

---

Continued

<b>Acronym</b>	<b>Definition</b>
D-A HJ	Donor–acceptor heterojunction
DBR	Distributed Bragg reflector
DFB	Distributed feedback
DFT	Density functional theory
DOS	Density of states
DRAM	Dynamic random access memory
DSMC	Direct simulation Monte Carlo
DUT	Device under test
EA	Electron affinity
EIL	Electron injection layer
EL	Electroluminescence
EML	Emission layer
EQE	External quantum efficiency
ETL	Electron transport layer
FC	Franck–Condon integral
FeFET	Ferroelectric field effect transistor
FET	Field effect transistor
FIB	Focused ion beam
FOLED	Flexible OLED
FPA	Focal plane array
FRET	Fluorescence (or Förster) resonant energy transfer
FTIR	Fourier transform infrared spectroscopy
FWHM	Full width at half maximum
G	Gate
GDM	Gaussian disorder model
GISAXS	Glancing incidence small angle X-ray scattering
GIWAXS	Grazing incidence wide angle X-ray scattering
GIXD	Grazing incidence X-ray diffraction
GMR	Giant magnetoresistance
HCTE	Hybrid charge transfer exciton
HFPA	Hemispherical focal plane array
HIL	Hole injection layer
HJ	Heterojunction
HOMO	Highest occupied molecular orbital
HTL	Hole transport layer
ICT	Intramolecular charge transfer
IJP	Ink jet printing
IMF	Index matching fluid
IP	Ionization potential
IPES	Inverse photoelectron spectroscopy
IQE	Internal quantum efficiency
IR	Infrared
ISC	Intersystem crossing

*(Continued)*

Continued

<b>Acronym</b>	<b>Definition</b>
$j$ - $V$	Current density vs. voltage
L-B	Langmuir–Blodgett
LC	Ligand centered
LCAO	Linear combination of atomic orbitals
LCD	Liquid crystal display
LDI-TOF-MS	Laser desorption ionization-time of flight-mass spectroscopy
LED	Light emitting diode
LEP	Light emitting polymer
LIG	Low index grid
LP or LPB	Lower polariton branch
LTPS	Low temperature polycrystalline silicon
LUMO	Lowest unoccupied molecular orbital
MC	Metal centered
MCBJ	Mechanically controlled break junction
MD	Molecular dynamics
MIS	Metal–insulator–semiconductor
MISFET	Metal–insulator–semiconductor FET
ML	Monolayer
MLA	Micro lens array
MLCT	Metal ligand charge transfer
MMLCT	Metal–metal ligand charge transfer
MNR	Meyer–Neldel rule
MO	Molecular orbital
MOSFET	Metal–oxide–semiconductor FET
MPP	Maximum power point
MWIR	Mid wavelength infrared
MWNT	Multiwalled nanotube
NFA	Non-fullerene acceptor
NIR	Near infrared
NP	Nanoparticle
NTSC	National Television Standards Committee
O-B	Onsager–Braun
OFeFET	Organic ferroelectric field effect transistor
OI-HJ	Organic/inorganic heterojunction
OLED	Organic light emitting device (or diode)
OMBD	Organic molecular beam deposition
OPC	Organic photoconductor
OPD	Organic photodetector
OPT	Organic phototransistor
OPV	Organic photovoltaic cell
OSC	Organic semiconductor
OSL	Organic semiconductor laser
OTFT	Organic thin film transistor

Continued

<b>Acronym</b>	<b>Definition</b>
OTR	Oxygen transmission rate
OVJP	Organic vapor jet printing
OVPD	Organic vapor phase deposition
PAH	Polyaromatic hydrocarbon
PES	Photoelectron spectroscopy
PFEO	Perimeter free electron orbital
PHOLED	Phosphorescent organic light emitting device (or diode)
PL	Photoluminescence
PLQY	Photoluminescence quantum yield
PM-HJ	Planar-mixed heterojunction
PP	Polaron pair
PR	Photoresist
PVD	Plasma vapor deposition
QD	Quantum dot
QVGA	Quarter video graphics array
R2R	Roll-to-roll
RAM	Random access memory
RGA	Residual gas analysis (or analyzer)
RGB	Red, green, blue
RHEED	Reflection high energy electron diffraction
ROIC	Readout integrated circuit
ROM	Read only memory
S	Source
S/N	Signal-to-noise ratio
SAED	Selected area electron diffraction
SAM	Self-assembled monolayer
SCCM	Standard cubic centimeters per minute
SCL	Space charge limit
SEM	Scanning electron microscope
SF	Singlet fission
SOC	Spin-orbit coupling
SOLED	Stacked OLED
SOMO	Singly occupied molecular orbital
SPA	Singlet-polaron annihilation
SPP	Surface plasmon polariton
SQ	Shockley-Queisser (limit)
SRAM	Static random access memory
SRC	Standard reporting conditions
sRGB	Super RGB color gamut
SRH	Shockley-Read-Hall (recombination)
SSA	Singlet-singlet annihilation
SSSE	Solid state solvation effect
STA	Singlet-triplet annihilation

(Continued)

Continued

<b>Acronym</b>	<b>Definition</b>
STM	Scanning tunneling microscope
SVA	Solvent vapor annealing
SWIR	Short wavelength infrared
SWNT	Single walled nanotube
TADF	Thermally assisted delayed fluorescence
TD-DFT	Time dependent density functional theory
TDM	Transition dipole moment
TEC	Thermoelectric cooler
TEG	Thermoelectric generator
TEM	Transmission electron microscope
TFL	Trap filled limit
TFT	Thin film transistor
TIR	Total internal reflection
TMDC	Transition metal dichalcogenide
TMR	Tunneling magnetoresistance
TOF	Time of flight
TOF-SIMS	Time of flight secondary ion mass spectroscopy
TOLED	Transparent OLED
TPA	Triplet–polaron annihilation
TTA	Triplet–triplet annihilation
UHV	Ultrahigh vacuum
UP or UPB	Upper polariton branch
UPS	Ultraviolet photoelectron spectroscopy
UV	Ultraviolet
Vis	Visible
VTE	Vacuum thermal evaporation
W-M	Wannier–Mott
WOLED	White emitting OLED
WORM	Write once read many times
WVTR	Water vapor transmission rate

## APPENDIX B

# Identification of chemical names

Chemical name	IUPAC nomenclature
1-NPSQ	2,4-bis[4-( <i>N</i> -phenyl-1-naphthylamino)-2,6-dihydroxyphenyl]squaraine
26nCPy	2,6-bis( <i>N</i> -carbazolyl)pyridine
2CzPN	1,2-bis(carbazol-9-yl)-4,5-dicyanobenzene
2T-NATA	4,4',4''-tris( <i>N</i> -2-naphthyl- <i>N</i> -phenylamino)triphenylamine
44TCzPN	6,6'-(9H,9'H-[4,40-bicarbazole]-9,9'-diyl)bis(4-(9H-carbazol-9-yl) isophthalonitrile)
4CzCNPY	2,3,5,6-tetracarbazole-4-cyano-pyridine
4CzIPN	1,2,3,5-tetrakis(carbazol-9-yl)-4,6-dicyanobenzene
4CzPNPh	3,4,5,6-tetrakis(3,6-diphenylcarbazol-9-yl)-1,2-dicyanobenzene
4CzTPN-Ph	2,3,5,6-tetrakis(3,6-diphenylcarbazol-9-yl)-1,4-dicyanobenzene
4P-NPD	<i>N,N'</i> -di-1-naphthalenyl- <i>N,N'</i> -diphenyl-[1,1':4',1'':4'',1'''-quaterphenyl]-4,4'''-diamine
4TBPPZn	tetra-(2,6- <i>tert</i> -butyl)phenolporphyrin zinc
AC-DT	2,6-bis[(4-acetylthiophenyl)ethynyl]anthracene
ACRSA	10-phenyl-10H,10'H-spiro[acridine-9,9'-anthracen]-100-one
ACRXTN	3-(9,9-dimethylacridin-10(9H)-yl)-9H-xanthen-9-one
ADN	9,10-di(naphtha-2-yl)anthracene
AIDCN	2-amino-4,5-imidazoledicarbonitrile
Alq <sub>3</sub>	tris(8-hydroxyquinoline)aluminum
AMS	poly( $\alpha$ -methylstyrene)
APFO3	poly(2,7-(9,9-dioctyl-fluorene)- <i>alt</i> -5,5-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole))
AQ-DT	2,6-bis[(4-acetylthiophenyl)ethynyl]-9,10-anthraquinone
AQ-MT	2-[(4-acetylthiophenyl)ethynyl]-6-(phenylethynyl)-9,10-anthraquinone
ASSQ	2-[4-( <i>N,N</i> -diisobutylamino)-2,6-dihydroxyphenyl]-4-diphenylaminosquaraine

# Measuring ionization potentials and electron affinities

Measuring molecular frontier orbital energies is key to understanding the fundamental optical and electronic properties of a material. Once the transport energy levels are defined, the appropriate materials can be chosen for the design of high performance devices. There are numerous ways for measuring molecular energetics, ranging from ultraviolet and x-ray photoelectron spectroscopies, to scanning Kelvin probe microscopy and cyclic voltammetry. Here we discuss the two most common methods: ultraviolet photoelectron spectroscopy (UPS or PES), and cyclic voltammetry (CV), and their relationships to each other.

Photoelectron spectroscopy is a convenient method for determining the ionization (i.e. HOMO) energies of organic compounds. The complementary process of inverse photoelectron spectroscopy (IPES) is used for measuring the LUMO energies. The energetics of both processes are illustrated in Fig. C.1a for an organic semiconductor of energy gap,  $E_G$ , ionization energy,  $IE = q(IP)$ , where  $IP$  is the ionization potential, electron affinity,  $EA$ , and work function,  $\phi$ . Photoelectron spectroscopy is based on the photoelectric effect: a photon of kinetic energy,  $h\nu$ , is incident on the semiconductor, exciting a bound electron at initial energy  $E_i$  into the vacuum at final energy  $E_f$ . The initial state is that of an  $N$ -electron system. After the electron is ejected, the final state corresponds to a singly-ionized,  $N-1$  state. It leaves behind one electron in the singly occupied molecular orbital, or SOMO. The photoelectron has kinetic energy  $E_{kin}$  given by

$$E_{kin} = h\nu - [E_f(N-1) - E_i(N)]. \quad (C.1)$$

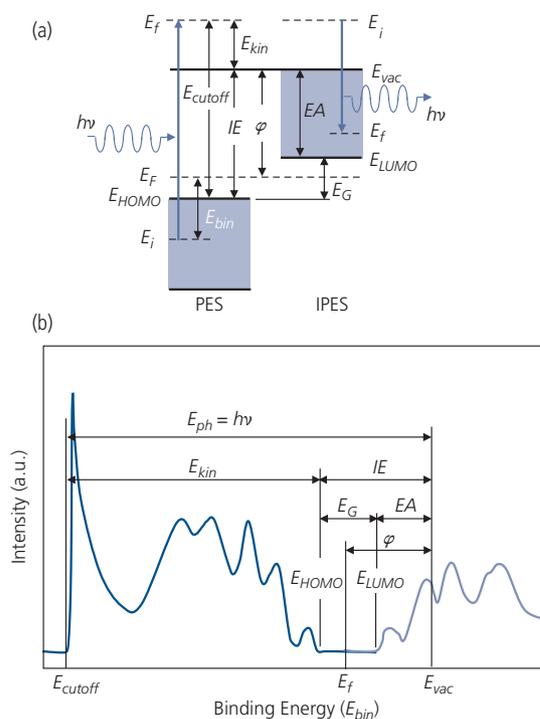

The binding energy,  $E_{bin}$ , of the electron in the  $i$ th orbital at energy,  $E_i$ , referenced to the Fermi energy,  $E_F$ , is thus given by the term in brackets in Eq. C.1. By inspection of Fig. C.1a, this yields

$$E_{bin} = h\nu - E_{kin} - \phi. \quad (C.2)$$

Furthermore, we obtain the ionization energy via

$$IE = h\nu - E_{kin} = h\nu - [E_{cutoff} - E_{HOMO}], \quad (C.3)$$

where the cutoff energy,  $E_{cutoff}$ , is energy of the photon that results in the highest kinetic energy electron, and  $E_{HOMO}$  corresponds to the electron emitted with  $E_{kin} = 0$ . Thus, the ionization energy is determined from the difference between the onset and the cutoff energies in the PES spectrum in Fig. C.1b. The energies are typically referenced to  $E_F$ , which is determined by measuring the work function of a metal film on the substrate prior to deposition of the organic.

**Fig. C.1** (a) Energetics of photoelectron (PES) and inverse photoelectron spectroscopy (IPES) in relation to an organic semiconductor. (b) Example PES and IPES spectra, and the associated energies.

The binding energies of the bound-state orbitals can be obtained from the spectral features at  $E_{bin} > E_{HOMO}$ . Similarly, surface states, or defect states within the energy gap may also be apparent, although the sensitivity of the technique is limited only to states whose density is typically  $> 1\%$  of the HOMO density of states. The measurement resolution is typically 50–100 meV. Finally, since the electron penetration depths within the solid are only several Ångströms, PES is inherently a surface-sensitive probe. Hence, the measurements should be conducted in ultrahigh vacuum, where surface contamination and surface charging are minimized.

The electron energies are typically measured by an energy analyzer such as that shown in Fig. C.2. The UV light source used is frequently the 21.22 eV emission from the HeI $\alpha$  transition. It impinges onto the surface of a thin film sample, ejecting photoelectrons into an electron lens. The kinetic energies of the electrons, all travelling at different velocities, are dispersed in the hemispherical “clam shell” analyzer that has a field between the inner and outer hemispheres. The higher energy electrons travel near the outer hemisphere, with the lower energy electrons describing tighter radii near the inner hemisphere. The dispersed electrons are then detected by a multi-channel detector to resolve the PES spectrum, yielding the integrated density of states. Rotating the sample relative to the input aperture, resolves the electron momenta parallel and perpendicular to the sample ( $k_{\parallel}$  and  $k_{\perp}$ , respectively). This variation on

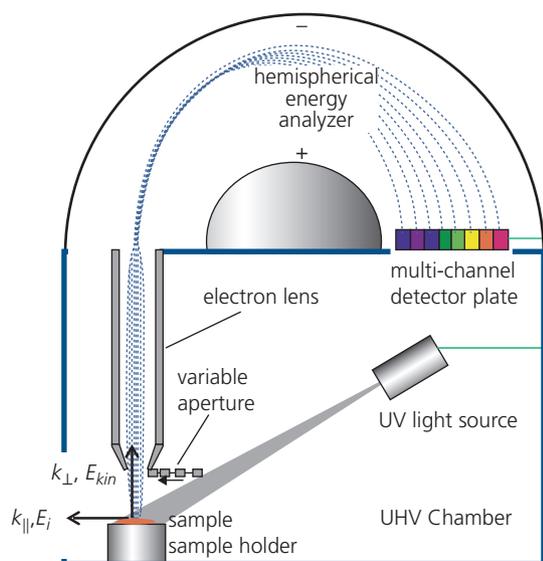

Fig. C.2 Experimental configuration used in PES.

PES is known as angle resolved ultraviolet electron spectroscopy, or ARUPS.

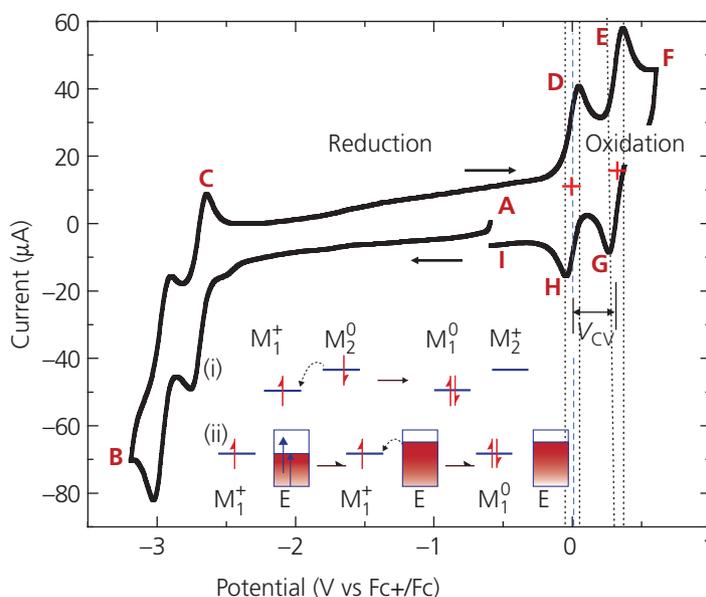

The EA, and hence  $E_{LUMO}$ , are measured using the complementary technique of inverse photoelectron spectroscopy. In IPES, an electron beam is incident on the sample, populating high energy initial states, shown on right hand side of Fig. C.1a. As the electrons relax, they emit light of energy  $h\nu$  whose spectrum is measured using a monochromator. The lowest energy photons correspond to the electron affinity, and the various high energy LUMO level densities of states can be inferred from the spectral features at energies higher than  $E_{LUMO}$ . Since the density of electrons is limited, the signal from the IPES spectrum is considerably smaller than from PES, and hence the accuracy of the method is correspondingly limited to 100–150 meV. The measured difference between  $E_{HOMO}$  and  $E_{LUMO}$  using a combination of PES and IPES, respectively, gives the energy gap.

Cyclic voltammetry is unlike PES, in that it is carried out in solution on individual molecules within a room ambient, eliminating the need for ultraclean environments and the associated costly equipment. Cyclic voltammetry is an electrochemical process whereby a molecular species dissolved in solution is reduced or oxidized, depending on its energy relative to a second molecular species or an electrode. A singly ionized molecule corresponds to its +1 oxidation state, or its –1 reduced state. The energies required for oxidation and reduction therefore have a one-to-one correspondence with the IE and the EA, respectively. The reduction of the singly ionized molecule,  $M_1^+$ , due to charge transfer from neutral  $M_2^0$  is shown in inset (i) of Fig. C.3. This so-called homogeneous electron transfer occurs when the HOMO of  $M_2$  is higher than that of  $M_1$ . Heterogeneous charge transfer from an electrode that occurs in CV is shown in inset (ii). At a particular bias applied between the so-called working electrode and the solute (or analyte), the metal work function is higher than the HOMO of the analyte, promoting charge transfer that results in a reduction reaction. The potential that leads to oxidation or reduction thus provides a relative measurement of the ionization and electron affinity energies, respectively.

One-electron transfer results in an energy in the electrochemical cell,  $E$ , governed by the Nernst equation, viz. (Bard and Faulkner, 1980)

$$E = E^0 + \frac{RT}{F} \ln \frac{[M^+]}{[M^0]}. \quad (\text{C.4})$$

Here,  $E^0$  is the formal potential determined by the details of the electrochemical cell,  $R$  is the universal

**Fig. C.3** Cyclic voltammogram of a subject molecular solute ( $\text{Ir}(\text{ppy})_3$ ) in a solution containing the reference, ferrocene/ferrocenium ( $\text{Fc}/\text{Fc}^+$ ).  $V_{CV} = 0.32$  V is the voltage difference between the oxidation potentials of the reference and the solute. The blue arrow is the direction of the voltage sweep. Data from D'Andrade et al. (2005). Inset: (i) Homogeneous electron transfer from the HOMO of molecule  $M_2$  to  $M_1$ ; (ii) heterogeneous electron transfer from an electrode, E, to  $M_1$ . The horizontal line in E is its work function.

gas constant, and  $F = qN_A$  is Faraday's constant where  $N_A$  is Avogadro's number. Also,  $[M^+]$  and  $[M^0]$  are concentrations of the oxidized and neutral analytes, respectively. Thus,  $E = E^0$  when the concentrations of the oxidized and neutral species at the electrode are equal.

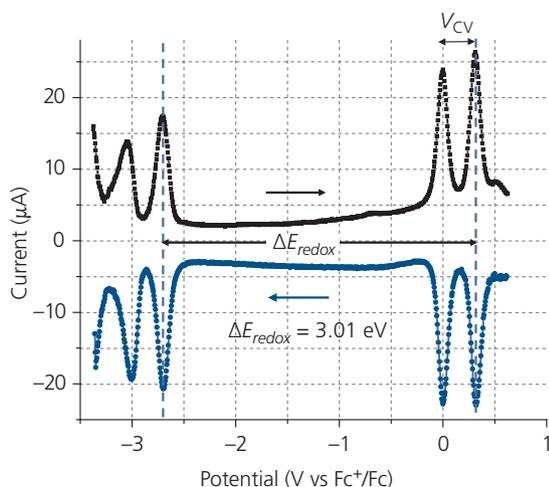

A representative voltammogram for micromolar concentrations of  $\text{Ir}(\text{ppy})_3$  with a ferrocene (Fc) reference in a DMF solution with a tetra(*n*-butyl)ammonium hexafluorophosphate salt to increase solution conductivity, is shown in Fig. C.3. The voltage is swept in the direction of the blue arrow at 100 mV/s starting at point A, reversing sweep direction at B, sweeping in the positive direction until point F, once more reversing direction, and completing the cycle at I. The sweep is reversible, indicating that the molecule is stable under oxidation and reduction at the working electrode.

The oxidation potential of the analyte relative to the Fc reference is obtained from the several peaks D, E, G, and H. The anodic scan in the positive direction generates a peak anodic current at D corresponding to the point where the transport of Fc to the electrode is maximum. At higher potentials, Fc becomes depleted from solution near the electrode, and the current drops until it once more begins to increase to a second peak at E. This second peak is due to oxidation of the analyte,  $\text{Ir}(\text{ppy})_3$ . In the reverse, cathodic scan, the opposite reactions occur in reverse order, where the analyte is now

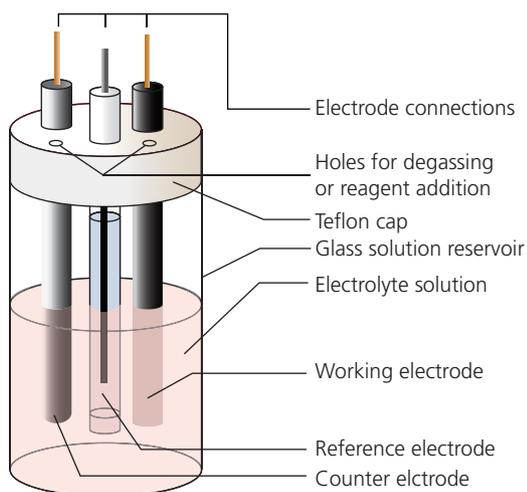

reduced. The midpoints between the corresponding peaks, indicated by "+" are  $E_{1/2} = E^0$ , the formal potential. From these data, the relative oxidation potentials of the analyte and Fc is  $V_{CV} = 0.32$  V. Similar reduction peaks are found by the structure in the scan near  $V = -3$  V. The first reduction peak of  $\text{Ir}(\text{ppy})_3^+ \rightarrow \text{Ir}(\text{ppy})_3$  is at point C.

The peak positions are considerably easier to resolve using differential pulse voltammetry (DPV). The DPV data are a differential of the conventional voltammogram that are obtained by plotting the current immediately prior to increasing the baseline voltage using a linear voltage ramp or a pulse staircase. A differential voltammogram of the sample in Fig. C.3 is shown in Fig. C.4. The resolution of this technique is approximately 50 meV, or at least twice that achieved using PES. From the oxidation and reduction peaks of the analyte, we obtain a redox potential difference of  $\Delta E_{redox} = 3.01$  eV.

The experimental setup for CV measurements is illustrated in Fig. C.5. It consists of a working electrode that is resistant to corrosion in the electrolytic solution (typically Pt or glassy carbon), and a counter electrode often of the same composition. The reference electrode should have a stable equilibrium potential. The voltammograms in Figs. C.3 and C.4 use a  $\text{Fc}^+/\text{Fc}$  couple that is commonly used for analyzing organic electronic materials. The electrolyte itself comprises a solvent such as DMF, DCM, acetonitrile,

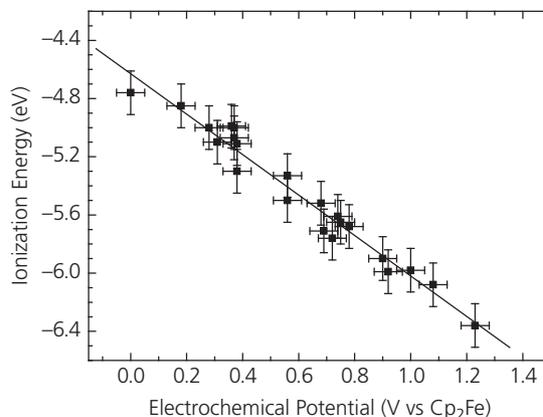

**Fig. C.4** Differential pulse voltammograms for the anodic (top) and cathodic (bottom) sweeps of the sample in Fig. C.3. The sweep directions are shown by arrows. Data courtesy of P. Djurovich (private communication, 2019).

**Fig. C.5** Electrochemical test cell used in cyclic voltammetry (Elgrishi et al., 2017).

etc. The solvent also contains a high concentration of an electrolyte to minimize resistance that might distort the data by increasing the voltages of the peak anodic and cathodic currents. Ammonium salts are preferred for this purpose. Similarly, the voltage sweep must be sufficiently slow to avoid overtaking the rate of ionic diffusion. This can flatten the peaks, reducing the measurement resolution (Elgrishi et al., 2017). Finally, accurate data are obtained only for molecules that can be reversibly cycled. Irreversible oxidation or reduction implies that the molecule

**Fig. C.6** Ionization energy measured by PES vs. the electrochemical potential measured in DMF referenced to biphenyl-substituted ferrocene for a population of common organic electronic molecules (data points). The line is a fit to Eq. C.6 (D'Andrade et al., 2005).

Reprinted from Organic Electronics, 6, D'Andrade, B. W., Datta, S., Forrest, S. R., Djurovich, P., Polikarpov, E. & Thompson, M. E., Relationship between the ionization and oxidation potentials of molecular organic semiconductors. 11–20, Copyright 2005 with permission from Elsevier.

decomposes during measurement. Irreversibility results in an open voltammogram.

A correspondence between  $V_{CV}$ , the ionization energy measured by PES, and  $E_{HOMO}$  is obtained by compensating for image charge effects between the analyte and the working electrode, and solvation effects that depend on the relative dielectric constants of the solution ( $\epsilon_{CV}$ ) used in CV, and the thin film ( $\epsilon_{film}$ ) analyzed by photoelectron spectroscopy. It has been shown that CV and PES potentials are related by (D'Andrade et al., 2005)

$$V_{CV} = -\frac{1}{qf(r,d)} \frac{\epsilon_{film}}{\epsilon_{CV}} E_{HOMO} - V_{REF}, \quad (C.5)$$

where  $f(r, d)$  is a function due to Coulomb attraction between a “spherical” molecule of effective radius  $r$  forming an adsorbed film on the electrode of approximate thickness,  $d$ , and its image charge in the electrode. Also,  $V_{REF}$  is the oxidation potential of the reference molecule. Figure C.6 shows a plot of the ionization potential vs.  $V_{CV}$  referenced to  $Fc^+/Fc$  of a population of common organic electronic molecules. The reference ionization potential is  $-4.76$  eV for a biphenyl-substituted ferrocene ( $Cp_2Fe$ ). This reference is indicated by the point at a  $V_{CV} = 0$  V. The straight line is a best fit to the data using:

$$E_{HOMO} = -(1.4 \pm 0.1) \times (qV_{CV}) - (4.60 \pm 0.08) \text{ eV}. \quad (C.6)$$

This functional form is within measurement error of Eq. C.5, where  $qV_{REF} = -4.76$  eV. The fits are largely

independent of the solvent used, suggesting that image charge effects have a more significant contribution to the slope than solvation effects.

Empirical fits between the LUMO energies measured by IPES and the reduction potentials (again relative to  $\text{Fc}^+/\text{Fc}$ ) in a DMF solution using a tetra(*n*-butyl)ammonium hexafluorophosphate electrolyte of a similarly large population of organic electronic small molecules results in the following linear relationship (Djurovich et al., 2009):

$$E_{LUMO}(\text{IPES}) = -(1.19 \pm 0.08) \times qV_{CV} - (4.78 \pm 0.17). \quad (\text{C.7})$$

Note that reduction potentials are measured at  $V_{CV} < 0$ .

Finally, it is reasonable to expect that the redox potential, which is equal to the difference between adding and subtracting an electron from the molecule, should be related to  $E_{LUMO} - E_{HOMO} = E_G$ , the transport energy gap. Indeed, a statistical analysis of organic electronic compounds results in a correlation that is accurately fit by (Sworakowski, 2018)

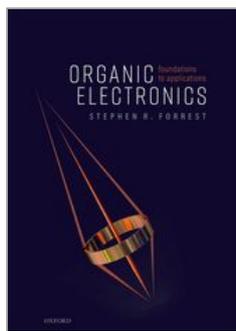

$$E_G = 1.16 \Delta E_{redox}. \quad (\text{C.8})$$

The 16% difference in these values is due to dielectric polarization. In the thin film, the molecules must collectively respond to the presence or absence of charge in the solid. However, in CV, the molecular species are

diluted (often at micromolar concentrations), and thus the redox energies correspond to those of isolated molecules within the polar dielectric medium of the solvent. The solvent dielectric constant is generally considerably higher than that of the solid ( $\epsilon_{CV} \approx 30$  vs.  $\epsilon_{film} \approx 3-4$ ). This substantially screens the electric field in the solution, reducing the energy required to remove, or add a charge. Quantitative analysis shows that this leads to a systematically smaller  $\Delta E_{redox}$  compared to  $E_G$  whose magnitude is consistent with the empirical fit in Eq. C.8.
